²⁴ Indeed, the period λ_u is typically a few centimeters (see the numbers in Fig. 10), i.e. is much larger than the interval $\Delta r' \sim R/\gamma^3$ estimated above. Hence the synchrotron radiation results may be applied locally, to each electron beam’s bend. (In this context, a simple problem for the reader: use Eqs. (19) and (63) to explain the difference between shapes of the in-plane electric field pulses emitted at opposite magnetic poles of the wiggler, which is schematically shown in Fig. 12a.)

where the first two relations are valid at $\lambda_u \ll R$ (the relation typically satisfied very well, see the numbers in Fig. 10), and the last two relations assume the ultra-relativistic limit. As a result, the radiation intensity, which is proportional to the number of the poles, is much higher than that from the bend magnets – see Fig. 10 again.

The situation is different in undulators – similar structures with a smaller spatial period λ_u , in which the electron's velocity vector oscillates with an angular amplitude smaller than γ^{-1} . As a result, the radiation pulses overlap (Fig. 12b), and the radiation waveform is closer to the sinusoidal one. As a result, the radiation spectrum narrows to the central frequency²⁵

$$\omega_0 = \frac{2\pi}{\Delta t} \approx 2\gamma^2 \frac{2\pi c}{\lambda_u}. \quad (10.74)$$

For example, for the LSNL-II undulators with $\lambda_u = 2$ cm, this formula predicts a radiation peak at phonon energy $\hbar\omega_0 \approx 4$ keV, in reasonable agreement with the quantitative calculation results shown in Fig. 10.²⁶ Due to the spectrum narrowing, the undulator's radiation intensity is higher than that of wigglers using the same electron beam.

This spectrum-narrowing trend is brought to its logical conclusion in the so-called *free-electron lasers*²⁷ whose basic structure is the same as that of wigglers and undulators (Fig. 11), but the radiation at each beam bend is so intense and narrow-focused that it affects the electron motion downstream of the radiation cone. As a result, the radiation spectrum narrows around the central frequency (74), and its power grows as a square of the number N of electrons in the structure (rather than proportionately to N in wigglers and undulators).

Finally, note that wigglers, undulators, and free-electron lasers may be also used at the end of a linear electron accelerator (such as SLAC) which, as was noted above, may provide extremely high values of γ , and hence radiation frequencies, due to the smallness of radiation energy losses at the electron acceleration stage. Very unfortunately, I do not have time/space to discuss the (very interesting) physics of these devices in more detail.²⁸

10.4. Bremsstrahlung and Coulomb losses

Surprisingly, a very similar mechanism of radiation by charged particles works on a much smaller spatial scale, namely at their scattering by charged particles of the propagation medium. This

²⁵ This important formula may be also derived in the following way. Due to the relativistic length contraction (9.20), the undulator structure period as perceived by beam electrons is $\lambda' = \lambda_u/\gamma$, so that the central frequency of the radiation in the reference frame moving with the electrons is $\omega_0' = 2\pi c/\lambda' = 2\pi c/\lambda_u$. For the lab-frame observer, this frequency is Doppler-upshifted in accordance with Eq. (9.44): $\omega_0 = \omega_0'[(1 + \beta)/(1 - \beta)]^{1/2} \approx 2\gamma\omega_0'$, giving the same result as Eq. (74).

²⁶ Some of the difference is due to the fact that those plots show the spectral density of the number of photons $n = \mathcal{E}/\hbar\omega$ per second, which peaks at a frequency below that of the density of power, i.e. of the energy \mathcal{E} per second.

²⁷ This name is somewhat misleading, because in contrast to the usual (“quantum”) lasers, a free-electron laser is essentially a classical device, and the dynamics of electrons in it is very similar to that in vacuum-tube microwave generators, such as the magnetrons briefly discussed in Sec. 9.6.

²⁸ The interested reader may be referred, for example, to either P. Luchini and H. Motz, *Undulators and Free-electron Lasers*, Oxford U. Press, 1990; or E. Salin *et al.*, *The Physics of Free Electron Lasers*, Springer, 2000.

effect, traditionally called by its German name *bremsstrahlung* (“brake radiation”), is responsible, in particular, for the continuous part of the frequency spectrum of the radiation produced in standard vacuum X-ray tubes, at the electron collisions with a metallic “anticathode”.²⁹

The bremsstrahlung in condensed matter is generally a rather complicated phenomenon because of the simultaneous involvement of many particles, and (frequently) some quantum electrodynamic effects. This is why I will give only a very brief glimpse at the theoretical description of this effect, for the simplest case when the scattering of incoming, relatively light charged particles (such as electrons, protons, α -particles, etc.) is produced by atomic nuclei, which remain virtually immobile during the scattering event (Fig. 13a). This is a reasonable approximation if the energy of incoming particles is not too low; otherwise, most scattering is produced by atomic electrons whose dynamics is substantially quantum – see below.

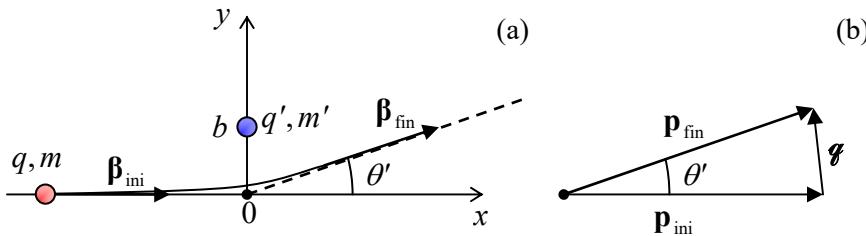

Fig. 10.13. The basic geometry of the bremsstrahlung and the Coulomb loss problems in the (a) direct and (b) reciprocal spaces.

To calculate the frequency spectrum of the radiation emitted during a single scattering event, it is convenient to use a byproduct of the last section’s analysis, namely Eq. (59) with the replacement (60):³⁰

$$I(\omega) = \frac{1}{4\pi^2 c} \frac{q^2}{4\pi\epsilon_0} \left| \int_{-\infty}^{+\infty} \left[\frac{d}{dt} \frac{\mathbf{n} \times (\mathbf{n} \times \boldsymbol{\beta})}{1 - \boldsymbol{\beta} \cdot \mathbf{n}} \exp \left\{ i\omega \left(t - \frac{\mathbf{n} \cdot \mathbf{r}'}{c} \right) \right\} \right]_{\text{ret}} dt \right|^2. \quad (10.75)$$

A typical duration τ of a single scattering event we are discussing is of the order of $\tau \equiv a_0/c \sim (10^{-10} \text{ m})/(3 \times 10^8 \text{ m/s}) \sim 10^{-18} \text{ s}$ in solids, and only an order of magnitude longer in gases at ambient conditions. This is why for most frequencies of interest, from zero all the way up to at least soft X-rays,³¹ we can use the so-called *low-frequency approximation*, taking the exponent in Eq. (75) for 1 through the whole collision event, i.e. the integration interval. This approximation immediately yields

Bremsstrahlung:
single collision

$$I(\omega) = \frac{1}{4\pi^2 c} \frac{q^2}{4\pi\epsilon_0} \left| \frac{\mathbf{n} \times (\mathbf{n} \times \boldsymbol{\beta}_{\text{fin}})}{1 - \boldsymbol{\beta}_{\text{fin}} \cdot \mathbf{n}} - \frac{\mathbf{n} \times (\mathbf{n} \times \boldsymbol{\beta}_{\text{ini}})}{1 - \boldsymbol{\beta}_{\text{ini}} \cdot \mathbf{n}} \right|^2. \quad (10.76)$$

²⁹ Such X-ray radiation had been first observed experimentally (though not correctly interpreted) by N. Tesla in 1887, i.e. before it was rediscovered and studied in detail by W. Röntgen.

³⁰ In publications on this topic (whose development peak was in the 1920s-1930s), the Gaussian units are more common, and the uppercase letter Z is usually reserved for expressing charges as multiples of the fundamental charge e , rather than for the wave impedance. This is why, in order to avoid confusion and facilitate the comparison with other texts, in this section I (while still staying with the SI units used throughout my series) will use the fraction $1/\epsilon_0 c$, instead of its equivalent Z_0 , for the free-space wave impedance, and write the coefficients in a form that makes the transfer to the Gaussian units elementary: it is sufficient to replace all $(qq'/4\pi\epsilon_0)_\text{SI}$ with $(qq')_\text{Gaussian}$. In the (rare) cases when I spell out the charge values, I will use a different font: $q \equiv \mathcal{Z}e$, $q' \equiv \mathcal{Z}'e$.

³¹ A more careful analysis shows that this approximation is actually quite reasonable up to much higher frequencies, of the order of γ^2/τ .

In the non-relativistic limit ($\beta_{\text{ini}}, \beta_{\text{fin}} \ll 1$), this formula is reduced to the following result:

$$I(\omega) = \frac{1}{4\pi^2 c} \frac{q^2}{4\pi\epsilon_0} \frac{\mathbf{q}^2}{m^2 c^2} \sin^2 \theta \quad (10.77)$$

(which may be derived from Eq. (8.27) as well), where \mathbf{q} is the momentum transferred from the scattering center to the scattered charge (Fig. 13b):³²

$$\mathbf{q} \equiv \mathbf{p}_{\text{fin}} - \mathbf{p}_{\text{ini}} = m\Delta\mathbf{u} = mc\Delta\mathbf{v} = mc(\mathbf{v}_{\text{fin}} - \mathbf{v}_{\text{ini}}), \quad (10.78)$$

and θ (not to be confused with the particle scattering angle θ' shown in Fig. 13!) is the angle between the vector \mathbf{q} and the direction \mathbf{n} toward the observer – at the collision moment.

The most important feature of the result (77)-(78) is the frequency-independent (“white”) spectrum of the radiation, very typical for any rapid pulses that may be approximated as delta functions of time.³³ (Note, however, that Eq. (77) implies a fixed value of \mathbf{q} , so that the statistics of this parameter, to be discussed in a minute, may “color” the radiation.)

Note also the “doughnut-shaped” angular distribution of the radiation, typical for non-relativistic systems, with the symmetry axis directed along the momentum transfer vector \mathbf{q} . In particular, this means that in typical cases when $|\theta'| \ll 1$, i.e. $\mathbf{q} \ll \mathbf{p}$, when the vector \mathbf{q} is nearly normal to the vector \mathbf{p}_{ini} (see, e.g., the example shown in Fig. 13b), the bremsstrahlung produces a significant radiation flow in the direction back to the particle source – the fact significant for the operation of X-ray tubes.

Now integrating Eq. (77) over all wave propagation angles, just as we did for the instant radiation power in Sec. 8.2, we get the following spectral density of the particle energy loss,

$$-\frac{d\mathcal{E}}{d\omega} = \oint_{4\pi} I(\omega) d\Omega = \frac{2}{3\pi c} \frac{q^2}{4\pi^2 \epsilon_0} \frac{\mathbf{q}^2}{m^2 c^2}. \quad (10.79)$$

In most applications of the bremsstrahlung theory (as in most scattering problems³⁴), the impact parameter b (Fig. 13a), and hence the scattering angle θ' and the transferred momentum \mathbf{q} , have to be

³² Please note the font-marked difference between this variable (\mathbf{q}) and the particle’s electric charge (q).

³³ This is the basis, in particular, of the so-called *High-Harmonic Generation* (HHG) effect, discovered in 1977, which takes place at the irradiation of gases by intensive laser beams. The high electric field of the beam strips valent electrons from initially neutral atoms, and accelerates them away from the remaining ions, just to slam them back into the ions as the field’s polarity changes in time. The electrons change their momentum sharply during their recombination with the ions, resulting in bremsstrahlung-like radiation. The spectrum of radiation from each such event obeys Eq. (77), but since the ionization/acceleration/recombination cycles repeat periodically with the frequency ω_0 of the laser field, the final spectrum consists of many equidistant lines, with frequencies $n\omega_0$. The classical theory of the bremsstrahlung does not give a cutoff $\omega_{\text{max}} = n_{\text{max}}\omega_0$ of the spectrum; this limit is imposed by quantum mechanics: $\hbar\omega_{\text{max}} \sim \mathcal{E}_p$, where the so-called *ponderomotive energy* $\mathcal{E}_p = (eE_0/\omega_0)^2/4m_e$ is the average kinetic energy given to a free electron by the periodic electric field of the laser beam, with amplitude E_0 . In practice, n_{max} may be as high as ~ 100 , enabling alternative compact sources of X-ray radiation. For a detailed quantitative theory of this effect, see, for example, M. Lewenstein *et al.*, *Phys. Rev. A* **49**, 2117 (1994).

³⁴ See, e.g., CM Sec. 3.5 and QM Sec. 3.3.

considered random. For elastic ($\beta_{\text{ini}} = \beta_{\text{fin}} \equiv \beta$) Coulomb collisions we can use the so-called *Rutherford formula* for the differential cross-section of scattering³⁵

$$\frac{d\sigma}{d\Omega'} = \left(\frac{qq'}{4\pi\epsilon_0} \right)^2 \left(\frac{1}{2pc\beta} \right)^2 \frac{1}{\sin^4(\theta'/2)}. \quad (10.80)$$

Here $d\sigma = 2\pi bdb$ is the elementary area of the sample cross-section (as visible from the direction of the incident particles) corresponding to their scattering into an elementary body angle³⁶

$$d\Omega' = 2\pi \sin \theta' |d\theta'|. \quad (10.81)$$

Differentiating the geometric relation, which is evident from Fig. 13b,

$$q = 2p \sin \frac{\theta'}{2}, \quad (10.82)$$

we may represent Eq. (80) in a more convenient form

$$\frac{d\sigma}{dq} = 8\pi \left(\frac{qq'}{4\pi\epsilon_0} \right)^2 \frac{1}{u^2 q^3}. \quad (10.83)$$

Now combining Eqs. (79) and (83), we get

$$-\frac{d\mathcal{E}}{d\omega} \frac{d\sigma}{dq} = \frac{16}{3} \frac{q^2}{4\pi\epsilon_0} \left(\frac{qq'}{4\pi\epsilon_0 mc^2} \right)^2 \frac{1}{c\beta^2} \frac{1}{q}. \quad (10.84)$$

This product is called the *differential radiation cross-section*. When integrated over all values of q (which is equivalent to averaging over all values of the impact parameter), it gives a convenient measure of the radiation intensity. Indeed, after the multiplication by the volume density n of independent scattering centers, such integral yields the particle's energy loss per unit bandwidth of radiation per unit path length, $-d^2\mathcal{E}/d\omega dx$. A minor problem here is that the integral of $1/q$ formally diverges at both infinite and zero values of q . However, these divergences are very weak (logarithmic), and the integral converges due to virtually any reason unaccounted for in our simple analysis. The standard (though slightly approximate) way to account for these effects is to write

$$-\frac{d^2\mathcal{E}}{d\omega dx} \approx \frac{16}{3} n \frac{q^2}{4\pi\epsilon_0} \left(\frac{qq'}{4\pi\epsilon_0 mc^2} \right)^2 \frac{1}{c\beta^2} \ln \frac{q_{\max}}{q_{\min}}, \quad (10.85)$$

Bremsstrahlung:
intensity

and then plug, instead of q_{\max} and q_{\min} , the scales of the most important effects limiting the range of the transferred momentum's magnitude. In the classical-mechanics analysis, according to Eq. (82), $q_{\max} = 2p \equiv 2mu$. To estimate q_{\min} , let us note that the very small momentum transfer takes place when the impact parameter b is very large, and hence the effective scattering time $\tau \sim b/v$ is very long. Recalling the condition of the low-frequency approximation, we may associate q_{\min} with $\tau \sim 1/\omega$ and hence with $b \sim$

³⁵ See, e.g., CM Eq. (3.73) with $\alpha = qq'/4\pi\epsilon_0$. In the form used in Eq. (80), the Rutherford formula is also valid for the small-angle scattering of relativistic particles, the criterion being $|\Delta\beta| \ll 2/\gamma$.

³⁶ Again, the angle θ' and the differential $d\Omega'$, describing the scattered particles (see Fig. 13) should not be confused with the parameters θ and $d\Omega$ describing the *radiation* emitted at the scattering event.

$ut \sim v/\omega$. Since for the small scattering angles, γ is close to the impulse $F\tau \sim (qq'/4\pi\epsilon_0 b^2)\tau$ of the Coulomb force, we get the estimate $\gamma_{\min} \sim (qq'/4\pi\epsilon_0)\omega/u^2$, and Eq. (85) should be used with

$$\ln \frac{\gamma_{\max}}{\gamma_{\min}} = \ln \left(\frac{2mu^3}{\omega} \Big/ \frac{qq'}{4\pi\epsilon_0} \right). \quad (10.86)$$

Classical
brems-
strahlung

This is *Bohr's formula* for what is called the *classical bremsstrahlung*. We see that the low momentum cutoff indeed makes the spectrum slightly colored, with more energy going to lower frequencies. There is even a formal divergence at $\omega \rightarrow 0$; however, this divergence is integrable, so it does not present a problem for finding the total energy radiative losses ($-dE/dx$) as an integral of Eq. (86) over all radiated frequencies ω . A larger problem for this procedure is the upper integration limit, $\omega \rightarrow \infty$, at which the integral diverges. This means that our approximate description, which considers the collision as an elastic process, becomes invalid and needs to be amended by taking into account the difference between the initial and final kinetic energies of the particle due to radiation of the energy quantum $\hbar\omega$ of the emitted photon, so that

$$\frac{p_{\text{ini}}^2}{2m} - \frac{p_{\text{fin}}^2}{2m} = \hbar\omega, \quad \text{i.e. } \frac{p_{\text{ini}}^2}{2m} = E, \quad \frac{p_{\text{fin}}^2}{2m} = E - \hbar\omega, \quad . \quad (10.87)$$

As a result, taking into account that the minimum and maximum values of γ correspond to, respectively, the parallel and antiparallel alignments of the vectors \mathbf{p}_{ini} and \mathbf{p}_{fin} , we get

$$\ln \frac{\gamma_{\max}}{\gamma_{\min}} = \ln \frac{p_{\text{ini}} + p_{\text{fin}}}{p_{\text{ini}} - p_{\text{fin}}} \equiv \ln \frac{(p_{\text{ini}} + p_{\text{fin}})^2 / 2m}{(p_{\text{ini}}^2 - p_{\text{fin}}^2) / 2m} = \ln \frac{[E^{1/2} + (E - \hbar\omega)^{1/2}]^2}{\hbar\omega}, \quad (10.88)$$

Quantum
brems-
strahlung

Plugged into Eq. (85), this expression yields the so-called *Bethe-Heitler formula* for *quantum bremsstrahlung*.³⁷ Note that at this approach, γ_{\max} is close to that of the classical approximation, but γ_{\min} is of the order of $\hbar\omega/u$, so that

$$\frac{\gamma_{\min}|_{\text{classical}}}{\gamma_{\min}|_{\text{quantum}}} \sim \frac{\alpha \mathcal{T} \mathcal{T}'}{\beta}, \quad (10.89)$$

where \mathcal{T} and \mathcal{T}' are the particles' charges in the units of e , and α is the dimensionless *fine structure* ("Sommerfeld") *constant*,

$$\alpha \equiv \frac{e^2}{4\pi\epsilon_0 \hbar c}|_{\text{SI}} = \frac{e^2}{\hbar c}|_{\text{Gaussian}} \approx \frac{1}{137} \ll 1, \quad (10.90)$$

which is one of the basic notions of quantum mechanics.³⁸ Due to the smallness of the constant, the ratio (89) is below 1 for most cases of practical interest, and since the integral of (84) over γ is limited by the largest of all possible cutoffs γ_{\min} , it is the Bethe-Heitler formula that should be used.

³⁷ The modifications of this formula necessary for the relativistic description are surprisingly minor – see, e.g., Chapter 15 in J. Jackson, *Classical Electrodynamics*, 3rd ed., Wiley 1999. For even more detail, the standard reference monograph on bremsstrahlung is W. Heitler, *The Quantum Theory of Radiation*, 3rd ed., Oxford U. Press 1954 (reprinted in 1984 and 2010 by Dover).

³⁸ See, e.g., QM Secs. 4.4, 6.3, 6.4, 9.3, 9.5, and 9.7.

Now nothing prevents us from calculating the total radiative losses of energy per unit length:

$$-\frac{d\mathcal{E}}{dx} = \int_0^\infty \left(-\frac{d^2\mathcal{E}}{d\omega dz} \right) d\omega = \frac{16}{3} n \frac{q^2}{4\pi\epsilon_0 c} \left(\frac{qq'}{4\pi\epsilon_0 mc^2} \right)^2 \frac{1}{\beta^2} 2 \int_0^{\omega_{\max}} \ln \frac{\mathcal{E}^{1/2} - (\mathcal{E} - \hbar\omega)^{1/2}}{(\hbar\omega)^{1/2}} d\omega, \quad (10.91)$$

where $\hbar\omega_{\max} = \mathcal{E}$ is the maximum energy of the radiation quantum. By introducing the dimensionless integration variable $\xi \equiv \hbar\omega/\mathcal{E} = 2\hbar\omega/(mu^2/2)$, this integral is reduced to a table one,³⁹ and we get

$$-\frac{d\mathcal{E}}{dx} = \frac{16}{3} n \frac{q^2}{4\pi\epsilon_0 c} \left(\frac{qq'}{4\pi\epsilon_0 mc^2} \right)^2 \frac{1}{\beta^2} \frac{u^2}{\hbar} \equiv \frac{16}{3} n \left(\frac{q'^2}{4\pi\epsilon_0 \hbar c} \right) \left(\frac{q^2}{4\pi\epsilon_0} \right)^2 \frac{1}{mc^2}. \quad (10.92)$$

Following my usual style, at this point I would give you an estimate of the losses for a typical case; however, let me first discuss a parallel particle energy loss mechanism, the so-called *Coulomb losses*, due to the transfer of mechanical impulse from the scattered particle to the scattering centers. (This energy eventually goes into an increase of the thermal energy of the scattering medium, rather than to the electromagnetic radiation.)

Using Eqs. (9.139) for the electric field of a linearly moving charge q , we can readily find the momentum it transfers to the counterpart charge q' :⁴⁰

$$\Delta p' = |(\Delta p')_y| = \left| \int_{-\infty}^{+\infty} (\dot{p}')_y dt \right| = \left| \int_{-\infty}^{+\infty} q'E_y dt \right| = \frac{qq'}{4\pi\epsilon_0} \int_{-\infty}^{+\infty} \frac{\gamma b}{(b^2 + \gamma^2 u^2 t^2)^{3/2}} dt = \frac{qq'}{4\pi\epsilon_0} \frac{2}{bu}. \quad (10.93)$$

Hence, the kinetic energy acquired by the scattering particle (and hence to the loss of the energy \mathcal{E} of the incident particle) is

$$-\Delta\mathcal{E} = \frac{(\Delta p')^2}{2m'} = \left(\frac{qq'}{4\pi\epsilon_0} \right)^2 \frac{2}{m'u^2 b^2}. \quad (10.94)$$

Such elementary energy losses have to be summed up over all collisions, with random values of the impact parameter b . At the scattering center density n , the number of collisions per small path length dx per small range db is $dN = n 2\pi b db dx$, so that

Coulomb losses

$$-\frac{d\mathcal{E}}{dx} = - \int \Delta\mathcal{E} dN = n \left(\frac{qq'}{4\pi\epsilon_0} \right)^2 \frac{2}{m'u^2} 2\pi \int_{b_{\min}}^{b_{\max}} \frac{db}{b} = 4\pi n \left(\frac{qq'}{4\pi\epsilon_0} \right)^2 \frac{\ln B}{m'u^2}, \quad \text{where } B \equiv \frac{b_{\max}}{b_{\min}}. \quad (10.95)$$

Here, at the last step, the logarithmic integral over b was treated similarly to that over q in the bremsstrahlung theory. This approximation is adequate because the ratio b_{\max}/b_{\min} is much larger than 1. Indeed, b_{\min} may be estimated from $(\Delta p')_{\max} \sim p = \gamma mu$. For this value, Eq. (93) with $q' \sim q$ gives $b_{\min} \sim r_c$ (see Eq. (8.41) and its discussion), which, for elementary particles, is of the order of 10^{-15} m. On the other hand, for the most important case when the Coulomb energy absorbers are electrons (which, according to Eq. (94), are the most efficient ones, due to their very low mass m'), b_{\max} may be estimated from the condition $\tau = b/\gamma u \sim 1/\omega_{\min}$, where $\omega_{\min} \sim 10^{16}$ s⁻¹ is the characteristic frequency of electron

³⁹ See, e.g., MA Eq. (6.14).

⁴⁰ According to Eq. (9.139), $E_z = 0$, while the net impulse of the longitudinal force $q'E_x$ is zero, so that Eq. (93) gives the full momentum transfer.

transitions in atoms. (Quantum mechanics forbids such energy transfer at lower frequencies.) From here, we have the estimate $b_{\max} \sim \gamma u / \omega_{\min}$, so that

$$B \equiv \frac{b_{\max}}{b_{\min}} \sim \frac{\gamma u}{r_c \omega_{\min}}, \quad (10.96)$$

for $\gamma \sim 1$ and $u \sim c \approx 3 \times 10^8$ m/s giving $b_{\max} \sim 3 \times 10^{-8}$ m, so that $B \sim 10^9$ (give or take a couple of orders of magnitude – this does not change the estimate $\ln B \approx 20$ too much).⁴¹

Now we can compare the non-radiative Coulomb losses (95) with the radiative losses due to the bremsstrahlung, given by Eq. (92):

$$\frac{-d\mathcal{E}|_{\text{radiation}}}{-d\mathcal{E}|_{\text{Coulomb}}} \sim \alpha \mathcal{F} \frac{m'}{m} \beta^2 \frac{1}{\ln B}, \quad (10.97)$$

Since $\alpha \sim 10^{-2} \ll 1$, for non-relativistic particles ($\beta \ll 1$) the bremsstrahlung losses of energy are much lower (that is why I did not want to rush with their estimates), and only for ultra-relativistic particles, the relation may be opposite.

According to Eqs. (95)-(96), for electron-electron scattering ($q = q' = -e$, $m = m' = m_e$),⁴² at the value $n = 6 \times 10^{26}$ m⁻³ typical for air at ambient conditions, the characteristic length of energy loss,

$$l_c \equiv \frac{\mathcal{E}}{(-d\mathcal{E}/dx)}, \quad (10.98)$$

for electrons with kinetic energy $\mathcal{E} = 6$ keV is close to 2×10^{-4} m $\equiv 0.2$ mm. (This is why we need high vacuum in electron microscope columns and other vacuum electron devices.) Since $l_c \propto \mathcal{E}^2$, more energetic particles penetrate to matter deeper, until the bremsstrahlung steps in, and limits this trend at very high energies.

10.5. Density effects and the Cherenkov radiation

For condensed matter, the Coulomb loss estimate made in the last section is not quite suitable, because it is based on the upper cutoff $b_{\max} \sim \gamma u / \omega_{\min}$. For the example given above, the incoming electron velocity u is close to 5×10^7 m/s, and for the typical value $\omega_{\min} \sim 10^{16}$ s⁻¹ ($\hbar \omega_{\min} \sim 10$ eV), this cutoff b_{\max} is of the order of $\sim 5 \times 10^{-9}$ m = 5 nm. Even for air at ambient conditions, this is somewhat larger than the average distance (~ 2 nm) between the molecules, so that at the high end of the impact parameter range, at $b \sim b_{\max}$, the Coulomb loss events in adjacent molecules are not quite independent, and the theory needs some corrections. For condensed matter, with much higher particle density n , most collisions satisfy the following condition:

⁴¹ A quantum analysis (carried out by Hans Bethe in 1940) replaces, in Eq. (95), $\ln B$ with $\ln(2\gamma^2 m u^2 / \hbar \langle \omega \rangle) - \beta^2$, where $\langle \omega \rangle$ is the average frequency of the atomic quantum transitions weight by their oscillator strength. This refinement does not change the estimate given below. Note that both the classical and quantum formulas describe a fast increase (as $1/\beta$) of the energy loss rate ($-d\mathcal{E}/dx$) at $\gamma \rightarrow 1$, and its slow increase (as $\ln \gamma$) at $\gamma \rightarrow \infty$, so that the losses have a minimum at $(\gamma - 1) \sim 1$.

⁴² Actually, the above analysis has neglected the change of momentum of the incident particle. This is legitimate at $m' \ll m$, but for $m = m'$ the change approximately doubles the energy losses. Still, this does not change the order of magnitude of the estimate.

$$nb^3 \gg 1, \quad (10.99)$$

and the treatment of Coulomb collisions as a set of independent events is inadequate. However, this condition enables the opposite approach: treating the medium as a continuum. In the time-domain formulation used in the previous sections of this chapter, this would be a very complex problem, because it would require an explicit description of the medium dynamics. Here the frequency-domain approach, based on the Fourier transform in both time and space, helps a lot, provided that the functions $\epsilon(\omega)$ and $\mu(\omega)$ are considered known – either calculated or taken from experiment. Let us have a good look at this approach because it gives some interesting (and practically important) results.

In Chapter 6, we have used the macroscopic Maxwell equations to derive Eqs. (6.118), which describe the time evolution of electrodynamic potentials in a linear medium with frequency-independent ϵ and μ . Looking for all functions participating in Eqs. (6.118) in the plane-wave expansion form⁴³

$$f(\mathbf{r}, t) = \int d^3k \int d\omega f_{\mathbf{k}, \omega} e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)}, \quad (10.100)$$

and requiring all coefficients at similar exponents to be balanced, we get their Fourier images:⁴⁴

$$(k^2 - \omega^2 \epsilon \mu) \phi_{\mathbf{k}, \omega} = \frac{\rho_{\mathbf{k}, \omega}}{\epsilon}, \quad (k^2 - \omega^2 \epsilon \mu) \mathbf{A}_{\mathbf{k}, \omega} = \mu \mathbf{j}_{\mathbf{k}, \omega}. \quad (10.101)$$

As was discussed in Chapter 7, in such a Fourier form, the macroscopic Maxwell theory remains valid even for dispersive (but isotropic and linear!) media, so that Eqs. (101) may be generalized as

$$[k^2 - \omega^2 \epsilon(\omega) \mu(\omega)] \phi_{\mathbf{k}, \omega} = \frac{\rho_{\mathbf{k}, \omega}}{\epsilon(\omega)}, \quad [k^2 - \omega^2 \epsilon(\omega) \mu(\omega)] \mathbf{A}_{\mathbf{k}, \omega} = \mu(\omega) \mathbf{j}_{\mathbf{k}, \omega}, \quad (10.102)$$

An evident advantage of these equations is that their formal solution is elementary:

$$\phi_{\mathbf{k}, \omega} = \frac{\rho_{\mathbf{k}, \omega}}{\epsilon(\omega) [k^2 - \omega^2 \epsilon(\omega) \mu(\omega)]}, \quad \mathbf{A}_{\mathbf{k}, \omega} = \frac{\mu(\omega) \mathbf{j}_{\mathbf{k}, \omega}}{[k^2 - \omega^2 \epsilon(\omega) \mu(\omega)]}, \quad (10.103)$$

Field
potentials
in a linear
medium

so that the “only” remaining things to do is, first, to calculate the Fourier transforms of the functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$, describing stand-alone charges and currents, using the transform reciprocal to Eq. (100), with one factor $1/2\pi$ per each scalar dimension,

$$f_{\mathbf{k}, \omega} = \frac{1}{(2\pi)^4} \int d^3r \int dt f(\mathbf{r}, t) e^{-i(\mathbf{k} \cdot \mathbf{r} - \omega t)}, \quad (10.104)$$

and then to carry out the integration (100) of Eqs. (103).

For our problem of a single charge q uniformly moving through a medium with velocity \mathbf{u} ,

$$\rho(\mathbf{r}, t) = q \delta(\mathbf{r} - \mathbf{u}t), \quad \mathbf{j}(\mathbf{r}, t) = q \mathbf{u} \delta(\mathbf{r} - \mathbf{u}t), \quad (10.105)$$

⁴³ All integrals here and below are in infinite limits unless specified otherwise.

⁴⁴ As was discussed in Sec. 7.2, the Ohmic conductivity of the medium (generally, also a function of frequency) may be readily incorporated into the dielectric permittivity: $\epsilon(\omega) \rightarrow \epsilon_{\text{ef}}(\omega) + i\sigma(\omega)/\omega$. In this section, I will assume that such incorporation, which is especially natural for high frequencies, has been performed, so that the current density $\mathbf{j}(\mathbf{r}, t)$ describes only stand-alone currents – for example, the current (105) of the incident particle.

the first task is easy:

$$\rho_{\mathbf{k},\omega} = \frac{q}{(2\pi)^4} \int d^3r \int dt q \delta(\mathbf{r} - \mathbf{u}t) e^{-i(\mathbf{k}\cdot\mathbf{r} - \omega t)} = \frac{q}{(2\pi)^4} \int e^{i(\omega t - \mathbf{k}\cdot\mathbf{u}t)} dt = \frac{q}{(2\pi)^3} \delta(\omega - \mathbf{k}\cdot\mathbf{u}). \quad (10.106)$$

Since the expressions (105) for $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ differ only by a constant factor \mathbf{u} , it is clear that the absolutely similar calculation for the current gives

$$\mathbf{j}_{\mathbf{k},\omega} = \frac{q\mathbf{u}}{(2\pi)^3} \delta(\omega - \mathbf{k}\cdot\mathbf{u}). \quad (10.107)$$

Let us summarize what we have got by now, by plugging Eqs. (106)-(107) into Eqs. (103):

$$\phi_{\mathbf{k},\omega} = \frac{1}{(2\pi)^3} \frac{q\delta(\omega - \mathbf{k}\cdot\mathbf{u})}{\varepsilon(\omega)[k^2 - \omega^2\varepsilon(\omega)\mu(\omega)]}, \quad \mathbf{A}_{\mathbf{k},\omega} = \frac{1}{(2\pi)^3} \frac{\mu(\omega)q\mathbf{u}\delta(\omega - \mathbf{k}\cdot\mathbf{u})}{[k^2 - \omega^2\varepsilon(\omega)\mu(\omega)]} \equiv \varepsilon(\omega)\mu(\omega)\mathbf{u}\phi_{\mathbf{k},\omega}. \quad (10.108)$$

Now, at the last calculation step, namely the integration (100), we are starting to pay a heavy price for the easiness of the first steps. This is why let us think well about what exactly we need from it. First of all, for the calculation of power losses, the electric field is more convenient to use than the potentials, so let us calculate the Fourier images of \mathbf{E} and \mathbf{B} . Plugging the expansion (100) into the basic relations (6.7), and again requiring the balance of exponent's coefficients, we get

$$\mathbf{E}_{\mathbf{k},\omega} = -i\mathbf{k}\phi_{\mathbf{k},\omega} + i\omega\mathbf{A}_{\mathbf{k},\omega} = i[\omega\varepsilon(\omega)\mu(\omega)\mathbf{u} - \mathbf{k}]\phi_{\mathbf{k},\omega}, \quad \mathbf{B}_{\mathbf{k},\omega} = i\mathbf{k} \times \mathbf{A}_{\mathbf{k},\omega} = i\varepsilon(\omega)\mu(\omega)\mathbf{k} \times \mathbf{u}\phi_{\mathbf{k},\omega}, \quad (10.109)$$

so that Eqs. (100) and (108) yield

$$\mathbf{E}(\mathbf{r}, t) = \int d^3k \int d\omega \mathbf{E}_{\mathbf{k},\omega} e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t)} = \frac{iq}{(2\pi)^3} \int d^3k \int d\omega \frac{[\omega\varepsilon(\omega)\mu(\omega)\mathbf{u} - \mathbf{k}]\delta(\omega - \mathbf{k}\cdot\mathbf{u})}{\varepsilon(\omega)[k^2 - \omega^2\varepsilon(\omega)\mu(\omega)]} e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t)}. \quad (10.110)$$

This formula may be rewritten as the temporal Fourier integral (51), with the following \mathbf{r} -dependent complex amplitude:

$$\mathbf{E}_\omega(\mathbf{r}) = \int \mathbf{E}_{\mathbf{k},\omega} e^{i\mathbf{k}\cdot\mathbf{r}} d^3k = \frac{iq}{(2\pi)^3} \int \frac{[\omega\varepsilon(\omega)\mu(\omega)\mathbf{u} - \mathbf{k}]\delta(\omega - \mathbf{k}\cdot\mathbf{u})}{\varepsilon(\omega)[k^2 - \omega^2\varepsilon(\omega)\mu(\omega)]} e^{i\mathbf{k}\cdot\mathbf{r}} d^3k. \quad (10.111)$$

Let us calculate the Cartesian components of this partial Fourier image \mathbf{E}_ω , at a point separated by distance b from the particle's trajectory. Selecting the coordinates and time origin as shown in Fig. 3, we have $\mathbf{r} = \{0, b, 0\}$ and $\mathbf{u} = \{u, 0, 0\}$, so that only E_x and E_y are different from zero. In particular, according to Eq. (111),

$$(E_x)_\omega = \frac{iq}{(2\pi)^3\varepsilon(\omega)} \int dk_x \int dk_y \int dk_z \frac{\omega\varepsilon(\omega)\mu(\omega)u - k_x}{k^2 - \omega^2\varepsilon(\omega)\mu(\omega)} \delta(\omega - k_x u) \exp\{ik_y b\}. \quad (10.112)$$

The delta function kills one integral (over k_x) of the three, and we get

$$(E_x)_\omega = \frac{iq}{(2\pi)^3\varepsilon(\omega)u} \left[\omega\varepsilon(\omega)\mu(\omega)u - \frac{\omega}{u} \right] \int \exp\{ik_y b\} dk_y \int \frac{dk_z}{\omega^2/u^2 + k_y^2 + k_z^2 - \omega^2\varepsilon(\omega)\mu(\omega)}. \quad (10.113)$$

The internal integral (over k_z) may be readily reduced to the table integral $\int d\xi/(1 + \xi^2)$ in infinite limits, equal to π ,⁴⁵ and result represented as

$$(E_x)_\omega = -\frac{i\pi q\kappa^2}{(2\pi)^3 \omega \epsilon(\omega)} \int \frac{\exp\{ik_y b\}}{(k_y^2 + \kappa^2)^{1/2}} dk_y, \quad (10.114)$$

where the parameter κ (generally, a complex function of frequency) is defined as⁴⁶

Function $\kappa(\omega)$

$$\kappa^2(\omega) \equiv \omega^2 \left(\frac{1}{u^2} - \epsilon(\omega) \mu(\omega) \right). \quad (10.115)$$

The last integral may be expressed via the modified Bessel function of the second kind:⁴⁷

$$(E_x)_\omega = -\frac{iqu\kappa^2}{(2\pi)^2 \omega \epsilon(\omega)} K_0(\kappa b). \quad (10.116)$$

A very similar calculation yields

$$(E_y)_\omega = \frac{q\kappa}{(2\pi)^2 \epsilon(\omega)} K_1(\kappa b). \quad (10.117)$$

Now, instead of rushing to make the final integration (51) over ω to calculate $\mathbf{E}(t)$, let us realize that what we need most is the total energy loss through the whole time of the particle's passage over an elementary distance dx . According to Eq. (4.38), the energy loss per unit volume is

$$-\frac{d\mathcal{E}}{dV} = \int \mathbf{j} \cdot \mathbf{E} dt, \quad (10.118)$$

where \mathbf{j} is the current of the bound charges in the medium, and should not be confused with the stand-alone incident-particle current (105). This integral may be readily expressed via the partial Fourier image \mathbf{E}_ω and the similarly defined image \mathbf{j}_ω , just as it was done at the derivation of Eq. (54):

$$-\frac{d\mathcal{E}}{dV} = \int dt \int d\omega e^{-i\omega t} \int d\omega' e^{-i\omega' t} \mathbf{j}_\omega \cdot \mathbf{E}_{\omega'} = 2\pi \int d\omega \int d\omega' \mathbf{j}_\omega \cdot \mathbf{E}_{\omega'} \delta(\omega + \omega') = 2\pi \int \mathbf{j}_\omega \cdot \mathbf{E}_{-\omega} d\omega. \quad (10.119)$$

Let us incorporate the effective Ohmic conductivity $\sigma_{\text{ef}}(\omega)$ into the complex permittivity $\epsilon(\omega)$ just as this was discussed in Sec. 7.2, using Eq. (7.46) to write

$$\mathbf{j}_\omega = \sigma_{\text{ef}}(\omega) \mathbf{E}_\omega = -i\omega \epsilon(\omega) \mathbf{E}_\omega. \quad (10.120)$$

As a result, Eq. (119) yields

$$-\frac{d\mathcal{E}}{dV} = -2\pi i \int \epsilon(\omega) \mathbf{E}_\omega \cdot \mathbf{E}_{-\omega} \omega d\omega = 4\pi \text{Im} \int_0^\infty \epsilon(\omega) |E_\omega|^2 \omega d\omega. \quad (10.121)$$

(The last step was possible due to the property $\epsilon(-\omega) = \epsilon^*(\omega)$, which was discussed in Sec. 7.2.)

⁴⁵ See, e.g., MA Eq. (6.5a).

⁴⁶ The frequency-dependent parameter $\kappa(\omega)$ should not be confused with the dc low-frequency dielectric constant $\kappa \equiv \epsilon(0)/\epsilon_0$ that was discussed in Chapter 3.

⁴⁷ As a reminder, the main properties of these functions are listed in Sec. 2.7 – see, in particular, Fig. 2.22 and Eqs. (2.157)-(2.158).

Finally, just as in the last section, we have to average the energy loss rate over random values of the impact parameter b :

$$-\frac{d\mathcal{E}}{dx} = \int \left(-\frac{d\mathcal{E}}{dV} \right) d^2 b \approx 2\pi \int_{b_{\min}}^{\infty} \left(-\frac{d\mathcal{E}}{dV} \right) b db = 8\pi^2 \int_{b_{\min}}^{\infty} b db \int_0^{\infty} \left(|E_x|^2 + |E_y|^2 \right) \text{Im } \varepsilon(\omega) \omega d\omega. \quad (10.122)$$

Due to the (weak) divergence of the functions $K_0(\xi)$ and $K_1(\xi)$ at $\xi \rightarrow 0$, we have to cut the resulting integral over b at some b_{\min} where our theory loses legitimacy. (On that limit, we are not doing much better than in the past section). Plugging in the calculated expressions (116) and (117) for the field components, swapping the integrals over ω and b , and using the recurrence relations (2.142), which are valid for all Bessel functions, we finally get:

$$-\frac{d\mathcal{E}}{dx} = \frac{2}{\pi} q^2 \text{Im} \int_0^{\infty} (\kappa^* b_{\min}) K_1(\kappa^* b_{\min}) K_0(\kappa^* b_{\min}) \frac{d\omega}{\omega \varepsilon(\omega)}. \quad (10.123)$$

Radiation intensity

This general result is valid for a linear medium with arbitrary dispersion relations $\varepsilon(\omega)$ and $\mu(\omega)$. (The last function participates in Eq. (123) only via Eq. (115) that defines the parameter κ .) To get more concrete results, some particular model of the medium should be used. Let us explore the Lorentz-oscillator model that was discussed in Sec. 7.2, in its form (7.33) suitable for the transition to the quantum-mechanical description of atoms:

$$\varepsilon(\omega) = \varepsilon_0 + \frac{nq'^2}{m} \sum_j \frac{f_j}{(\omega_j^2 - \omega^2) - 2i\omega\delta_j}, \quad \text{with } \sum_j f_j = 1; \quad \mu(\omega) = \mu_0. \quad (10.124)$$

If the damping of the effective atomic oscillators is low, $\delta_j \ll \omega_j$, as it typically is, and the particle's speed u is much lower than the typical wave's phase velocity v (and hence than c !), then for most frequencies Eq. (115) gives

$$\kappa^2(\omega) \equiv \omega^2 \left(\frac{1}{u^2} - \frac{1}{v^2(\omega)} \right) \approx \frac{\omega^2}{u^2}, \quad (10.125)$$

i.e. $\kappa \approx \kappa^* \approx \omega/u$ is virtually real. In this case, Eq. (123) may be reduced to Eq. (95) with

$$b_{\max} = \frac{1.123u}{\langle \omega \rangle}. \quad (10.126)$$

The good news here is that both approaches (the microscopic analysis of Sec. 4 and the macroscopic analysis of this section) give essentially the same result. The same fact may be also perceived as bad news: the treatment of the medium as a continuum does not give any new results here. The situation somewhat changes at relativistic velocities, at which such treatment provides noticeable corrections (called *density effects*), in particular reducing the energy loss estimates.

Let me, however, leave these details for special topic courses and focus on a much more important effect described by our formulas. Consider the dependence of the electric field components on the impact parameter b , i.e. on the closest distance between the particle's trajectory and the field observation point. At $b \rightarrow \infty$, we can use, in Eqs. (116)-(117), the asymptotic formula (2.158),

$$K_n(\xi) \rightarrow \left(\frac{\pi}{2\xi} \right)^{1/2} e^{-\xi}, \quad \text{at } \xi \rightarrow \infty, \quad (10.127)$$

to conclude that if $\kappa^2 > 0$, i.e. if κ is real, the complex amplitudes E_ω of both components E_x and E_y of the electric field decrease with b exponentially. However, let us consider what happens at frequencies where $\kappa^2(\omega) < 0$,⁴⁸ i.e.

$$\varepsilon(\omega)\mu(\omega) \equiv \frac{1}{v^2(\omega)} < \frac{1}{u^2} < \frac{1}{c^2} \equiv \varepsilon_0\mu_0. \quad (10.128)$$

(This condition means that the particle's velocity is larger than the phase velocity of the waves at this particular frequency.) In this case, the parameter $\kappa(\omega)$ is purely imaginary, so that the functions $\exp\{kb\}$ in the asymptotes (127) of Eqs. (116)-(117) become just phase factors, and the field component amplitudes fall very slowly:

$$|E_x(\omega)| \propto |E_y(\omega)| \propto \frac{1}{b^{1/2}}. \quad (10.129)$$

This means that the Poynting vector drops as $1/b$, so that its flux through a surface of a round cylinder of radius b , with its axis on the particle trajectory (i.e. the power flow from the particle), does not depend on b at all. This is an electromagnetic wave emission – the famous *Cherenkov radiation*.⁴⁹

The direction \mathbf{n} of its propagation may be readily found taking into account that at large distances from the particle's trajectory, the emitted wave has to be locally planar and transverse ($\mathbf{n} \perp \mathbf{E}$), so that the so-called *Cherenkov angle* θ between the vector \mathbf{n} and the particle's velocity \mathbf{u} may be simply found from the ratio of the electric field components – see Fig. 14a:

$$\tan \theta = -\frac{E_x}{E_y}. \quad (10.130)$$

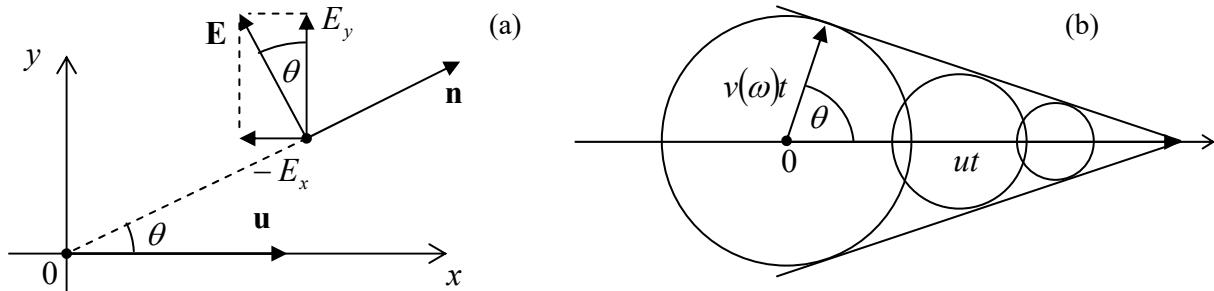

Fig. 10.14. (a) The Cherenkov radiation's propagation angle θ , and (b) its interpretation.

The ratio on the right-hand side of this relation may be calculated by plugging the asymptotic formula (127) into Eqs. (116) and (117) and calculating their ratio:

⁴⁸ Strictly speaking, the inequality $\kappa^2(\omega) < 0$ does not make sense for a medium with a complex product $\varepsilon(\omega)\mu(\omega)$, and hence complex $\kappa^2(\omega)$. However, in a typical medium where particles can propagate over substantial distances, the imaginary part of the product $\varepsilon(\omega)\mu(\omega)$ does not vanish only in very limited frequency intervals, much more narrow than the intervals that we are discussing now – please have one more look at Fig. 7.5.

⁴⁹ This radiation was observed experimentally by Pavel Alekseevich Cherenkov (in older Western texts, “Čerenkov”) in 1934, with the observations explained by Ilya Mikhailovich Frank and Igor Yevgenyevich Tamm in 1937. Note, however, that the effect had been predicted theoretically as early as 1889 by the same Oliver Heaviside whose name was mentioned in this course so many times – and whose genius I believe is still underappreciated.

$$\tan \theta = -\frac{E_x}{E_y} = \frac{i\kappa u}{\omega} = [\epsilon(\omega)\mu(\omega)u^2 - 1]^{1/2} \equiv \left(\frac{u^2}{v^2(\omega)} - 1 \right)^{1/2}, \quad (10.131a)$$

so that

$$\cos \theta = \frac{v(\omega)}{u} < 1. \quad (10.131b)$$

Cherenkov
radiation:
angle

Remarkably, this direction does not depend on the emission time t_{ret} , so that the radiation of frequency ω , at each instant, forms a hollow cone led by the particle. This simple result allows an evident interpretation (Fig. 14b): the cone's interior is just the set of all observation points that have already been reached by the radiation, propagating with the speed $v(\omega) < u$, emitted from all previous points of the particle's trajectory by the given time t . This phenomenon is an analog of the so-called *Mach cone* in fluid dynamics,⁵⁰ besides that in the Cherenkov radiation, there is a separate cone for each frequency (of the range in which $v(\omega) < u$): the smaller is the $\epsilon(\omega)\mu(\omega)$ product, i.e. the higher is the wave velocity $v(\omega) = 1/[\epsilon(\omega)\mu(\omega)]^{1/2}$, the broader is the cone, so that the earlier the corresponding “shock wave” arrives to an observer. Please note that the Cherenkov radiation is a unique radiative phenomenon: it takes place even if a particle moves without acceleration, and (in agreement with our analysis in Sec. 2), is impossible in free space, where $v(\omega) = c = \text{const}$ is larger than u for any particle.

The Cherenkov radiation's intensity may be also readily found by plugging the asymptotic expression (127), with imaginary κ , into Eq. (123). The result is

$$-\frac{d\mathcal{E}}{dx} \approx \left(\frac{3e}{4\pi} \right)^2 \int_{v(\omega) < u} \omega \left(1 - \frac{v^2(\omega)}{u^2} \right) d\omega. \quad (10.132)$$

Cherenkov
radiation:
intensity

For non-relativistic particles ($u \ll c$), the Cherenkov radiation condition $u > v(\omega)$ is fulfilled only in relatively narrow frequency intervals where the product $\epsilon(\omega)\mu(\omega)$ is very large (usually, due to optical resonance peaks of the electric permittivity – see Fig. 7.5 and its discussion). In this case, the emitted light consists of a few nearly-monochromatic components. On the contrary, if the condition $u > v(\omega)$, i.e. $u^2/\epsilon(\omega)\mu(\omega) > 1$ is fulfilled in a broad frequency range, as it is for ultra-relativistic particles in condensed media, then the radiated power, according to Eq. (132), is dominated by higher frequencies of the range – hence the famous bluish color of the Cherenkov radiation glow from water-filled nuclear reactors – see Fig. 15.

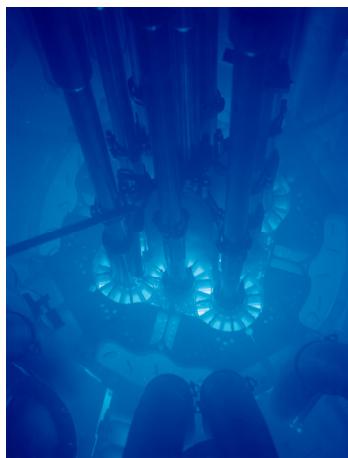

Fig. 10.15. The Cherenkov radiation glow in the Advanced Test Reactor of the Idaho National Laboratory in Arco, ID. (Adapted from http://en.wikipedia.org/wiki/Cherenkov_radiation under the Creative Commons CC-BY-SA-2.0 license.)

⁵⁰ Its brief discussion may be found in CM Sec. 8.6.

The Cherenkov radiation is broadly used in high-energy experiments for particle identification and speed measurement (since it is easy to pass the particles through layers of different densities and hence with different dielectric constants) – for example, in the so-called Ring Imaging Cherenkov (RICH) detectors that have been designed for the DELPHI experiment⁵¹ at the Large Electron-Positron Collider (LEP) in CERN.

A little bit counter-intuitively, the formalism described in this section is also very useful for the description of an apparently rather different effect – the so-called *transition radiation* that takes place when a charged particle crosses a border between two media.⁵² The effect may be interpreted as the result of the time dependence of the electric dipole formed by the moving charge q and its mirror image q' in the counterpart medium – see Fig. 16.

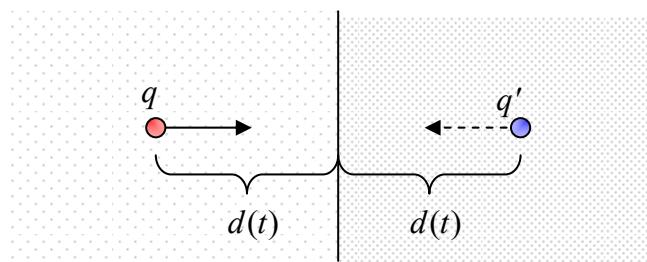

Fig. 10.16. The transition radiation's physics.

In the non-relativistic limit, this effect allows a straightforward description combining the electrostatics picture of Sec. 3.4 (see Fig. 3.9 and its discussion), and Eq. (8.27), corrected for the media polarization effects. However, if the particle's velocity u is comparable with the phase velocity of waves in either medium, the adequate theory of the transition radiation becomes very close to that of the Cherenkov radiation.

In comparison with the Cherenkov radiation, the transition radiation is rather weak, and its practical use (mostly for the measurement of the Lorentz factor γ , to which the radiation intensity is nearly proportional) requires multi-layered stacks.⁵³ In these systems, the radiation emitted at sequential borders may be coherent, and the system's physics may become close to that of the free-electron lasers mentioned in Sec. 4.

10.6. Radiation's back-action

An attentive and critically-minded reader could notice that so far our treatment of charged particle dynamics has never been fully self-consistent. Indeed, in Sec. 9.6 we have analyzed particle's motion in various external fields, ignoring those radiated by the particle itself, while in Sec. 8.2 and earlier in this chapter these fields have been calculated (admittedly, just for a few simple cases), but, again, their back-action on the emitting particle has been ignored. Only in very few cases we have taken

⁵¹ See, e.g., <http://delphiwww.cern.ch/offline/physics/delphi-detector.html>. For an in-depth review of radiation detectors (including the Cherenkov ones), the reader may be referred, for example, to the classical text by G. F. Knoll, *Radiation Detection and Measurement*, 4th ed., Wiley, 2010, and a newer treatment by K. Kleinknecht, *Detectors for Particle Radiation*, Cambridge U. Press, 1999.

⁵² The effect was predicted theoretically in 1946 by V. Ginzburg and I. Frank, and only later observed experimentally.

⁵³ See, e.g., Sec. 5.3 in K. Kleinknecht's monograph cited above.

the back effects of the radiation implicitly, via the energy conservation arguments. However, even in these cases, the near-field effects, such as the first term in Eq. (19), which affect the moving particle most, have been ignored.

At the same time, it is clear that in sharp contrast with electrostatics, the interaction of a moving point charge with its own field cannot be always ignored. As the simplest example, if an electron is made to fly through a resonant cavity, thus inducing electromagnetic oscillations in it, and then is forced (say, by an appropriate static field) to return into the cavity before the oscillations have decayed, its motion will certainly be affected by the oscillating fields, just as if they had been induced by another source. There is no conceptual problem with applying the Maxwell theory to such “field-particle rendezvous” effects; moreover, it is the basis of the engineering design of such vacuum electron devices as klystrons, magnetrons, and free-electron lasers.

A problem arises only when no clear “rendezvous” points are enforced by boundary conditions, so that the most important self-field effects are at $R \equiv |\mathbf{r} - \mathbf{r}'| \rightarrow 0$, the most evident example being the charged particle’s radiation into free space, described earlier in this chapter. We already know that such radiation takes away a part of the charge’s kinetic energy, i.e. has to cause its deceleration. One should wonder, however, whether such self-action effects might be described in a more direct, non-perturbative way.

As the first attempt, let us try a phenomenological approach based on the already derived formulas for the radiation power \mathcal{P} . For the sake of simplicity, let us consider a non-relativistic point charge q in free space, so that \mathcal{P} is described by Eq. (8.27), with the electric dipole moment’s derivative over time equal to $q\dot{\mathbf{u}}$:

$$\mathcal{P} = \frac{Z_0 q^2}{6\pi c^2} \dot{u}^2 \equiv \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \dot{u}^2. \quad (10.133)$$

The most naïve approach would be to write the equation of the particle’s motion in the form

$$m\ddot{\mathbf{u}} = \mathbf{F}_{\text{ext}} + \mathbf{F}_{\text{self}}, \quad (10.134)$$

and try to calculate the radiation back-action force \mathbf{F}_{self} by requiring its instant power, $-\mathbf{F}_{\text{self}} \cdot \mathbf{u}$, to be equal to \mathcal{P} . However, this approach (say, for a 1D motion) would give a very unnatural result,

$$F_{\text{self}} \propto \frac{\dot{u}^2}{u}, \quad (10.135)$$

that might diverge at some points of the particle’s trajectory. This failure is clearly due to the retardation effect: as the reader may recall, Eq. (133) results from the analysis of radiation fields in the far-field zone, i.e. at *large* distances R from the particle, e.g., from the second term in Eq. (19), i.e. when the non-radiative first term (which is much larger at *small* distances, $R \rightarrow 0$) is ignored.

Before exploring the effects of this term, let us, however, make one more attempt at Eq. (133), considering its *average* effect on some periodic motion of the particle. (A possible argument for this step is that at the periodic motion, the retardation effects should be averaged out – just as at the transfer from Eq. (8.27) to Eq. (8.28).) To calculate the average, let us write the identity

$$\overline{\dot{u}^2} \equiv \frac{1}{T} \int_0^T \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} dt, \quad (10.136)$$

and carry out the integration on the right-hand side of Eq. (133) by parts over the motion period τ :

$$\overline{\mathcal{P}} = \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \overline{(\ddot{\mathbf{u}})^2} = \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \frac{1}{\tau} \left(\dot{\mathbf{u}} \cdot \mathbf{u} \Big|_0^\tau - \int_0^\tau \ddot{\mathbf{u}} \cdot \mathbf{u} dt \right) = -\frac{1}{\tau} \int_0^\tau \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \ddot{\mathbf{u}} \cdot \mathbf{u} dt. \quad (10.137)$$

On the other hand, the back-action force should give

$$\overline{\mathcal{P}} = -\frac{1}{\tau} \int_0^\tau \mathbf{F}_{\text{self}} \cdot \mathbf{u} dt. \quad (10.138)$$

These two averages coincide if⁵⁴

Abraham-Lorentz force

$$\boxed{\mathbf{F}_{\text{self}} = \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \ddot{\mathbf{u}}}. \quad (10.139)$$

This is the so-called *Abraham-Lorentz force* of back-action. Before going after a more serious derivation of this formula, let us estimate its scale, representing Eq. (139) as

$$\mathbf{F}_{\text{self}} = m\tau\ddot{\mathbf{u}}, \quad \text{with } \tau \equiv \frac{2}{3mc^3} \frac{q^2}{4\pi\epsilon_0}, \quad (10.140)$$

where the constant τ evidently has the dimension of time. Recalling the definition (8.41) of the classical radius r_c of the particle, Eq. (140) for τ may be rewritten as

$$\tau = \frac{2}{3} \frac{r_c}{c}. \quad (10.141)$$

For the electron, τ is of the order of 10^{-23} s, so that the right-hand side of Eq. (140) is very small. This means that in most cases the Abraham-Lorentz force is either negligible or leads to the same results as the perturbative treatments of energy loss we have used earlier in this chapter.

However, Eq. (140) brings some unpleasant surprises. For example, let us consider a 1D oscillator with frequency ω_0 . For it, Eq. (134), with the back-action force given by Eq. (140), takes the form

$$m\ddot{x} + m\omega_0^2 x = m\tau\ddot{x}. \quad (10.142)$$

Looking for the solution of this linear differential equation in the usual exponential form, $x(t) \propto \exp\{\lambda t\}$, we get the following characteristic equation,

$$\lambda^2 + \omega_0^2 = \tau\lambda^3. \quad (10.143)$$

It may look like that for any “reasonable” value of $\omega_0 \ll 1/\tau \sim 10^{23}$ s⁻¹, the right-hand side of this nonlinear algebraic equation may be treated as a perturbation. Indeed, looking for its solutions in the

⁵⁴ Just for the reader’s reference, this formula may be readily generalized to the relativistic case, in the 4-form:

$$F_{\text{self}}^\alpha = \frac{2}{3mc^3} \frac{q^2}{4\pi\epsilon_0} \left[\frac{d^2 p^\alpha}{d\tau^2} + \frac{p^\alpha}{(mc)^2} \left(\frac{dp_\beta}{d\tau} \frac{dp^\beta}{d\tau} \right) \right],$$

– the so-called *Abraham-Lorentz-Dirac force*.

natural form $\lambda_{\pm} = \pm i\omega_0 + \lambda'$, with $|\lambda'| \ll \omega_0$, expanding both parts of Eq. (143) in the Taylor series in the small parameter λ' , and keeping only the terms linear in λ' , we get

$$\lambda' \approx -\frac{\omega_0^2 \tau}{2}. \quad (10.144)$$

This means that the energy of free oscillations decreases in time as $\exp\{2\lambda' t\} = \exp\{-\omega_0^2 \tau t\}$; this is exactly the radiative damping analyzed earlier. However, Eq. (143) is deceiving; it has the third root corresponding to unphysical, exponentially growing (so-called *run-away*) solutions. It is easiest to see this for a free particle, with $\omega_0 = 0$. Then Eq. (143) becomes very simple,

$$\lambda^2 = \tau \lambda^3, \quad (10.145)$$

and it is easy to find all its three roots explicitly: $\lambda_1 = \lambda_2 = 0$ and $\lambda_3 = 1/\tau$. While the first two roots correspond to the values λ_{\pm} found earlier, the last one describes an exponential (and extremely rapid!) acceleration.

In order to remove this artifact, let us try to develop a self-consistent approach to the back-action effects, taking into account the near-field terms of particle fields. For that, we need to somehow overcome the divergence of Eqs. (10) and (19) at $R \rightarrow 0$. The most reasonable way to do this is to spread the particle's charge over a ball of radius a , with a spherically symmetric (but not necessarily constant) density $\rho(r)$, and at the end of the calculations trace the limit $a \rightarrow 0$.⁵⁵ Again sticking to the non-relativistic case (so that the magnetic component of the Lorentz force is not important), we should calculate

$$\mathbf{F}_{\text{self}} = \int_V \rho(\mathbf{r}) \mathbf{E}(\mathbf{r}, t) d^3 r, \quad (10.146)$$

where the electric field is that of the charge itself, with the field of any elementary charge $dq = \rho(r)d^3r$ described by Eq. (19).

To enable an analytical calculation of the force, we need to make the assumption $a \ll r_c$, treat the ratio $R/r_c \sim a/r_c$ as a small parameter, and expand the resulting right-hand side of Eq. (146) into the Taylor series in small R . This procedure yields

$$\mathbf{F}_{\text{self}} = -\frac{2}{3} \frac{1}{4\pi\epsilon_0} \sum_{n=0}^{\infty} \frac{(-1)^n}{c^{n+2} n!} \frac{d^{n+1} \mathbf{u}}{dt^{n+1}} \int_V d^3 r \int_V d^3 r' \rho(r) R^{n-1} \rho(r'). \quad (10.147)$$

The distance R cancels only in the term with $n = 1$,

$$\mathbf{F}_1 = \frac{2}{3c^3} \frac{\ddot{\mathbf{u}}}{4\pi\epsilon_0} \int_V d^3 r \int_V d^3 r' \rho(r) \rho(r') \equiv \frac{2}{3c^3} \frac{q^2}{4\pi\epsilon_0} \ddot{\mathbf{u}}, \quad (10.148)$$

showing that we have recovered (now in an *apparently* legitimate fashion) Eq. (139) for the Abrahams-Lorentz force. One could argue that in the limit $a \rightarrow 0$ the terms higher in $R \sim a$ (with $n > 1$) could be

⁵⁵ Note: this operation cannot be interpreted as describing a quantum spread due to the finite extent of the point particle's wavefunction. In quantum mechanics, different parts of the wavefunction of the same charged particle do *not* interact with each other!

ignored. However, we have to notice that the main contribution to the series (147) is *not* described by Eq. (148) for $n = 1$, but is given by the much larger term with $n = 0$:

$$\mathbf{F}_0 = -\frac{2}{3} \frac{1}{4\pi\epsilon_0} \frac{\dot{\mathbf{u}}}{c^2} \int_V d^3r \int_V d^3r' \frac{\rho(r)\rho(r')}{R} \equiv -\frac{4}{3} \frac{\dot{\mathbf{u}}}{c^2} \frac{1}{4\pi\epsilon_0} \frac{1}{2} \int_V d^3r \int_V d^3r' \frac{\rho(r)\rho(r')}{R} \equiv -\frac{4}{3c^2} \dot{\mathbf{u}} U, \quad (10.149)$$

where U is the electrostatic energy (1.59) of the static charge's self-interaction. This term may be interpreted as the inertial "force"⁵⁶ ($-m_{\text{ef}}\mathbf{a}$) with the following effective *electromagnetic mass*:

Electro-magnetic mass

$$m_{\text{ef}} = \frac{4}{3} \frac{U}{c^2}, \quad (10.150)$$

which is a factor of $4/3$ larger than it should be according to Einstein's formula (9.73). This is the famous (or rather infamous :–) *4/3 problem* that does not allow one to interpret the electron's mass as that of its electric field. Some (admittedly, rather formal) resolution of this paradox is possible only in quantum electrodynamics with its renormalization techniques – beyond the framework of this course.

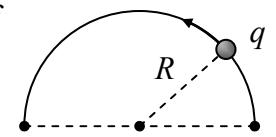

Note, however, that all these issues are only important for motions with frequencies of the order of $1/\tau \sim 10^{23} \text{ s}^{-1}$, i.e. at energies $\mathcal{E} \sim \hbar/\tau \sim 10^8 \text{ eV}$, while other quantum electrodynamics effects may be observed at much lower frequencies, starting from $\sim 10^{10} \text{ s}^{-1}$. Hence the $4/3$ problem is by no means the only motivation for the transfer from classical to quantum electrodynamics. However, the reader should not think that their time spent on this course has been lost: quantum electrodynamics is heavily based on classical electrodynamics, incorporates virtually all its results, and the basic transition between them is surprisingly straightforward.⁵⁷ So, I look forward to welcoming the reader to the next, quantum-mechanics part of this series.

10.6. Exercise problems

10.1. Derive Eqs. (10) from Eqs. (1) by a direct (but careful!) integration.

10.2. Derive the radiation-related parts of Eqs. (19)-(20) from the Liénard-Wiechert potentials (10) by direct differentiation.

10.3. A point charge q that had been in a stationary position on a circle of radius R is carried over, along the circle, to the opposite position on the same diameter (see the figure on the right) as fast as only physically possible, and then is kept steady at this new position. Calculate and sketch the time dependence of its electric field \mathbf{E} at the center of the circle.

10.4. Express the instantaneous power of electromagnetic radiation by a relativistic particle with electric charge q and rest mass m , moving with velocity \mathbf{u} , via the external Lorentz force \mathbf{F} exerted on it.

⁵⁶ See, e.g., CM Sec. 4.6.

⁵⁷ See, e.g., QM Secs. 9.1-9.4.

10.5. A relativistic particle with rest mass m and electric charge q , initially at rest, is accelerated by a constant force \mathbf{F} until it reaches a certain velocity u , and then moves by inertia. Calculate the total energy radiated during the acceleration.

10.6. A charged relativistic particle with initial momentum \mathbf{p}_0 flies ballistically from a free-space region into a region of a constant, uniform electric field \mathbf{E} , whose force is directed opposite to \mathbf{p}_0 . Calculate the energy radiated by the particle during its motion in the field, assuming that it is small in comparison with the particle's initial kinetic energy.

10.7. Calculate

- (i) the instantaneous power, and
- (ii) the power spectrum

of the radiation emitted, into a unit solid angle, by a relativistic particle with charge q , performing 1D harmonic oscillations with frequency ω_0 and displacement amplitude a .

10.8. Analyze the polarization and the spectral contents of the synchrotron radiation propagating in the direction normal to the particle's rotation plane. How do the results change if not one, but $N > 1$ similar particles move around the circle, at equal angular distances?

10.9. Calculate and analyze the time dependence of the energy of a charged relativistic particle performing synchrotron motion in a constant and uniform magnetic field \mathbf{B} , and hence emitting the synchrotron radiation. Qualitatively, what is the particle's trajectory?

Hint: You may assume that the energy loss is relatively slow ($-d\mathcal{E}/dt \ll \omega_c \mathcal{E}$), but should spell out the condition of validity of this assumption.

10.10. Analyze the polarization of the synchrotron radiation propagating within the particle's rotation plane.

10.11.* The basic quantum theory of radiation shows that the electric dipole radiation by a particle is allowed only if the change of its angular momentum's magnitude L at the transition is of the order of Planck's constant \hbar .

(i) Estimate the change of L of an ultra-relativistic particle due to its emission of a typical single photon of the synchrotron radiation.

(ii) Do you think quantum mechanics forbid such radiation? If not, why?

10.12. A relativistic particle moves along the z -axis, with velocity u_z , through an undulator – a system of permanent magnets providing (in the simplest model) a perpendicular magnetic field, whose distribution near the axis is sinusoidal:⁵⁸

$$\mathbf{B} = \mathbf{n}_y B_0 \cos k_0 z .$$

⁵⁸ As the Maxwell equation for $\nabla \times \mathbf{H}$ shows, this field distribution cannot be created in any non-zero volume of free space. However, it may be created on a line – e.g., on the particle's trajectory.

Assuming that the field is so weak that it causes negligible deviations of the particle's trajectory from the straight line, calculate the angular distribution of the resulting radiation. What condition does the above assumption impose on the system's parameters?

10.13. Discuss possible effects of the interference of the undulator radiation from different periods of its static field distribution. In particular, calculate the angular positions of the power density maxima.

10.14. An electron launched directly toward a plane surface of a perfect conductor is instantly absorbed by it at the collision. Calculate the angular distribution and the frequency spectrum of the electromagnetic waves radiated at this collision if the initial kinetic energy T of the particle is much larger than the conductor's workfunction ψ .⁵⁹ Is your result valid near the conductor's surface?

10.15. A relativistic particle, with rest mass m and electric charge q , flies ballistically, with velocity u , by an immobile point charge q' , with an impact parameter b so large that the deviations of its trajectory from the straight line are negligible. Calculate the total energy loss due to the electromagnetic radiation during the passage. Formulate the conditions of validity of your result.

⁵⁹ See Sec. 2.9, in particular Fig. 2.27a.

Chapter 1. Introduction

This introductory chapter briefly reviews the major experimental motivations for quantum mechanics, and then discusses its simplest formalism – Schrödinger’s wave mechanics. Much of this material (besides the last section) may be found in undergraduate textbooks,¹ so that the discussion is rather brief, and focused on the most important conceptual issues.

1.1. Experimental motivations

By the beginning of the 1900s, physics (which by that time included what we now call non-relativistic classical mechanics, classical thermodynamics and statistics, and classical electrodynamics including the geometric and wave optics) looked like an almost completed discipline, with most human-scale phenomena reasonably explained, and just a couple of mysterious “dark clouds”² on the horizon. However, rapid technological progress and the resulting development of more refined scientific instruments have led to a fast multiplication of observed phenomena that could not be explained on a classical basis. Let me list the most consequential of those experimental findings.

(i) The blackbody radiation measurements, pioneered by G. Kirchhoff in 1859, have shown that in the thermal equilibrium, the power of electromagnetic radiation by a fully absorbing (“black”) surface, per unit frequency interval, drops exponentially at high frequencies. This is not what could be expected from the combination of classical electrodynamics and statistics, which predicted an infinite growth of the radiation density with frequency. Indeed, classical electrodynamics shows³ that electromagnetic field modes evolve in time just as harmonic oscillators, and that the number dN of these modes in a large free-space volume $V \gg \lambda^3$, within a small frequency interval $d\omega \ll \omega$ near some frequency ω , is

$$dN = 2V \frac{d^3 k}{(2\pi)^3} = 2V \frac{4\pi k^2 dk}{(2\pi)^3} = V \frac{\omega^2}{\pi^2 c^3} d\omega, \quad (1.1)$$

where $c \approx 3 \times 10^8$ m/s is the free-space speed of light, $k = \omega/c$ the free-space wave number, and $\lambda = 2\pi/k$ is the radiation wavelength. On the other hand, classical statistics⁴ predicts that in the thermal equilibrium at temperature T , the average energy E of each 1D harmonic oscillator should be equal to $k_B T$, where k_B is the Boltzmann constant.⁵

Combining these two results, we readily get the so-called *Rayleigh-Jeans formula* for the average electromagnetic wave energy per unit volume:

¹ See, for example, D. Griffith, *Quantum Mechanics*, 2nd ed., Cambridge U. Press, 2016.

² This famous expression was used in a 1900 talk by Lord Kelvin (born William Thomson), in reference to the results of blackbody radiation measurements and the Michelson-Morley experiments, i.e. the precursors of quantum mechanics and relativity theory.

³ See, e.g., EM Sec. 7.8, in particular Eq. (7.211).

⁴ See, e.g., SM Sec. 2.2.

⁵ In the SI units, used throughout this series, $k_B \approx 1.38 \times 10^{-23}$ J/K – see *Appendix CA: Selected Physical Constants* for the exact value.

$$u \equiv \frac{1}{V} \frac{dE}{d\omega} = \frac{k_B T}{V} \frac{dN}{d\omega} = \frac{\omega^2}{\pi^2 c^3} k_B T, \quad (1.2)$$

that diverges at $\omega \rightarrow \infty$ (Fig. 1) – the so-called *ultraviolet catastrophe*. On the other hand, the blackbody radiation measurements, improved by O. Lummer and E. Pringsheim, and also by H. Rubens and F. Kurlbaum to reach a 1%-scale accuracy, were compatible with the phenomenological law suggested in 1900 by Max Planck:

$$u = \frac{\omega^2}{\pi^2 c^3} \frac{\hbar \omega}{\exp\{\hbar \omega / k_B T\} - 1}. \quad (1.3a)$$

Planck's
radiation
law

This law may be reconciled with the fundamental Eq. (1) if the following replacement is made for the average energy of each field oscillator:

$$k_B T \rightarrow \frac{\hbar \omega}{\exp(\hbar \omega / k_B T) - 1}, \quad (1.3b)$$

with a factor

$$\hbar \approx 1.055 \times 10^{-34} \text{ J} \cdot \text{s}, \quad (1.4)$$

Planck's
constant

now called the *Planck's constant*.⁶ At low frequencies ($\hbar \omega \ll k_B T$), the denominator in Eq. (3) may be approximated as $\hbar \omega / k_B T$, so that the average energy (3b) tends to its classical value $k_B T$, and the Planck's law (3a) reduces to the Rayleigh-Jeans formula (2). However, at higher frequencies ($\hbar \omega \gg k_B T$), Eq. (3) describes the experimentally observed rapid decrease of the radiation density – see Fig. 1.

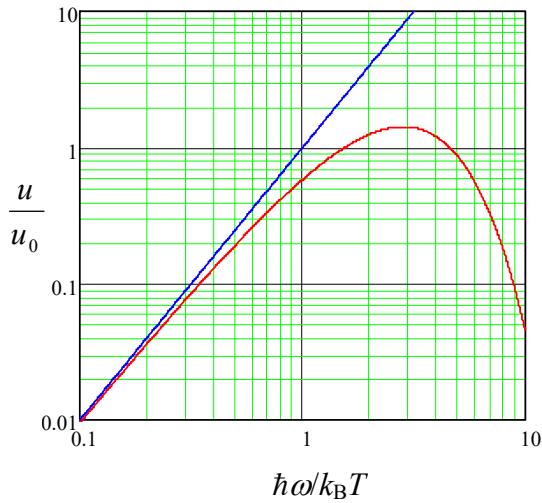

Fig. 1.1. The blackbody radiation density u , in units of $u_0 \equiv (k_B T)^3 / (\pi^2 \hbar^2 c^3)$, as a function of frequency, according to the Rayleigh-Jeans formula (blue line) and the Planck's law (red line).

(ii) The photoelectric effect, discovered in 1887 by H. Hertz, shows a sharp lower boundary for the frequency of the incident light that may kick electrons out from metallic surfaces, independent of the light's intensity. Albert Einstein, in one of his three famous 1905 papers, noticed that this threshold ω_{\min} could be explained assuming that light consisted of certain particles (now called *photons*) with energy

⁶ Max Planck himself wrote $\hbar \omega$ as $h\nu$, where $\nu = \omega/2\pi$ is the “cyclic” frequency (the number of periods per second) so that in early texts on quantum mechanics the term “Planck's constant” referred to $h \equiv 2\pi\hbar$, while \hbar was called “the Dirac constant” for a while. I will use the contemporary terminology, and abstain from using the “old Planck's constant” h at all, to avoid confusion.

Energy
vs
frequency

$$E = \hbar\omega, \quad (1.5)$$

with the same Planck's constant that participates in Eq. (3).⁷ Indeed, with this assumption, at the photon absorption by an electron, its energy $E = \hbar\omega$ is divided between a fixed energy U_0 (nowadays called the *workfunction*) of electron's binding inside the metal, and the excess kinetic energy $m_e v^2/2 > 0$ of the freed electron – see Fig. 2. In this picture, the frequency threshold finds a natural explanation as $\omega_{\min} = U_0/\hbar$.⁸ Moreover, as was shown by Satyendra Nath Bose in 1924,⁹ Eq. (5) explains Planck's law (3).

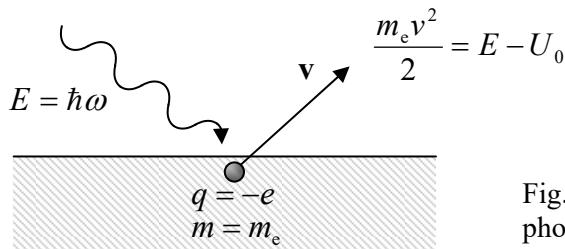

Fig. 1.2. Einstein's explanation of the photoelectric effect's frequency threshold.

(iii) The discrete frequency spectra of the electromagnetic radiation by excited atomic gases could not be explained by classical physics. (Applied to the planetary model of atoms, proposed by Ernst Rutherford, classical electrodynamics predicts the collapse of electrons on nuclei in $\sim 10^{-10}$ s, due to the electric-dipole radiation of electromagnetic waves.¹⁰) Especially challenging was the observation by Johann Jacob Balmer (in 1885) that the radiation frequencies of simple atoms may be well described by simple formulas. For example, for the lightest, hydrogen atom, all radiation frequencies may be numbered with just two positive integers n and n' :

$$\omega_{n,n'} = \omega_0 \left(\frac{1}{n^2} - \frac{1}{n'^2} \right), \quad (1.6)$$

with $\omega_0 \equiv \omega_{1,\infty} \approx 2.07 \times 10^{16}$ s⁻¹. This observation, and the experimental value of ω_0 , have found its first explanation in the famous 1913 theory by Niels Henrik David Bohr, which was a phenomenological precursor of the present-day quantum mechanics. In this theory, $\omega_{n,n'}$ was interpreted as the frequency of a photon that obeys Einstein's formula (5), with its energy $E_{n,n'} = \hbar\omega_{n,n'}$ being the difference between two *quantized* (discrete) energy levels of the atom (Fig. 3):

$$E_{n,n'} = E_{n'} - E_n > 0. \quad (1.7)$$

Bohr showed that Eq. (6) may be obtained from Eqs. (5) and (7), and non-relativistic¹¹ classical mechanics, augmented with just one additional postulate, equivalent to the assumption that the angular

⁷ As a reminder, A. Einstein received his only Nobel Prize (in 1921) for exactly this work, rather than for his relativity theory, i.e. essentially for jumpstarting the same quantum theory which he later questioned.

⁸ For most metals, U_0 is between 4 and 5 electron-volts (eV), so that the threshold corresponds to $\lambda_{\max} = 2\pi c/\omega_{\min} = 2\pi c/(U_0/\hbar) \approx 300$ nm – approximately at the border between the visible light and the ultraviolet radiation.

⁹ See, e.g., SM Sec. 2.5.

¹⁰ See, e.g., EM Sec. 8.2.

¹¹ The non-relativistic approach to the problem may be justified *a posteriori* by the fact the resulting energy scale E_H , given by Eq. (13), is much smaller than the electron's rest energy, $m_e c^2 \approx 0.5$ MeV.

momentum $L = m_e v r$ of an electron moving with velocity v on a circular orbit of radius r about the hydrogen's nucleus (the proton, assumed to be at rest because of its much higher mass), is quantized as

$$L = \hbar n, \quad (1.8)$$

where \hbar is again the same Planck's constant (4), and n is an integer. (In Bohr's theory, n could not be equal to zero, though in the genuine quantum mechanics, it can.)

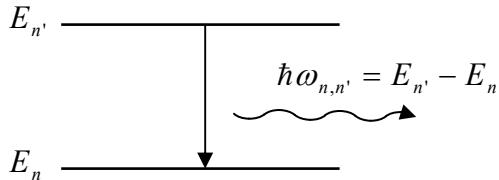

Fig. 1.3. The electromagnetic radiation of a system at a result of the transition between its quantized energy levels.

Indeed, it is sufficient to solve Eq. (8), $m_e v r = \hbar n$, together with the equation

$$m_e \frac{v^2}{r} = \frac{e^2}{4\pi\epsilon_0 r^2}, \quad (1.9)$$

which expresses the 2nd Newton's law for an electron rotating in the Coulomb field of the nucleus. (Here $e \approx 1.6 \times 10^{-19} \text{ C}$ is the fundamental electric charge, and $m_e \approx 0.91 \times 10^{-30} \text{ kg}$ is the electron's rest mass.) The result for r is

$$r = n^2 r_B, \quad \text{where } r_B \equiv \frac{\hbar^2 / m_e}{e^2 / 4\pi\epsilon_0} \approx 0.0529 \text{ nm}. \quad (1.10)$$

Bohr radius

The constant r_B , called the *Bohr radius*, is the most important spatial scale of phenomena in atomic, molecular, and condensed-matter physics – and hence in all chemistry and biochemistry.

Now plugging these results into the non-relativistic expression for the full electron energy (with its rest energy taken for reference),

$$E = \frac{m_e v^2}{2} - \frac{e^2}{4\pi\epsilon_0 r}, \quad (1.11)$$

we get the following simple expression for the electron's energy levels:

$$E_n = -\frac{E_H}{2n^2} < 0, \quad (1.12)$$

Hydrogen atom's energy levels

which, together with Eqs. (5) and (7), immediately gives Eq. (6) for the radiation frequencies. Here E_H is called the so-called *Hartree energy constant* (or just the “Hartree energy”)¹²

$$E_H \equiv \frac{(e^2 / 4\pi\epsilon_0)^2}{\hbar^2 / m_e} \approx 4.360 \times 10^{-18} \text{ J} \approx 27.21 \text{ eV}. \quad (1.13a)$$

Hartree energy constant

(Note the useful relations, which follow from Eqs. (10) and (13a):

¹² Unfortunately, another name, the “Rydberg constant”, is sometimes used for either this energy unit or its half, $E_H/2 \approx 13.6 \text{ eV}$. To add to the confusion, the same term “Rydberg constant” is used in some sub-fields of physics for the reciprocal free-space wavelength ($1/\lambda_0 = \omega_0/2\pi c$) corresponding to the frequency $\omega_0 = E_H/2\hbar$.

$$E_H = \frac{e^2}{4\pi\epsilon_0 r_B} = \frac{\hbar^2}{m_e r_B^2}, \quad \text{i.e. } r_B = \frac{e^2 / 4\pi\epsilon_0}{E_H} = \left(\frac{\hbar^2 / m_e}{E_H} \right)^{1/2}; \quad (1.13b)$$

the first of them shows, in particular, that r_B is the distance at which the natural scales of the electron's potential and kinetic energies are equal.)

Note also that Eq. (8), in the form $pr = \hbar n$, where $p = m_e v$ is the electron momentum's magnitude, may be rewritten as the condition than an integer number (n) of wavelengths λ of certain (before the late 1920s, hypothetic) waves¹³ fits the circular orbit's perimeter: $2\pi r \equiv 2\pi\hbar n/p = n\lambda$. Dividing both parts of the last equality by n , we see that for this statement to be true, the wave number $k \equiv 2\pi/\lambda$ of the de Broglie waves should be proportional to the electron's momentum $p = mv$:

Momentum
vs wave
number

$$p = \hbar k, \quad (1.14)$$

again with the same Planck's constant as in Eq. (5).

(iv) The Compton effect¹⁴ is the reduction of frequency of X-rays at their scattering on free (or nearly-free) electrons – see Fig. 4.

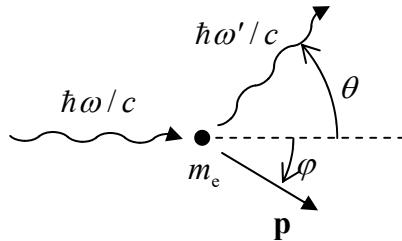

Fig. 1.4. The Compton effect.

The effect may be explained assuming that the X-ray photon also has a momentum that obeys the vector-generalized version of Eq. (14):

$$\mathbf{p}_{\text{photon}} = \hbar \mathbf{k} = \frac{\hbar \omega}{c} \mathbf{n}, \quad (1.15)$$

where \mathbf{k} is the wavevector (whose magnitude is equal to the wave number k , and whose direction coincides with the unit vector \mathbf{n} directed along the wave propagation¹⁵), and that the momenta of both the photon and the electron are related to their energies E by the classical relativistic formula¹⁶

$$E^2 = (cp)^2 + (mc^2)^2. \quad (1.16)$$

(For a photon, the rest energy m is zero, and this relation is reduced to Eq. (5): $E = cp = c\hbar k = \hbar\omega$.) Indeed, a straightforward solution of the following system of three equations,

¹³ This fact was first noticed and discussed in 1924 by Louis Victor Pierre Raymond de Broglie (in his PhD thesis!), so that instead of speaking of wavefunctions, we are still frequently speaking of the *de Broglie waves*, especially when free particles are discussed.

¹⁴ This effect was observed in 1922, and explained a year later by Arthur Holly Compton, using Eqs. (5) and (15).

¹⁵ See, e.g., EM Sec. 7.1.

¹⁶ See, e.g., EM Sec. 9.3, in particular Eq. (9.78).

$$\hbar\omega + m_e c^2 = \hbar\omega' + [(cp)^2 + (m_e c^2)^2]^{1/2}, \quad (1.17)$$

$$\frac{\hbar\omega}{c} = \frac{\hbar\omega'}{c} \cos\theta + p \cos\varphi, \quad (1.18)$$

$$0 = \frac{\hbar\omega'}{c} \sin\theta - p \sin\varphi, \quad (1.19)$$

(which express the conservation of, respectively, the full energy of the system and the two relevant Cartesian components of its full momentum, at the scattering event – see Fig. 4), yields the result:

$$\frac{1}{\hbar\omega'} = \frac{1}{\hbar\omega} + \frac{1}{m_e c^2} (1 - \cos\theta), \quad (1.20a)$$

which is traditionally represented as the relation between the initial and final values of the photon's wavelength $\lambda = 2\pi/k = 2\pi(\omega/c)$:¹⁷

$$\lambda' = \lambda + \frac{2\pi\hbar}{m_e c} (1 - \cos\theta) \equiv \lambda + \lambda_C (1 - \cos\theta), \quad \text{with } \lambda_C \equiv \frac{2\pi\hbar}{m_e c}, \quad (1.20b)$$

Compton effect

and is in agreement with experiment.

(v) De Broglie wave diffraction. In 1927, Clinton Joseph Davisson and Lester Germer, and independently George Paget Thomson succeeded to observe the diffraction of electrons on solid crystals (Fig. 5). Specifically, they have found that the intensity of the elastic reflection of electrons from a crystal increases sharply when the angle α between the incident beam of electrons and the crystal's atomic planes, separated by distance d , satisfies the following relation:

$$2d \sin\alpha = n\lambda, \quad (1.21)$$

Bragg condition

where $\lambda = 2\pi/k = 2\pi\hbar/p$ is the de Broglie wavelength of the electrons, and n is an integer. As Fig. 5 shows, this is just the well-known condition¹⁸ that the path difference $\Delta l = 2ds\sin\alpha$ between the de Broglie waves reflected from two adjacent crystal planes coincides with an integer number of λ , i.e. of the constructive interference of the waves.¹⁹

To summarize, all the listed experimental observations could be explained starting from two very simple (and similarly looking) formulas: Eq. (5) (at that stage, for photons only), and Eq. (15) for both photons and electrons – both relations involving the same Planck's constant. This fact might give an impression of experimental evidence sufficient to declare the light consisting of discrete particles

¹⁷ The constant λ_C that participates in this relation, is close to 2.46×10^{-12} m, and is called the electron's *Compton wavelength*. This term is somewhat misleading: as the reader can see from Eqs. (17)-(19), no wave in the Compton problem has such a wavelength – either before or after the scattering.

¹⁸ See, e.g., EM Sec. 8.4, in particular Fig. 8.9 and Eq. (8.82). Frequently, Eq. (21) is called the *Bragg condition*, due to the pioneering experiments by W. Bragg on X-ray scattering from crystals, which were started in 1912.

¹⁹ Later, spectacular experiments on diffraction and interference of heavier particles (with the correspondingly smaller de Broglie wavelength), e.g., neutrons and even C₆₀ molecules, have also been performed – see, e.g., the review by A. Zeilinger *et al.*, *Rev. Mod. Phys.* **60**, 1067 (1988) and a later publication by O. Nairz *et al.*, *Am. J. Phys.* **71**, 319 (2003). Nowadays, such interference of heavy particles is used, for example, for ultrasensitive measurements of gravity – see, e.g., a popular review by M. Arndt, *Phys. Today* **67**, 30 (May 2014), and more recent experiments by S. Abend *et al.*, *Phys. Rev. Lett.* **117**, 203003 (2016).

(photons), and, on the contrary, electrons being some “matter waves” rather than particles. However, by that time (the mid-1920s), physics has accumulated overwhelming evidence of *wave* properties of light, such as interference and diffraction.²⁰ In addition, there was also strong evidence for the lumped-particle (“corpuscular”) behavior of electrons. It is sufficient to mention the famous oil-drop experiments by Robert Andrew Millikan and Harvey Fletcher (1909–1913), in which only single (and whole!) electrons could be added to an oil drop, changing its total electric charge by multiples of electron’s charge ($-e$) – and never its fraction. It was apparently impossible to reconcile these observations with a purely wave picture, in which an electron and hence its charge need to be spread over the wave’s extension, so that its arbitrary part of it could be cut off using an appropriate experimental setup.

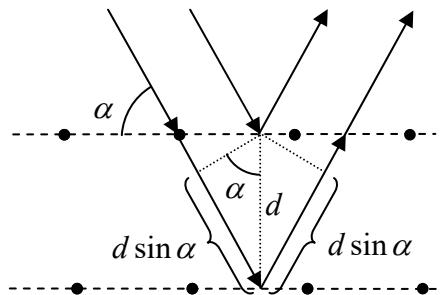

Fig. 1.5. The De Broglie wave interference at electron scattering from a crystal lattice.

Thus the founding fathers of quantum mechanics faced a formidable task of reconciling the wave and corpuscular properties of electrons and photons – and other particles. The decisive breakthrough in that task has been achieved in 1926 by Ervin Schrödinger and Max Born, who formulated what is now known either formally as the *Schrödinger picture of non-relativistic quantum mechanics of the orbital motion*²¹ in the coordinate representation (this term will be explained later in the course), or informally just as the *wave mechanics*. I will now formulate the main postulates of this theory.

1.2. Wave mechanics postulates

Let us consider a spinless,²² non-relativistic point-like particle, whose classical dynamics may be described by a certain Hamiltonian function $H(\mathbf{r}, \mathbf{p}, t)$,²³ where \mathbf{r} is the particle’s radius-vector and \mathbf{p} is its momentum. (This condition is important because it excludes from our current discussion the systems whose interaction with their environment results in *irreversible* effects, in particular the friction leading to particle energy’s decay. Such “open” systems need a more general description, which will be discussed in Chapter 7.) Wave mechanics of such *Hamiltonian particles* may be based on the following set of postulates that are comfortingly elegant – though their final justification is given only by the agreement of all their corollaries with experiment.²⁴

²⁰ See, e.g., EM Sec. 8.4.

²¹ The *orbital motion* is the historic (and rather misleading) term used for *any* motion of the particle as a whole.

²² Actually, in wave mechanics, the spin of the described particle has not to be equal to zero. Rather, it is assumed that the particle spin’s *effects* on its orbital motion are negligible.

²³ As a reminder, for many systems (including those whose kinetic energy is a quadratic-homogeneous function of generalized velocities, like $mv^2/2$), H coincides with the total energy E – see, e.g., CM Sec. 2.3. In what follows, I will assume that $H = E$.

²⁴ Quantum mechanics, like any theory, may be built on different sets of postulates/axioms leading to the same final conclusions. In this text, I will not try to beat down the number of postulates to the absolute possible

(i) Wavefunction and probability. Such variables as \mathbf{r} or \mathbf{p} cannot be always measured exactly, even at “perfect conditions” when all external uncertainties, including measurement instrument imperfection, varieties of the initial state preparation, and unintended particle interactions with its environment, have been removed.²⁵ Moreover, \mathbf{r} and \mathbf{p} of the same particle can *never* be measured exactly simultaneously. Instead, the *most detailed* description of the particle’s state allowed by Nature, is given by a certain complex function $\Psi(\mathbf{r}, t)$, called the *wavefunction* (or “wave function”), which generally enables only *probabilistic* predictions of the measured values of \mathbf{r} , \mathbf{p} , and other directly measurable variables – in quantum mechanics, usually called *observables*.

Specifically, the probability dW of finding a particle inside an elementary volume $dV \equiv d^3r$ is proportional to this volume, and hence may be characterized by a volume-independent *probability density* $w \equiv dW/d^3r$, which in turn is related to the wavefunction as

$$w = |\Psi(\mathbf{r}, t)|^2 \equiv \Psi^*(\mathbf{r}, t)\Psi(\mathbf{r}, t), \quad (1.22a)$$

where the sign * denotes the usual complex conjugation. As a result, the total probability of finding the particle somewhere inside a volume V may be calculated as

$$W = \int_V w d^3r = \int_V \Psi^* \Psi d^3r. \quad (1.22b)$$

In particular, if volume V contains the particle *definitely* (i.e. with the 100% probability, $W = 1$), Eq. (22b) is reduced to the so-called *wavefunction normalization condition*

$$\int_V \Psi^* \Psi d^3r = 1. \quad (1.22c)$$

Probability
via
wavefunction

Normalization
condition

(ii) Observables and operators. With each observable A , quantum mechanics associates a certain *linear operator* \hat{A} , such that (in the perfect conditions mentioned above) the average measured value of A (usually called the *expectation value*) is expressed as²⁶

$$\langle A \rangle = \int_V \Psi^* \hat{A} \Psi d^3r, \quad (1.23)$$

Observable's
expectation
value

where $\langle \dots \rangle$ means the statistical average, i.e. the result of averaging the measurement results over a large *ensemble* (set) of macroscopically similar experiments, and Ψ is the normalized wavefunction that obeys Eq. (22c). Note immediately that for Eqs. (22) and (23) to be compatible, the *identity* (or “unit”) *operator* defined by the relation

$$\hat{I}\Psi = \Psi, \quad (1.24)$$

Identity
operator

has to be associated with a particular type of measurement, namely with the particle’s detection.

minimum, not only because that would require longer argumentation, but chiefly because such attempts typically result in making certain implicit assumptions hidden from the reader – the practice as common as regrettable.

²⁵ I will imply such perfect conditions in the further narrative, until the discussion of the system’s interaction with its environment in Chapter 7.

²⁶ This key measurement postulate is sometimes called the *Born rule*, though sometimes this term is used for the (less general) Eqs. (22).

(iii) The Hamiltonian operator and the Schrödinger equation. Another particular operator, *Hamiltonian* \hat{H} , whose observable is the particle's energy E , also plays in wave mechanics a very special role, because it participates in the *Schrödinger equation*,

Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi, \quad (1.25)$$

that determines the wavefunction's dynamics, i.e. its time evolution.

(iv) The radius-vector and momentum operators. In wave mechanics (in the “coordinate representation”), the vector operator of particle’s radius-vector \mathbf{r} just multiples the wavefunction by this vector, while the operator of the particle’s momentum is proportional to the spatial derivative:

$$\hat{\mathbf{r}} = \mathbf{r}, \quad \hat{\mathbf{p}} = -i\hbar\nabla, \quad (1.26a)$$

Operators of coordinate and momentum

where ∇ is the *del* (or “nabla”) vector operator.²⁷ Thus in the Cartesian coordinates,

$$\hat{\mathbf{r}} = \mathbf{r} = \{x, y, z\}, \quad \hat{\mathbf{p}} = -i\hbar \left\{ \frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z} \right\}. \quad (1.26b)$$

(v) The correspondence principle. In the limit when quantum effects are insignificant, e.g., when the characteristic scale of action²⁸ (i.e. the product of the relevant energy and time scales of the problem) is much larger than Planck’s constant \hbar , all wave mechanics results have to tend to those given by classical mechanics. Mathematically, this correspondence is achieved by duplicating the classical relations between various observables by similar relations between the corresponding operators. For example, for a free particle, the Hamiltonian (which in this particular case corresponds to the kinetic energy $T = p^2/2m$ alone) has the form

$$\hat{H} = \hat{T} = \frac{\hat{p}^2}{2m} = -\frac{\hbar^2}{2m} \nabla^2. \quad (1.27)$$

Free particle's Hamiltonian

Now, even before a deeper discussion of the postulates’ physics (offered in the next section), we may immediately see that they indeed provide a formal way toward resolution of the apparent contradiction between the wave and corpuscular properties of particles. Indeed, for a free particle, the Schrödinger equation (25), with the substitution of Eq. (27), takes the form

Free particle's Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Psi, \quad (1.28)$$

Plane wave

whose particular, but the most important solution is a plane, single-frequency (“monochromatic”) traveling wave,²⁹

$$\Psi(\mathbf{r}, t) = ae^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)}, \quad (1.29)$$

²⁷ If you need, see, e.g., Secs. 8-10 of the *Selected Mathematical Formulas* appendix – below, referred to as MA. Note that according to those formulas, the del operator follows all the rules of the usual (geometric) vectors. This is, by definition, true for other quantum-mechanical vector operators to be discussed below.

²⁸ See, e.g., CM Sec. 10.3.

²⁹ See, e.g., CM Sec. 6.4 and/or EM Sec. 7.1.

where a , \mathbf{k} and ω are constants. Indeed, plugging Eq. (29) into Eq. (28), we immediately see that such plane wave, with an arbitrary complex amplitude a , is indeed a solution of this Schrödinger equation, provided a specific *dispersion relation* between the wave number $k \equiv |\mathbf{k}|$ and the frequency ω :

$$\hbar\omega = \frac{(\hbar k)^2}{2m}. \quad (1.30)$$

Free
particle's
dispersion
relation

The constant a may be calculated, for example, assuming that the wave (29) is extended over a certain volume V , while beyond it, $\Psi = 0$. Then from the normalization condition (22c) and Eq. (29), we get³⁰

$$|a|^2 V = 1. \quad (1.31)$$

Let us use Eqs. (23), (26), and (27) to calculate the expectation values of the particle's momentum \mathbf{p} and energy $E = H$ in the state (29). The result is

$$\langle \mathbf{p} \rangle = \hbar \mathbf{k}, \quad \langle E \rangle = \langle H \rangle = \frac{(\hbar k)^2}{2m}; \quad (1.32)$$

according to Eq. (30), the last equality may be rewritten as $\langle E \rangle = \hbar\omega$.

Next, Eq. (23) enables calculation of not only the average (in the math speak, the *first moment*) of an observable but also its higher moments, notably the *second moment* – in physics, usually called *variance*:

$$\langle \tilde{A}^2 \rangle \equiv \langle (A - \langle A \rangle)^2 \rangle = \langle A^2 \rangle - \langle A \rangle^2, \quad (1.33)$$

Observable's
variance

and hence its *uncertainty*, alternatively called the “root-mean-square (r.m.s.) fluctuation”,

$$\delta A \equiv \langle \tilde{A}^2 \rangle^{1/2}. \quad (1.34)$$

Observable's
uncertainty

The uncertainty is a scale of deviations $\tilde{A} \equiv A - \langle A \rangle$ of measurement results from their average. In the particular case when the uncertainty δA equals zero, every measurement of the observable A will give the same value $\langle A \rangle$; such a state is said to have a *definite value* of the variable. For example, in application to the state with wavefunction (29), these relations yield $\delta E = 0$, $\delta \mathbf{p} = 0$. This means that in this plane-wave, monochromatic state, the energy and momentum of the particle have definite values, so that the statistical average signs in Eqs. (32) might be removed. Thus, these relations are reduced to the experimentally-inferred Eqs. (5) and (15).

Hence the wave mechanics postulates indeed may describe the observed wave properties of non-relativistic particles. (For photons, we would need its relativistic generalization – see Chapter 9 below.) On the other hand, due to the linearity of the Schrödinger equation (25), any sum of its solutions is also a solution – the so-called *linear superposition principle*. For a free particle, this means that any set of plane waves (29) is also a solution to this equation. Such sets, with close values of \mathbf{k} and hence $\mathbf{p} = \hbar \mathbf{k}$ (and, according to Eq. (30), of ω as well), may be used to describe spatially localized “pulses”, called *wave packets* – see Fig. 6. In Sec. 2.1, I will prove (or rather reproduce H. Weyl's proof :-) that the wave packet's extension δx in any direction (say, x) is related to the width δk_x of the distribution of the

³⁰ For infinite space ($V \rightarrow \infty$), Eq. (31) yields $a \rightarrow 0$, i.e. wavefunction (29) vanishes. This formal problem may be readily resolved considering sufficiently long wave packets – see Sec. 2.2 below.

corresponding component of its wave vector as $\delta x \delta k_x \geq \frac{1}{2}$, and hence, according to Eq. (15), to the width δp_x of the momentum component distribution as

Heisenberg's
uncertainty
relation

$$\delta x \cdot \delta p_x \geq \frac{\hbar}{2}. \quad (1.35)$$

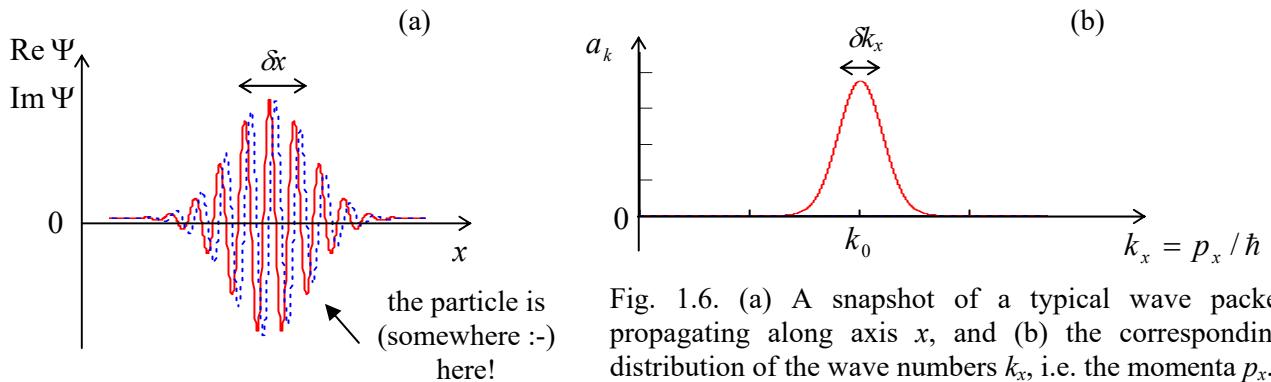

Fig. 1.6. (a) A snapshot of a typical wave packet propagating along axis x , and (b) the corresponding distribution of the wave numbers k_x , i.e. the momenta p_x .

This is the famous *Heisenberg's uncertainty principle*, which quantifies the first postulate's point that the coordinate and the momentum cannot be defined exactly simultaneously. However, since the Planck's constant, $\hbar \sim 10^{-34}$ J·s, is extremely small on the human scale of things, it still allows for particle localization in a very small volume even if the momentum spread in a wave packet is also small on that scale. For example, according to Eq. (35), a 0.1% spread of momentum of a 1 keV electron ($p \sim 1.7 \times 10^{-24}$ kg·m/s) allows its wave packet to be as small as $\sim 3 \times 10^{-10}$ m. (For a heavier particle such as a proton, the packet would be even tighter.) As a result, wave packets may be used to describe the particles that are quite point-like from the macroscopic point of view.

In a nutshell, this is the main idea of wave mechanics, and the first part of this course (Chapters 1-3) will be essentially a discussion of various effects described by this approach. During this discussion, however, we will not only witness wave mechanics' many triumphs within its applicability domain but also gradually accumulate evidence for its handicaps, which will force an eventual transfer to a more general formalism – to be discussed in Chapter 4 and beyond.

1.3. Postulates' discussion

The wave mechanics' postulates listed in the previous section (hopefully, familiar to the reader from their undergraduate studies) may look very simple. However, the physics of these axioms is very deep, leading to some counter-intuitive conclusions, and their in-depth discussion requires solutions of several key problems of wave mechanics. This is why in this section I will give only an initial, admittedly superficial discussion of the postulates, and will be repeatedly returning to the conceptual foundations of quantum mechanics throughout the course, especially in Chapter 10.

First of all, the fundamental uncertainty of observables, which is in the core of the first postulate, is very foreign to the basic ideas of classical mechanics, and historically has made quantum mechanics so hard to swallow for many star physicists, notably including Albert Einstein – despite his 1905 work, which essentially launched the whole field! However, this fact has been confirmed by numerous

experiments, and (more importantly) there has not been a single confirmed experiment that would contradict this postulate, so that quantum mechanics was long ago promoted from a theoretical hypothesis to the rank of a reliable scientific theory.

One more remark in this context is that Eq. (25) itself is *deterministic*, i.e. conceptually enables an *exact* calculation of the wavefunction's distribution in space at any instant t , provided that its initial distribution, and the particle's Hamiltonian, are known exactly. Note that in the classical statistical mechanics, the probability density distribution $w(\mathbf{r}, t)$ may be also calculated from deterministic differential equations, for example, the Liouville equation.³¹ The quantum-mechanical description differs from that situation in two important aspects. First, in the perfect conditions outlined above (the best possible initial state preparation and measurements), the Liouville equation is reduced to the 2nd Newton law of classical mechanics, i.e. the statistical uncertainty of its results disappears. In quantum mechanics this is not true: the quantum uncertainty, such as described by Eq. (35), persists even in this limit. Second, the wavefunction $\Psi(\mathbf{r}, t)$ gives more information than just $w(\mathbf{r}, t)$, because besides the modulus of Ψ , involved in Eq. (22), this complex function also has the *phase* $\varphi \equiv \arg \Psi$, which may affect some observables, describing, in particular, interference of the de Broglie waves.

Next, it is very important to understand that the relation between the quantum mechanics and experiment, given by the second postulate, necessarily involves another key notion: that of the corresponding *statistical ensemble*, in this case, a set of many experiments carried out at apparently (*macroscopically*) similar conditions, including the initial conditions – which nevertheless may lead to different measurement results (*outcomes*). Indeed, the probability of a certain (n^{th}) outcome of an experiment may be only defined for a certain statistical ensemble, as the limit

$$W_n \equiv \lim_{M \rightarrow \infty} \frac{M_n}{M}, \quad \text{with } M \equiv \sum_{n=1}^N M_n, \quad (1.36)$$

Probability:
definition

where M is the total number of experiments, M_n is the number of outcomes of the n^{th} type, and N is the number of different outcomes.

Note that a particular choice of statistical ensemble may affect probabilities W_n very significantly. For example, if we pull out playing cards at random from a standard pack of 52 different cards of 4 suits, the probability W_n of getting a certain card (e.g., the queen of spades) is 1/52. However, if the cards of a certain suit (say, hearts) had been taken out from the pack in advance, the probability of getting the queen of spades is higher, 1/39. It is important that we would also get the last number for the probability even if we had used the full 52-card pack, but by some reason discarded results of all experiments giving us any rank of hearts. Hence, the ensemble definition (or its *redefinition* in the middle of the game) may change outcome probabilities.

In wave mechanics, with its fundamental relation (22) between w and Ψ , this means that not only the outcome probabilities, but the wavefunction itself also may depend on the statistical ensemble we are using, i.e. not only on the preparation of the system and the experimental setup, but also on the subset of outcomes taken into account. The sometimes accounted attribution of the wavefunction to a single experiment, both before and after the measurement, may lead to very unphysical interpretations of the results, including some wavefunction's evolution which is not described by the Schrödinger equation (the so-called *wave packet reduction*), subluminal action on distance, etc. Later in the course, we will see that minding the fundamentally statistical nature of quantum mechanics, and in particular the

³¹ See, e.g., SM Sec. 6.1.

dependence of wavefunctions on the statistical ensembles' definition (or redefinition), readily resolves some, though not all, paradoxes of quantum measurements.

Note, however, again that the standard quantum mechanics, as discussed in Chapters 1-6 of this course, is limited to statistical ensembles with *the least possible uncertainty* of the considered systems, i.e. with the best possible knowledge of their state.³² This condition requires, first, the least uncertain initial preparation of the system, and second, its total isolation from the rest of the world, or at least from its disordered part (the “environment”), in the course of its evolution in time. Only such ensembles may be described by certain wavefunctions. A detailed discussion of more general ensembles, which are necessary if these conditions are not satisfied, will be given in Chapters 7, 8, and 10.

Finally, regarding Eq. (23): a better feeling of this definition may be obtained by its comparison with the general definition of the expectation value (i.e. the statistical average) in the probability theory. Namely, let each of N possible outcomes in a set of M experiments give a certain value A_n of observable A ; then

Definition
of statistical
average

$$\langle A \rangle \equiv \lim_{M \rightarrow \infty} \frac{1}{M} \sum_{n=1}^N A_n M_n = \sum_{n=1}^N A_n W_n. \quad (1.37)$$

Taking into account Eq. (22), which relates W and Ψ , the structures of Eq. (23) and the final form of Eq. (37) are similar. Their exact relation will be further discussed in Sec. 4.1.

1.4. Continuity equation

The wave mechanics postulates survive one more sanity check: they satisfy the natural requirement that the particle does not appear or vanish in the course of the quantum evolution.³³ Indeed, let us use Eq. (22b) to calculate the rate of change of the probability W to find a particle within a certain volume V :

$$\frac{dW}{dt} = \frac{d}{dt} \int_V \Psi \Psi^* d^3r. \quad (1.38)$$

Assuming for simplicity that the boundaries of the volume V do not move, it is sufficient to carry out the partial differentiation of the product $\Psi \Psi^*$ inside the integral. Using the Schrödinger equation (25), together with its complex conjugate,

$$-i\hbar \frac{\partial \Psi^*}{\partial t} = (\hat{H}\Psi)^*, \quad (1.39)$$

we readily get

$$\frac{dW}{dt} = \int_V \frac{\partial}{\partial t} (\Psi \Psi^*) d^3r \equiv \int_V \left(\Psi^* \frac{\partial \Psi}{\partial t} + \Psi \frac{\partial \Psi^*}{\partial t} \right) d^3r = \frac{1}{i\hbar} \int_V [\Psi^* (\hat{H}\Psi) - \Psi (\hat{H}\Psi)^*] d^3r. \quad (1.40)$$

³² The reader should not be surprised by the use of the notion of “knowledge” (or “information”) in this context. Indeed, due to the statistical character of experiment outcomes, quantum mechanics (or at least its relation to experiment) is intimately related to information theory. In contrast to much of classical physics, which may be discussed without any reference to information, in quantum mechanics, as in classical statistical physics, such abstraction is possible only in some very special (and not the most interesting) cases.

³³ Note that this requirement may be violated in the *relativistic* quantum theory – see Chapter 9.

Let the particle move in a field of external forces (not necessarily constant in time), so that its classical Hamiltonian function H is the sum of the particle's kinetic energy $T = p^2/2m$ and its potential energy $U(\mathbf{r}, t)$.³⁴ According to the correspondence principle, and Eq. (27), the Hamiltonian operator may be represented as the sum³⁵:

$$\hat{H} = \hat{T} + \hat{U} = \frac{\hat{p}^2}{2m} + U(\mathbf{r}, t) = -\frac{\hbar^2}{2m} \nabla^2 + U(\mathbf{r}, t). \quad (1.41)$$

Potential field:
Hamiltonian

At this stage, we should notice that this operator, when acting on a real function, returns a real function.³⁶ Hence, the result of its action on an arbitrary complex function $\Psi = a + ib$ (where a and b are real) is

$$\hat{H}\Psi = \hat{H}(a + ib) = \hat{H}a + i\hat{H}b, \quad (1.42)$$

where $\hat{H}a$ and $\hat{H}b$ are also real, while

$$(\hat{H}\Psi)^* = (\hat{H}a + i\hat{H}b)^* = \hat{H}a - i\hat{H}b = \hat{H}(a - ib) = \hat{H}\Psi^*. \quad (1.43)$$

This means that Eq. (40) may be rewritten as

$$\frac{dW}{dt} = \frac{1}{i\hbar} \int_V [\Psi^* \hat{H}\Psi - \Psi \hat{H}\Psi^*] d^3r = -\frac{\hbar^2}{2m} \frac{1}{i\hbar} \int_V [\Psi^* \nabla^2 \Psi - \Psi \nabla^2 \Psi^*] d^3r. \quad (1.44)$$

Now let us use general rules of vector calculus³⁷ to write the following identity:

$$\nabla \cdot (\Psi^* \nabla \Psi - \Psi \nabla \Psi^*) = \Psi^* \nabla^2 \Psi - \Psi \nabla^2 \Psi^*, \quad (1.45)$$

A comparison of Eqs. (44) and (45) shows that we may write

$$\frac{dW}{dt} = - \int_V (\nabla \cdot \mathbf{j}) d^3r, \quad (1.46)$$

where the vector \mathbf{j} is defined as

$$\mathbf{j} \equiv \frac{i\hbar}{2m} (\Psi \nabla \Psi^* - \text{c.c.}) \equiv \frac{\hbar}{m} \text{Im}(\Psi^* \nabla \Psi), \quad (1.47)$$

Probability
current
density

where c.c. means the complex conjugate of the previous expression – in this case, $(\Psi \nabla \Psi^*)^*$, i.e. $\Psi^* \nabla \Psi$. Now using the well-known divergence theorem,³⁸ Eq. (46) may be rewritten as the *continuity equation*

$$\frac{dW}{dt} + I = 0, \quad \text{with } I \equiv \int_S j_n d^2r, \quad (1.48)$$

Continuity
equation:
integral
form

³⁴ As a reminder, such description is valid not only for conservative forces (in that case U has to be time-independent), but also for any force $\mathbf{F}(\mathbf{r}, t)$ that may be expressed via the gradient of $U(\mathbf{r}, t)$ – see, e.g., CM Chapters 2 and 10. (A good example when such a description is *impossible* is given by the magnetic component of the Lorentz force – see, e.g., EM Sec. 9.7, and also Sec. 3.1 below.)

³⁵ Historically, this was the main step made (in 1926) by E. Schrödinger on the background of L. de Broglie's idea. The probabilistic interpretation of the wavefunction was put forward, almost simultaneously, by M. Born.

³⁶ In Chapter 4, we will discuss a more general family of *Hermitian operators*, which have this property.

³⁷ See, e.g., MA Eq. (11.4a), combined with the del operator's definition $\nabla^2 \equiv \nabla \cdot \nabla$.

³⁸ See, e.g., MA Eq. (12.2).

where j_n is the component of the vector \mathbf{j} , along the outwardly directed normal to the closed surface S that limits the volume V , i.e. the scalar product $\mathbf{j} \cdot \mathbf{n}$, where \mathbf{n} is the unit vector along this normal.

Equalities (47) and (48) show that if the wavefunction on the surface vanishes, the total probability W of finding the particle within the volume does not change, providing the intended sanity check. In the general case, Eq. (48) says that dW/dt equals the flux I of the vector \mathbf{j} through the surface, with the minus sign. It is clear that this vector may be interpreted as the *probability current density* – and I , as the total *probability current* through the surface S . This interpretation may be further supported by rewriting Eq. (47) for the wavefunction represented in the polar form $\Psi = ae^{i\varphi}$, with real a and φ :

$$\mathbf{j} = a^2 \frac{\hbar}{m} \nabla \varphi. \quad (1.49)$$

Note that for a real wavefunction, or even for a wavefunction with an arbitrary but space-constant phase φ , the probability current density vanishes. On the contrary, for the traveling wave (29), with a constant probability density $w = a^2$, Eq. (49) yields a non-zero (and physically very transparent) result:

$$\mathbf{j} = w \frac{\hbar}{m} \mathbf{k} = w \frac{\mathbf{p}}{m} = w \mathbf{v}, \quad (1.50)$$

where $\mathbf{v} = \mathbf{p}/m$ is particle's velocity. If multiplied by the particle's mass m , the probability density w turns into the (average) mass density ρ , and the probability current density, into the *mass flux density* $\rho \mathbf{v}$. Similarly, if multiplied by the total electric charge q of the particle, with w turning into the *charge density* σ , \mathbf{j} becomes the electric current density. As the reader (hopefully :-) knows, both these currents satisfy classical continuity equations similar to Eq. (48).³⁹

Finally, let us recast the continuity equation, rewriting Eq. (46) as

$$\int_V \left(\frac{\partial w}{\partial t} + \nabla \cdot \mathbf{j} \right) d^3 r = 0. \quad (1.51)$$

Now we may argue that this equality may be true for any choice of the volume V only if the expression under the integral vanishes everywhere, i.e. if

$$\frac{\partial w}{\partial t} + \nabla \cdot \mathbf{j} = 0. \quad (1.52)$$

This differential form of the continuity equation may be more convenient than its integral form (48).

1.5. Eigenstates and eigenvalues

Now let us discuss the most important corollaries of wave mechanics' *linearity*. First of all, it uses only *linear operators*. This term means that the operators must obey the following two rules:⁴⁰

$$(\hat{A}_1 + \hat{A}_2)\Psi = \hat{A}_1\Psi + \hat{A}_2\Psi, \quad (1.53)$$

³⁹ See, e.g., respectively, CM 8.3 and EM Sec. 4.1.

⁴⁰ By the way, if any equality involving operators is valid for an arbitrary wavefunction, the latter is frequently dropped from notation, resulting in an *operator equality*. In particular, Eq. (53) may be readily used to prove that the linear operators are *commutative*: $\hat{A}_2 + \hat{A}_1 = \hat{A}_1 + \hat{A}_2$, and *associative*: $(\hat{A}_1 + \hat{A}_2) + \hat{A}_3 = \hat{A}_1 + (\hat{A}_2 + \hat{A}_3)$.

$$\hat{A}(c_1 \Psi_1 + c_2 \Psi_2) = \hat{A}(c_1 \Psi_1) + \hat{A}(c_2 \Psi_2) = c_1 \hat{A}\Psi_1 + c_2 \hat{A}\Psi_2, \quad (1.54)$$

where Ψ_n are arbitrary wavefunctions, while c_n are arbitrary constants (in quantum mechanics, frequently called *c-numbers*, to distinguish them from operators and wavefunctions). The most important examples of linear operators are given by:

- (i) the multiplication by a function, such as for the operator $\hat{\mathbf{r}}$ given by Eq. (26), and
- (ii) the spatial or temporal differentiation, such as in Eqs. (25)-(27).

Next, it is of key importance that the Schrödinger equation (25) is also linear. (This fact was already used in the discussion of wave packets in the last section.) This means that if each of several functions Ψ_n are (particular) solutions of Eq. (25) with a certain Hamiltonian, then their arbitrary linear combination,

$$\Psi = \sum_n c_n \Psi_n, \quad (1.55)$$

is also a solution of the same equation.⁴¹

Let us use the linearity to accomplish an apparently impossible feat: immediately find the *general* solution of the Schrödinger equation for the most important case when the system's Hamiltonian does not depend on time explicitly – for example, like in Eq. (41) with time-independent potential energy $U = U(\mathbf{r})$, when the Schrödinger equation has the form

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Psi + U(\mathbf{r}) \Psi. \quad (1.56)$$

Potential field:
Schrödinger equation

First of all, let us prove that the following product,

$$\Psi_n = a_n(t) \psi_n(\mathbf{r}), \quad (1.57)$$

Variable separation

qualifies as a (particular) solution of such an equation. Indeed, plugging Eq. (57) into Eq. (25) with *any* time-independent Hamiltonian, using the fact that in this case

$$\hat{H}a_n(t)\psi_n(\mathbf{r}) = a_n(t)\hat{H}\psi_n(\mathbf{r}), \quad (1.58)$$

and dividing both parts of the equation by $a_n \psi_n$, we get

$$\frac{i\hbar}{a_n} \frac{da_n}{dt} = \frac{\hat{H}\psi_n}{\psi_n}. \quad (1.59)$$

The left-hand side of this equation may depend only on time, while the right-hand side, only on coordinates. These facts may be only reconciled if we assume that each of these parts is equal to (the same) constant of the dimension of energy, which I will denote as E_n .⁴² As a result, we are getting two separate equations for the temporal and spatial parts of the wavefunction:

⁴¹ At the first glance, it may seem strange that the *linear* Schrödinger equation correctly describes quantum properties of systems whose classical dynamics is described by *nonlinear* equations of motion (e.g., an anharmonic oscillator – see, e.g., CM Sec. 5.2). Note, however, that statistical equations of classical dynamics (see, e.g., SM Chapters 5 and 6) also have this property, so it is not specific to quantum mechanics.

⁴² This argumentation, leading to *variable separation*, is very common in mathematical physics – see, e.g., its discussion in CM Sec. 6.5, and in EM Sec. 2.5 and beyond.

Stationary
Schrödinger
equation

$$\hat{H}\psi_n = E_n\psi_n, \quad (1.60)$$

$$i\hbar \frac{da_n}{dt} = E_n a_n. \quad (1.61a)$$

The latter of these equations, rewritten in the form

$$\frac{da_n}{a_n} = -i \frac{E_n}{\hbar} dt, \quad (1.61b)$$

is readily integrable, giving

Stationary
state:
time
evolution

$$\ln a_n = -i\omega_n t + \text{const}, \quad \text{so that } a_n = \text{const} \times \exp\{-i\omega_n t\}, \quad \text{with } \omega_n \equiv \frac{E_n}{\hbar}. \quad (1.62)$$

Now plugging Eqs. (57) and (62) into Eq. (22), we see that in the quantum state described by Eqs. (57)-(62), the probability w of finding the particle at a certain location does not depend on time:

$$w \equiv \psi_n^*(\mathbf{r})\psi_n(\mathbf{r}) = w(\mathbf{r}). \quad (1.63)$$

With the same substitution, Eq. (23) shows that the expectation value of any operator that does not depend on time explicitly is also time-independent:

$$\langle A \rangle \equiv \int \psi_n^*(\mathbf{r})\hat{A}\psi_n(\mathbf{r})d^3r = \text{const}. \quad (1.64)$$

Due to this property, the states described by Eqs. (57)-(62) are called *stationary*; they are fully defined by the possible solutions of the *stationary* (or “time-independent”) Schrödinger equation (60).⁴³ Note that for the time-independent Hamiltonian (41), the stationary Schrödinger equation (60),

Potential field:
stationary
Schrödinger
equation

$$-\frac{\hbar^2}{2m}\nabla^2\psi_n + U(\mathbf{r})\psi_n = E_n\psi_n, \quad (1.65)$$

is a linear, homogeneous differential equation for the function ψ_n , with *a priori* unknown parameter E_n . Such equations fall into the mathematical category of *eigenproblems*,⁴⁴ whose *eigenfunctions* ψ_n and *eigenvalues* E_n should be found simultaneously, i.e. self-consistently.⁴⁵

Mathematics⁴⁶ tells us that for such equations with space-confined eigenfunctions ψ_n , tending to zero at $r \rightarrow \infty$, the spectrum of eigenvalues is *discrete*. It also proves that the eigenfunctions corresponding to different eigenvalues are *orthogonal*, i.e. that space integrals of the products $\psi_n\psi_{n'}^*$ vanish for all pairs with $n \neq n'$. Due to the Schrödinger equation’s linearity, each of these functions may be multiplied by a proper constant coefficient to make their set *orthonormal*:

$$\int \psi_n^*\psi_{n'}d^3r = \delta_{n,n'} \equiv \begin{cases} 1, & \text{for } n = n', \\ 0, & \text{for } n \neq n'. \end{cases} \quad (1.66)$$

⁴³ In contrast, the *full* Schrödinger equation (25) is frequently called *time-dependent* or *non-stationary*.

⁴⁴ From the German root *eigen*, meaning “particular” or “characteristic”.

⁴⁵ Eigenvalues of energy are frequently called *eigenenergies*, and it is often said that the eigenfunction ψ_n and the corresponding eigenenergy E_n together determine the n^{th} *stationary eigenstate* of the system.

⁴⁶ See, e.g., Sec. 9.3 of the wonderful handbook by G. Korn and T. Korn, listed in MA Sec. 16(ii).

Moreover, the eigenfunctions $\psi_n(\mathbf{r})$ form a *full set*, meaning that an arbitrary function $\psi(\mathbf{r})$, in particular the actual wavefunction Ψ of the system in the initial moment of its evolution (which I will always, with a few clearly marked exceptions, take for $t = 0$) may be represented as a unique expansion over the eigenfunction set:

$$\Psi(\mathbf{r},0) = \sum_n c_n \psi_n(\mathbf{r}). \quad (1.67)$$

The expansion coefficients c_n may be readily found by multiplying both sides of Eq. (67) by $\psi_n^*(\mathbf{r})$, integrating the results over the space, and using Eq. (66). The result is

$$c_n = \int \psi_n^*(\mathbf{r}) \Psi(\mathbf{r},0) d^3 r. \quad (1.68)$$

Now let us consider the following wavefunction

$$\Psi(\mathbf{r},t) = \sum_n c_n a_k(t) \psi_k(\mathbf{r}) = \sum_n c_n \exp\left\{-i \frac{E_n}{\hbar} t\right\} \psi_n(\mathbf{r}). \quad (1.69)$$

General solution for $U = U(\mathbf{r})$

Since each term of the sum has the form (57) and satisfies the Schrödinger equation, so does the sum as the whole. Moreover, if the coefficients c_n are derived in accordance with Eq. (68), then the solution (69) satisfies the initial conditions as well. At this moment we can use one more bit of help from mathematicians, who tell us that the linear, partial differential equation of type (65), with fixed initial conditions, may have only one (*unique*) solution. This means that in our case of time-independent potential Hamiltonian, Eq. (69) gives the *general* solution of the Schrödinger equation (25).

So, we have succeeded in our apparently over-ambitious goal. Now let us pause this mad mathematical dash for a minute, and discuss this key result.

1.6. Time evolution

For the time-dependent factor, $a_n(t)$, of each component (57) of the general solution (69), our procedure gave a very simple and universal result (62), describing a linear change of the phase $\varphi_n \equiv \arg(a_n)$ of this complex function in time, with the constant rate

$$\frac{d\varphi_n}{dt} = -\omega_n = -\frac{E_n}{\hbar}, \quad (1.70)$$

so that the real and imaginary parts of a_n oscillate sinusoidally with this frequency. The relation (70) coincides with Einstein's conjecture (5), but could these oscillations of the wavefunctions represent a physical reality? Indeed, for photons, described by Eq. (5), E may be (and as we will see in Chapter 9, is) the actual, well-defined energy of one photon, and ω is the frequency of the radiation so quantized. However, for non-relativistic particles, described by wave mechanics, the potential energy U , and hence the full energy E , are defined to an arbitrary constant, because we may measure them from an arbitrary reference level. How can such a change of the energy reference level (which may be made just in our mind) alter the frequency of oscillations of a variable?

According to Eqs. (22)-(23), this time evolution of a wavefunction does not affect the particle's probability distribution, or even any observable (including the energy E , provided that it is always referred to the same origin as U), in any stationary state. However, let us combine Eq. (5) with Bohr's assumption (7):

$$\hbar\omega_{nn'} = E_{n'} - E_n. \quad (1.71)$$

The *difference* $\omega_{nn'}$ of the eigenfrequencies ω_n and $\omega_{n'}$, participating in this formula, is evidently independent of the energy reference, and as will be proved later in the course, determines the measurable frequency of the electromagnetic radiation (or possibly of a wave of a different physical nature) emitted or absorbed at the quantum transition between the states.

As another but related example, consider two similar particles 1 and 2, each in the same (say, the lowest-energy) eigenstate, but with their potential energies (and hence the ground state energies $E_{1,2}$) different by a constant $\Delta U \equiv U_1 - U_2$. Then, according to Eq. (70), the difference $\varphi \equiv \varphi_1 - \varphi_2$ of their wavefunction phases evolves in time with the reference-independent rate

$$\frac{d\varphi}{dt} = -\frac{\Delta U}{\hbar}. \quad (1.72)$$

Certain measurement instruments, weakly coupled to the particles, may allow observation of this evolution, while keeping the particle's quantum dynamics virtually unperturbed, i.e. Eq. (70) intact. Perhaps the most dramatic measurement of this type is possible using the *Josephson effect* in weak links between two superconductors – see Fig. 7.⁴⁷

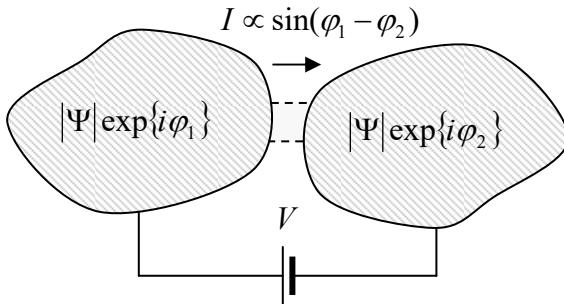

Fig. 1.7. The Josephson effect in a weak link between two bulk superconductor electrodes.

As a brief reminder,⁴⁸ superconductivity may be explained by a specific coupling between conduction electrons in solids, that leads, at low temperatures, to the formation of the so-called *Cooper pairs*. Such pairs, each consisting of two electrons with opposite spins and momenta, behave as Bose particles and form a coherent *Bose-Einstein condensate*.⁴⁹ Most properties of such a condensate may be described by a single, common wavefunction Ψ , evolving in time just as that of a free particle, with the effective potential energy $U = q\phi = -2e\phi$, where ϕ is the electrochemical potential,⁵⁰ and $q = -2e$ is the electric charge of a Cooper pair. As a result, for the system shown in Fig. 7, in which externally applied voltage V fixes the difference $\phi_1 - \phi_2$ between the electrochemical potentials of two superconductors, Eq. (72) takes the form

$$\frac{d\varphi}{dt} = \frac{2e}{\hbar}V. \quad (1.73)$$

Eq. (72) for
Josephson
effect

If the link between the superconductors is weak enough, the electric current I of the Cooper pairs (called the *supercurrent*) through the link may be approximately described by the following simple relation,

⁴⁷ The effect was predicted in 1962 by Brian Josephson (then a graduate student!) and observed soon after that.

⁴⁸ For a more detailed discussion, including the derivation of Eq. (75), see e.g. EM Chapter 6.

⁴⁹ A detailed discussion of the Bose-Einstein condensation may be found, e.g., in SM Sec. 3.4.

⁵⁰ For more on this notion see, e.g. SM Sec. 6.3.

$$I = I_c \sin \varphi, \quad (1.74)$$

where I_c is some constant, dependent on the weak link's strength.⁵¹ Now combining Eqs. (73) and (74), we see that if the applied voltage V is constant in time, the current oscillates sinusoidally, with the so-called *Josephson frequency*

$$\omega_J \equiv \frac{2e}{\hbar} V, \quad (1.75)$$

as high as ~ 484 MHz per microvolt of applied dc voltage. This effect may be readily observed experimentally: though its direct detection is a bit tricky, it is easy to observe the *phase locking* (synchronization)⁵² of the Josephson oscillations by an external microwave signal of frequency ω . Such phase locking results in the relation $\omega_J = n\omega$ fulfilled within certain dc current intervals, and hence in the formation, on the weak link's dc I - V curve, of virtually vertical current steps at dc voltages

$$V_n = n \frac{\hbar\omega}{2e}, \quad (1.76)$$

where n is an integer.⁵³ Since frequencies may be stabilized and measured with very high precision, this effect is being used in highly accurate standards of dc voltage.

1.7. Spatial dependence

In contrast to the simple and universal time dependence (62) of the stationary states, the spatial distributions of their wavefunction $\psi_n(\mathbf{r})$ need to be calculated from the problem-specific stationary Schrödinger equation (65). The solution of this equation for various particular cases is a major focus of the next two chapters. For now, let us consider just the simplest example, which nevertheless will be the basis for our discussion of more complex problems: let a particle be confined inside a rectangular hard-wall box. Such confinement may be described by the following potential energy profile:⁵⁴

$$U(\mathbf{r}) = \begin{cases} 0, & \text{for } 0 < x < a_x, \quad 0 < y < a_y, \quad \text{and } 0 < z < a_z, \\ +\infty, & \text{otherwise.} \end{cases} \quad (1.77)$$

Hard-wall box:
potential

The only way to keep the product $U(\mathbf{r})\psi_n$ in Eq. (65) finite outside the box, is to have $\psi = 0$ in these regions. Also, the function has to be continuous everywhere, to avoid the divergence of the

⁵¹ In some cases, the function $I(\varphi)$ may somewhat deviate from Eq. (74), but these deviations do not affect its fundamental 2π -periodicity, and hence the fundamental relations (75)-(76). (No corrections to them have been found yet.)

⁵² For the discussion of this very general effect, see, e.g., CM Sec. 5.4.

⁵³ The size of these dc current steps may be readily calculated from Eqs. (73) and (74). Let me leave this task for the reader's exercise.

⁵⁴ Another common name for such potentials, especially of lower dimensionality, is the *potential well*, in our current case "rectangular" one: with a flat "bottom" and vertical, infinitely high "walls". Note that sometimes, very unfortunately, such potential profiles are called "quantum wells". (This term seems to imply that the particle's confinement in such a well is a phenomenon specific for quantum mechanics. However, as we will repeatedly see in this course, the opposite is true: quantum effects do as much as they only can to *overcome* the particle's confinement in a potential well, letting it partly penetrate in the "classically forbidden" regions beyond the well's walls.)

kinetic-energy term $(-\hbar^2/2m)\nabla^2\psi_n$. Hence, in this case we may solve the stationary Schrödinger equation (60) just inside the box, i.e. with $U=0$, so that it takes a simple form

$$-\frac{\hbar^2}{2m}\nabla^2\psi_n = E_n\psi_n, \quad (1.78a)$$

with zero boundary conditions on all the walls.⁵⁵ For our particular geometry, it is natural to express the Laplace operator in the Cartesian coordinates $\{x, y, z\}$ aligned with the box sides, with the origin at one of the corners of its rectangular $a_x \times a_y \times a_z$ volume, so that our boundary problem becomes:

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right)\psi_n = E_n\psi_n, \quad \text{for } 0 < x < a_x, \quad 0 < y < a_y, \quad \text{and } 0 < z < a_z, \quad (1.78b)$$

$$\text{with } \psi_n = 0 \text{ for: } x = 0 \text{ and } a_x; \quad y = 0 \text{ and } a_y; \quad z = 0 \text{ and } a_z.$$

This problem may be readily solved using the same variable separation method as was used in Sec. 5 – now to separate the Cartesian spatial variables from each other, by looking for a partial solution of Eq. (78) in the form

$$\psi(\mathbf{r}) = X(x)Y(y)Z(z). \quad (1.79)$$

(Let us postpone assigning function indices for a minute.) Plugging this expression into Eq. (78b) and dividing all terms by the product XYZ , we get

$$-\frac{\hbar^2}{2m}\frac{1}{X}\frac{d^2X}{dx^2} - \frac{\hbar^2}{2m}\frac{1}{Y}\frac{d^2Y}{dy^2} - \frac{\hbar^2}{2m}\frac{1}{Z}\frac{d^2Z}{dz^2} = E. \quad (1.80)$$

Now let us repeat the standard argumentation of the variable separation method: since each term on the left-hand side of this equation may be only a function of the corresponding argument, the equality is possible only if each of them is a constant – in our case, with the dimensionality of energy. Calling these constants E_x , etc., we get three similar 1D equations

$$-\frac{\hbar^2}{2m}\frac{1}{X}\frac{d^2X}{dx^2} = E_x, \quad -\frac{\hbar^2}{2m}\frac{1}{Y}\frac{d^2Y}{dy^2} = E_y, \quad -\frac{\hbar^2}{2m}\frac{1}{Z}\frac{d^2Z}{dz^2} = E_z, \quad (1.81)$$

with Eq. (80) turning into the following energy-matching condition:

$$E_x + E_y + E_z = E. \quad (1.82)$$

All three ordinary differential equations (81), and their solutions, are similar. For example, for $X(x)$, we have the following 1D Helmholtz equation

$$\frac{d^2X}{dx^2} + k_x^2X = 0, \quad \text{with } k_x^2 \equiv \frac{2mE_x}{\hbar^2}, \quad (1.83)$$

and simple boundary conditions: $X(0) = X(a_x) = 0$. Let me hope that the reader knows how to solve this well-known 1D boundary problem – describing, for example, the usual mechanical waves on a guitar string. The problem allows an infinite number of sinusoidal standing-wave eigenfunctions,⁵⁶

⁵⁵ Rewritten as $\nabla^2f + k^2f = 0$, Eq. (78a) is just the *Helmholtz equation*, which describes waves of any nature (with the wave vector \mathbf{k}) in a uniform, isotropic, linear medium – see, e.g., EM Secs. 7.5-7.9 and 8.5.

⁵⁶ The front coefficient in the last expression for X ensures the (ortho)normality condition (66).

$$X \propto \sin k_x x, \quad \text{with } k_x = \frac{\pi n_x}{a_x}, \quad \text{so that } X = \left(\frac{2}{a_x} \right)^{1/2} \sin \frac{\pi n_x x}{a_x}, \quad \text{with } n_x = 1, 2, \dots, \quad (1.84)$$

Rectangular potential well:
1D eigenfunctions

corresponding to the following eigenenergies:

$$E_x = \frac{\hbar^2}{2m} k_x^2 = \frac{\pi^2 \hbar^2}{2ma_x^2} n_x^2 \equiv E_{x1} n_x^2. \quad (1.85)$$

Figure 8 shows these simple results, using a somewhat odd but very graphic and common representation, in that the eigenenergy values (frequently called the *energy levels*) are used as horizontal axes for plotting the eigenfunctions – despite their completely different dimensionality.

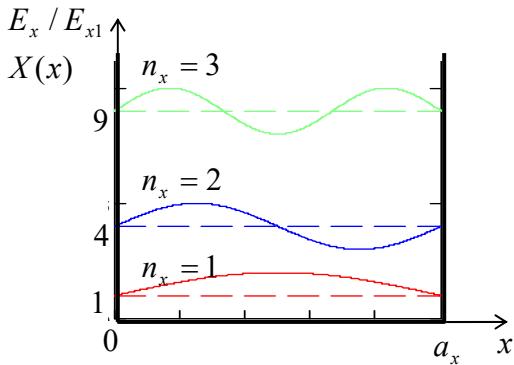

Fig. 1.8. The lowest eigenfunctions (solid lines) and eigenvalues (dashed lines) of Eq. (83) for a potential well of length a_x . Solid black lines show the effective potential of this 1D eigenproblem.

Due to the similarity of all Eqs. (81), $Y(y)$ and $Z(z)$ are absolutely similar functions of their arguments, and may also be numbered by integers (say, n_y and n_z) independent of n_x , so that the spectrum of values of the total energy (82) is

$$E_{n_x, n_y, n_z} = \frac{\pi^2 \hbar^2}{2m} \left(\frac{n_x^2}{a_x^2} + \frac{n_y^2}{a_y^2} + \frac{n_z^2}{a_z^2} \right). \quad (1.86)$$

Rectangular potential well:
energy levels

Thus, in this 3D problem, the role of the index n in the general Eq. (69) is played by a set of three independent integers $\{n_x, n_y, n_z\}$. In quantum mechanics, such integers play a key role and thus have a special name, the *quantum numbers*. Using them, that general solution, for our current simple problem may be represented as the sum

$$\Psi(\mathbf{r}, t) = \sum_{n_x, n_y, n_z=1}^{\infty} c_{n_x, n_y, n_z} \sin \frac{\pi n_x x}{a_x} \sin \frac{\pi n_y y}{a_y} \sin \frac{\pi n_z z}{a_z} \exp \left\{ -i \frac{E_{n_x, n_y, n_z}}{\hbar} t \right\}, \quad (1.87)$$

Rectangular potential well:
general solution

with the front coefficients that may be readily calculated from the initial wavefunction $\Psi(\mathbf{r}, 0)$, using Eq. (68) – again with the replacement $n \rightarrow \{n_x, n_y, n_z\}$.

This simplest problem is a good illustration of typical results the wave mechanics gives for spatially-confined motion, including the discrete energy spectrum, and (in this case, evidently) orthogonal eigenfunctions. Perhaps most importantly, its solution shows that the lowest value of the particle's kinetic energy (86), reached in the so-called *ground state* (in our case, the state with $n_x = n_y = n_z = 1$) is above zero for any finite size of the confining box.

An example of the opposite case of a *continuous spectrum* for the *unconfined motion* of a free particle is given by the plane waves (29). With the account of relations $E = \hbar\omega$ and $\mathbf{p} = \hbar\mathbf{k}$, such wavefunction may be viewed as the product of the time-dependent factor (62) by the eigenfunction,

Free
particle:
eigen-
functions

$$\psi_{\mathbf{k}} = a_{\mathbf{k}} \exp\{i\mathbf{k} \cdot \mathbf{r}\}, \quad (1.88)$$

which is the solution of the stationary Schrödinger equation (78a) if it is valid in the whole space.⁵⁷ The reader should not be worried too much by the fact that the fundamental solution (86) in free space is a *traveling* wave (having, in particular, a non-zero value of the probability current \mathbf{j}), while those inside a quantum box are *standing* waves, with $\mathbf{j} = 0$, even though the free space may be legitimately considered as the ultimate limit of a quantum box with volume $V = a_x \times a_y \times a_z \rightarrow \infty$. Indeed, due to the linearity of wave mechanics, two traveling-wave solutions (88) with equal and opposite values of the momentum (and hence with the same energy) may be readily combined to give a standing-wave solution,⁵⁸ for example, $\exp\{i\mathbf{k} \cdot \mathbf{r}\} + \exp\{-i\mathbf{k} \cdot \mathbf{r}\} = 2\cos(\mathbf{k} \cdot \mathbf{r})$, with the net current $\mathbf{j} = 0$. Thus, depending on the convenience for a particular problem, we may represent its general solution as a sum of either traveling-wave or standing-wave eigenfunctions. Since in the unlimited free space, there are no boundary conditions to satisfy, the Cartesian components of the wave vector \mathbf{k} in Eq. (88) can take any real values. (This is why it is more convenient to label these wavefunctions, and the corresponding eigenenergies,

Free
particle:
eigen-
energies

$$E_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m} \geq 0, \quad (1.89)$$

with their wave vector \mathbf{k} rather than an integer index.)

However, one aspect of continuous-spectrum systems requires a bit more caution with mathematics: the summation (69) should be replaced by the integration over a continuous index or indices – in our current case, the three Cartesian components of the vector \mathbf{k} . The main rule of such replacement may be readily extracted from Eq. (84): according to this relation, for standing-wave solutions, the eigenvalues of k_x are *equidistant*, i.e. separated by equal intervals $\Delta k_x = \pi/a_x$, with similar relations for other two Cartesian components of vector \mathbf{k} . Hence the number of different eigenvalues of the standing-wave vector \mathbf{k} (with $k_x, k_y, k_z \geq 0$), within a volume $d^3 k \gg 1/V$ of the \mathbf{k} space is $dN = d^3 k / (\Delta k_x \Delta k_y \Delta k_z) = (V/\pi^3) d^3 k$. Frequently, it is more convenient to work with traveling waves (88); in this case we should take into account that, as was just discussed, there are two different traveling wave numbers (say, $+k_x$ and $-k_x$) corresponding to each standing wave vector's $k_x > 0$. Hence the same number of physically different states corresponds to a $2^3 = 8$ -fold larger \mathbf{k} space or, equivalently, to an 8-fold smaller number of states per unit volume $d^3 k$:

Number
of 3D states

$$dN = \frac{V}{(2\pi)^3} d^3 k. \quad (1.90)$$

⁵⁷ In some systems (e.g., a particle interacting with a potential well of a finite depth), a discrete energy spectrum within a certain energy interval may coexist with a continuous spectrum in a complementary interval. However, the conceptual philosophy of eigenfunctions and eigenvalues remains the same even in this case.

⁵⁸ This is, of course, the general property of waves of any physical nature, propagating in a linear medium – see, e.g., CM Sec. 6.5 and/or EM Sec. 7.3.

For $dN \gg 1$, this expression is independent of the boundary conditions, and is frequently represented as the following *summation rule*

$$\lim_{k^3 V \rightarrow \infty} \sum_{\mathbf{k}} f(\mathbf{k}) = \int f(\mathbf{k}) dN = \frac{V}{(2\pi)^3} \int f(\mathbf{k}) d^3 k, \quad (1.91)$$

Summation over 3D states

where $f(\mathbf{k})$ is an arbitrary function of \mathbf{k} . Note that if the same wave vector \mathbf{k} corresponds to several internal quantum states (such as spin – see Chapter 4), the right-hand side of Eq. (91) requires its multiplication by the corresponding *degeneracy factor* of orbital states.⁵⁹

1.8. Dimensionality reduction

To conclude this introductory chapter, let me discuss the conditions when the spatial dimensionality of a wave-mechanical problem may be reduced.⁶⁰ Naively, one may think that if the particle's potential energy depends on just one spatial coordinate, say $U = U(x, t)$, then its wavefunction has to be one-dimensional as well: $\psi = \psi(x, t)$. Our discussion of the particular case $U = \text{const}$ in the previous section shows that this assumption is wrong. Indeed, though this potential⁶¹ is just a special case of the potential $U(x, t)$, most of its eigenfunctions, given by Eqs. (87) or (88), do depend on the other two coordinates. This is why the solutions $\psi(x, t)$ of the 1D Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} \Psi + U(x, t)\Psi, \quad (1.92)$$

1D time-dependent Schrödinger equation

which follows from Eq. (65) by assuming $\partial\Psi/\partial y = \partial\Psi/\partial z = 0$, are insufficient to form the general solution of Eq. (65) for this case.

This fact is easy to understand physically for the simplest case of a stationary 1D potential: $U = U(x)$. The absence of the y - and z -dependence of the potential energy U may be interpreted as a potential well that is flat in two directions, y and z . Repeating the arguments of the previous section for this case, we see that the eigenfunctions of a particle in such a well have the form

$$\psi(\mathbf{r}) = X(x) \exp\{i(k_y y + k_z z)\}, \quad (1.93)$$

where $X(x)$ is an eigenfunction of the following stationary 1D Schrödinger equation:

$$-\frac{\hbar^2}{2m} \frac{d^2 X}{dx^2} + U_{\text{ef}}(x)X = EX, \quad (1.94)$$

where $U_{\text{ef}}(x)$ is *not* the full potential energy of the particle, as it would follow from Eq. (92), but rather its effective value including the kinetic energy of the lateral motion:

$$U_{\text{ef}} \equiv U + (E_y + E_z) = U + \frac{\hbar^2}{2m} (k_y^2 + k_z^2). \quad (1.95)$$

⁵⁹ Such factor is similar to the front factor 2 in Eq. (1) for the number of electromagnetic wave modes, in that case describing two different polarizations of the waves with the same wave vector.

⁶⁰ Most textbooks on quantum mechanics jump to the formal solution of 1D problems without such discussion, ignoring the fact that such dimensionality restriction is adequate only under very specific conditions.

⁶¹ Following tradition, I will frequently use this shorthand for “potential energy”, returning to the full term in cases where there is any chance of confusion of this notion with another (say, electrostatic) potential.

In plain English, the particle's partial wavefunction $X(x)$ and its full energy, depend on its transverse momenta, which have continuous spectrum – see the discussion of Eq. (89). This means that Eq. (92) is adequate only if the condition $k_y = k_z = 0$ is somehow enforced, and in most physical problems, it is not. For example, if a de Broglie (or any other) plane wave $\Psi(x, t)$ is incident on a potential step, it would be reflected exactly back, i.e. with $k_y = k_z = 0$, only if the wall's surface is perfectly plane and exactly normal to the axis x . Any imperfection (and they are so many of them in real physical systems –:) may cause excitation of waves with non-zero values of k_y and k_z , due to the continuous character of the functions $E_y(k_y)$ and $E_z(k_z)$.⁶²

There is essentially one, perhaps counter-intuitive way to make the 1D solutions “robust” to small perturbations: it is to provide a *rigid lateral confinement*⁶³ in two other directions. As the simplest example, consider a narrow *quantum wire* (Fig. 9a), described by the following potential:

$$U(\mathbf{r}) = \begin{cases} U(x), & \text{for } 0 < y < a_y, \text{ and } 0 < z < a_z, \\ +\infty, & \text{otherwise.} \end{cases} \quad (1.96)$$

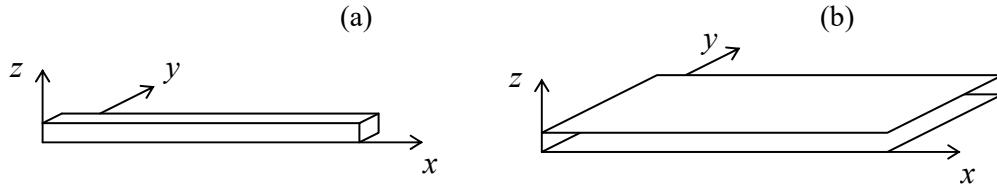

Fig. 1.9. Partial confinement in: (a) two dimensions, and (b) one dimension.

Performing the standard variable separation (79), we see that the corresponding stationary Schrödinger equation is satisfied if the partial wavefunction $X(x)$ obeys Eqs. (94)-(95), but now with a discrete energy spectrum in the transverse directions:

$$U_{\text{ef}} = U + \frac{\pi^2 \hbar^2}{2m} \left(\frac{n_y^2}{a_y^2} + \frac{n_z^2}{a_z^2} \right). \quad (1.97)$$

If the lateral confinement is tight, $a_y, a_z \rightarrow 0$, then there is a large energy gap,

$$\Delta U \sim \frac{\pi^2 \hbar^2}{2ma_{y,z}^2}, \quad (1.98)$$

between the ground-state energy of the lateral motion (with $n_y = n_z = 1$) and that for all its excited states. As a result, if the particle is initially placed into the lateral ground state, and its energy E is much smaller than ΔU , it would stay in such state, i.e. may be described by a 1D Schrödinger equation similar to Eq. (92) – even in the time-dependent case, if the characteristic frequency of energy variations is much smaller than $\Delta U/\hbar$. Absolutely similarly, the strong lateral confinement in just one dimension (say, z , see Fig. 9b) enables systems with a robust 2D evolution of the particle's wavefunction.

⁶² This problem is not specific to quantum mechanics. The classical motion of a particle in a 1D potential may be also unstable with respect to lateral perturbations, especially if the potential is time-dependent, i.e. capable of exciting low-energy lateral modes.

⁶³ The term “quantum confinement”, sometimes used to describe this phenomenon, is as unfortunate as the “quantum well” term discussed above, because of the same reason: the confinement is a purely classical effect, and as we will repeatedly see in this course, the quantum-mechanical effects reduce, rather than enable it.

The tight lateral confinement may ensure the dimensionality reduction even if the potential well is not exactly rectangular in the lateral direction(s), as described by Eq. (96), but is described by some x - and t -independent profile, if it still provides a sufficiently large energy gap ΔU . For example, many 2D quantum phenomena, such as the quantum Hall effect,⁶⁴ have been studied experimentally using electrons confined at semiconductor heterojunctions (e.g., epitaxial interfaces GaAs/Al_xGa_{1-x}As), where the potential well in the direction perpendicular to the interface has a nearly triangular shape, and provides an energy gap ΔU of the order of 10⁻² eV.⁶⁵ This gap corresponds to $k_B T$ with $T \sim 100$ K, so that careful experimentation at liquid helium temperatures (4K and below) may keep the electrons performing purely 2D motion in the “lowest subband” ($n_z = 1$).

Finally, note that in systems with reduced dimensionality, Eq. (90) for the number of states at large \mathbf{k} (i.e., for an essentially free particle motion) should be replaced accordingly: in a 2D system of area $A \gg 1/k^2$,

$$dN = \frac{A}{(2\pi)^2} d^2 k, \quad (1.99)$$
Number of 2D states

while in a 1D system of length $l \gg 1/k$,

$$dN = \frac{l}{2\pi} dk, \quad (1.100)$$
Number of 1D states

with the corresponding changes of the summation rule (91). This change has important implications for the density of states on the energy scale, dN/dE : it is straightforward (and hence left for the reader :-)) to use Eqs. (90), (99), and (100) to show that for free 3D particles the density increases with E (proportionally to $E^{1/2}$), for free 2D particles it does not depend on energy at all, while for free 1D particles it scales as $E^{1/2}$, i.e. decreases with energy.

1.9. Exercise problems

1.1. The actual postulate made by N. Bohr in his original 1913 paper was not directly Eq. (8), but the assumption that at quantum leaps between adjacent large (quasiclassical) orbits with $n \gg 1$, the hydrogen atom either emits or absorbs energy $\Delta E = \hbar\omega$, where ω is its classical radiation frequency – according to classical electrodynamics, equal to the angular velocity of electron’s rotation.⁶⁶ Prove that this postulate is indeed compatible with Eqs. (7)-(8).

1.2. Use Eq. (53) to prove that the linear operators of quantum mechanics are commutative: $\hat{A}_2 + \hat{A}_1 = \hat{A}_1 + \hat{A}_2$, and associative: $(\hat{A}_1 + \hat{A}_2) + \hat{A}_3 = \hat{A}_1 + (\hat{A}_2 + \hat{A}_3)$.

1.3. Prove that for any time-independent Hamiltonian operator \hat{H} and two arbitrary complex functions $f(\mathbf{r})$ and $g(\mathbf{r})$,

$$\int f(\mathbf{r}) \hat{H} g(\mathbf{r}) d^3 r = \int \hat{H} f(\mathbf{r}) g(\mathbf{r}) d^3 r.$$

⁶⁴ To be discussed in Sec. 3.2.

⁶⁵ See, e.g., P. Harrison, *Quantum Wells, Wires, and Dots*, 3rd ed., Wiley, 2010.

⁶⁶ See, e.g., EM Sec. 8.2.

1.4. Prove that the Schrödinger equation (25) with the Hamiltonian operator given by Eq. (41), is Galilean form-invariant, provided that the wavefunction is transformed as

$$\Psi'(\mathbf{r}', t') = \Psi(\mathbf{r}, t) \exp \left\{ -i \frac{m\mathbf{v} \cdot \mathbf{r}}{\hbar} + i \frac{mv^2 t}{2\hbar} \right\},$$

where the prime sign marks the variables measured in the reference frame 0' that moves, without rotation, with a constant velocity \mathbf{v} relatively to the “lab” frame 0. Give a physical interpretation of this transformation.

1.5.* Prove the so-called *Hellmann-Feynman theorem*:⁶⁷

$$\frac{\partial E_n}{\partial \lambda} = \left\langle \frac{\partial H}{\partial \lambda} \right\rangle_n,$$

where λ is some c -number parameter, on which the time-independent Hamiltonian \hat{H} , and hence its eigenenergies E_n , depend.

1.6.* Use Eqs. (73) and (74) to analyze the effect of phase locking of Josephson oscillations on the dc current flowing through a weak link between two superconductors (frequently called the *Josephson junction*), assuming that an external source applies to the junction a sinusoidal ac voltage with frequency ω and amplitude A .

1.7. Calculate $\langle x \rangle$, $\langle p_x \rangle$, δx , and δp_x for the eigenstate $\{n_x, n_y, n_z\}$ of a particle in a rectangular hard-wall box described by Eq. (77), and compare the product $\delta x \delta p_x$ with the Heisenberg’s uncertainty relation.

1.8. Looking at the lower (red) line in Fig. 8, it seems plausible that the 1D ground-state function (84) of the simple potential well (77) may be well approximated with an inverted quadratic parabola:

$$X_{\text{trial}}(x) = C x (a_x - x),$$

where C is a normalization constant. Explore how good this approximation is.

1.9. A particle placed in a hard-wall rectangular box with sides a_x , a_y , and a_z , is in its ground state. Calculate the average force acting on each face of the box. Can the forces be characterized by a certain pressure?

1.10. A 1D quantum particle was initially in the ground state of a very deep, rectangular potential well of width a :

$$U(x) = \begin{cases} 0, & \text{for } -a/2 < x < +a/2, \\ +\infty, & \text{otherwise.} \end{cases}$$

⁶⁷ Despite this common name, H. Hellmann (in 1937) and R. Feynman (in 1939) were not the first ones in the long list of physicists who had (apparently, independently) discovered this equality. Indeed, it has been traced back to a 1922 paper by W. Pauli, and was carefully proved by P. Güttinger in 1931.

At some instant, the well's width is abruptly increased to a new value $a' > a$, leaving the potential symmetric with respect to the point $x = 0$, and then left constant. Calculate the probability that after the change, the particle is still in the ground state of the system.

1.11. At $t = 0$, a 1D particle of mass m is placed into a hard-wall, flat-bottom potential well

$$U(x) = \begin{cases} 0, & \text{for } 0 < x < a, \\ +\infty, & \text{otherwise,} \end{cases}$$

in a 50/50 linear superposition of the lowest (ground) state and the first excited state. Calculate:

- (i) the normalized wavefunction $\Psi(x, t)$ for arbitrary time $t \geq 0$, and
- (ii) the time evolution of the expectation value $\langle x \rangle$ of the particle's coordinate.

1.12. Calculate the potential profiles $U(x)$ for that the following wavefunctions,

- (i) $\Psi = c \exp\{-ax^2 - ibt\}$, and
- (ii) $\Psi = c \exp\{-a|x| - ibt\}$

(with real coefficients $a > 0$ and b), satisfy the 1D Schrödinger equation for a particle with mass m . For each case, calculate $\langle x \rangle$, $\langle p_x \rangle$, δx , and δp_x , and compare the product $\delta x \delta p_x$ with the Heisenberg's uncertainty relation.

1.13. A 1D particle of mass m , moving in the field of a stationary potential $U(x)$, has the following eigenfunction

$$\psi(x) = \frac{C}{\cosh \kappa x},$$

where C is the normalization constant, and κ is a real constant. Calculate the function $U(x)$ and the state's eigenenergy E .

1.14. Calculate the density dN/dE of traveling-wave quantum states in large rectangular potential wells of various dimensions: $d = 1, 2$, and 3 .

1.15.* Use the finite-difference method with steps $a/2$ and $a/3$ to find as many eigenenergies as possible for a 1D particle in the infinitely deep, hard-wall 1D potential well of width a . Compare the results with each other, and with the exact formula.⁶⁸

⁶⁸ You may like to start by reading about the finite-difference method – see, e.g., CM Sec. 8.5 or EM Sec. 2.11.

Chapter 2. 1D Wave Mechanics

Even the simplest, 1D version of wave mechanics enables quantitative analysis of many important quantum-mechanical effects. The order of their discussion in this chapter is dictated mostly by mathematical convenience – going from the simplest potential profiles to more complex ones, so that we may build upon the previous results. However, I would advise the reader to focus more not on the math, but rather on the physics of the non-classical phenomena it describes, ranging from particle penetration into classically-forbidden regions, to quantum-mechanical tunneling, to the metastable state decay, to covalent bonding and quantum oscillations, to energy bands and gaps.

2.1. Basic relations

As was discussed at the end of Chapter 1, in several cases (in particular, at strong confinement within the $[y, z]$ plane), the general (3D) Schrödinger equation may be reduced to its 1D version, similar to Eq. (1.92):

$$\text{Schrödinger equation} \quad i\hbar \frac{\partial \Psi(x, t)}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \Psi(x, t)}{\partial x^2} + U(x, t)\Psi(x, t). \quad (2.1)$$

It is important, however, to remember that according to the discussion in Sec. 1.8, $U(x, t)$ in this equation is generally *effective* potential energy, which may include the energy of the lateral motion, while $\Psi(x, t)$ may be just one factor in the complete wavefunction $\Psi(x, t)\chi(y, z)$. If the transverse factor $\chi(y, z)$ is normalized to 1, then the integration of Eq. (1.22a) over the 3D space within a segment $[x_1, x_2]$ gives the following probability to find the particle on this segment:

$$\text{Probability} \quad W(t) \equiv \int_{x_1}^{x_2} \Psi(x, t)\Psi^*(x, t)dx. \quad (2.2)$$

If the particle under analysis is definitely somewhere inside the system, the normalization of its 1D wavefunction $\Psi(x, t)$ is provided by extending integral (2) to the whole axis x :

$$\text{Normalization} \quad \int_{-\infty}^{+\infty} w(x, t)dx = 1, \quad \text{where } w(x, t) \equiv \Psi(x, t)\Psi^*(x, t). \quad (2.3)$$

A similar integration of Eq. (1.23) shows that the expectation value of any observable depending only on the coordinate x (and possibly time), may be expressed as

$$\text{Expectation value} \quad \langle A \rangle(t) = \int_{-\infty}^{+\infty} \Psi^*(x, t)\hat{A}\Psi(x, t)dx. \quad (2.4)$$

It is also useful to introduce the notion of the *probability current* along the x -axis (a scalar):

$$\text{Probability current} \quad I(x, t) \equiv \int j_x dy dz = \frac{\hbar}{m} \text{Im} \left(\Psi^* \frac{\partial}{\partial x} \Psi \right) = \frac{\hbar}{m} |\Psi(x, t)|^2 \frac{\partial \varphi}{\partial x}, \quad (2.5)$$

where j_x is the x -component of the current density vector $\mathbf{j}(\mathbf{r}, t)$. Then the continuity equation (1.48) for any segment $[x_1, x_2]$ takes the form

$$\frac{dW}{dt} + I(x_2) - I(x_1) = 0. \quad (2.6)$$

Continuity
equation

The above formulas are sufficient for analysis of 1D problems of wave mechanics, but before proceeding to particular cases, let me deliver on my earlier promise to prove that Heisenberg's uncertainty relation (1.35) is indeed valid for any wavefunction $\Psi(x, t)$. For that, let us consider the following positive (or at least non-negative) integral

$$J(\lambda) \equiv \int_{-\infty}^{+\infty} \left| x\Psi + \lambda \frac{\partial\Psi}{\partial x} \right|^2 dx \geq 0, \quad (2.7)$$

where λ is an arbitrary real constant, and assume that at $x \rightarrow \pm\infty$ the wavefunction vanishes, together with its first derivative – as we will see below, a very common case. Then the left-hand side of Eq. (7) may be recast as

$$\begin{aligned} J(\lambda) &\equiv \int_{-\infty}^{+\infty} \left| x\Psi + \lambda \frac{\partial\Psi}{\partial x} \right|^2 dx = \int_{-\infty}^{+\infty} \left(x\Psi + \lambda \frac{\partial\Psi}{\partial x} \right) \left(x\Psi + \lambda \frac{\partial\Psi}{\partial x} \right)^* dx \\ &= \int_{-\infty}^{+\infty} x^2 \Psi \Psi^* dx + \lambda \int_{-\infty}^{+\infty} x \left(\Psi \frac{\partial\Psi^*}{\partial x} + \frac{\partial\Psi}{\partial x} \Psi^* \right) dx + \lambda^2 \int_{-\infty}^{+\infty} \frac{\partial\Psi}{\partial x} \frac{\partial\Psi^*}{\partial x} dx. \end{aligned} \quad (2.8)$$

According to Eq. (4), the first term in the last form of Eq. (8) is just $\langle x^2 \rangle$, while the second and the third integrals may be worked out by parts:

$$\int_{-\infty}^{+\infty} x \left(\Psi \frac{\partial\Psi^*}{\partial x} + \frac{\partial\Psi}{\partial x} \Psi^* \right) dx \equiv \int_{-\infty}^{+\infty} x \frac{\partial}{\partial x} (\Psi \Psi^*) dx = \int_{x=-\infty}^{x=+\infty} x d(\Psi \Psi^*) = \Psi \Psi^* x \Big|_{x=-\infty}^{x=+\infty} - \int_{-\infty}^{+\infty} \Psi \Psi^* dx = -1, \quad (2.9)$$

$$\int_{-\infty}^{+\infty} \frac{\partial\Psi}{\partial x} \frac{\partial\Psi^*}{\partial x} dx = \int_{x=-\infty}^{x=+\infty} \frac{\partial\Psi}{\partial x} d\Psi^* = \frac{\partial\Psi}{\partial x} \Psi^* \Big|_{x=-\infty}^{x=+\infty} - \int_{-\infty}^{+\infty} \Psi^* \frac{\partial^2\Psi}{\partial x^2} dx = \frac{1}{\hbar^2} \int_{-\infty}^{+\infty} \Psi^* \hat{p}_x^2 \Psi dx = \frac{\langle p_x^2 \rangle}{\hbar^2}. \quad (2.10)$$

As a result, Eq. (7) takes the following form:

$$J(\lambda) = \langle x^2 \rangle - \lambda + \lambda^2 \frac{\langle p_x^2 \rangle}{\hbar^2} \geq 0, \quad \text{i.e. } \lambda^2 + a\lambda + b \geq 0, \quad \text{with } a \equiv -\frac{\hbar^2}{\langle p_x^2 \rangle}, \quad b \equiv \frac{\hbar^2 \langle x^2 \rangle}{\langle p_x^2 \rangle}. \quad (2.11)$$

This inequality should be valid for any real λ , so that the corresponding quadratic equation, $\lambda^2 + a\lambda + b = 0$, can have either one (degenerate) real root – or no real roots at all. This is only possible if its determinant, $\text{Det} = a^2 - 4b$, is non-positive, leading to the following requirement:

$$\langle x^2 \rangle \langle p_x^2 \rangle \geq \frac{\hbar^2}{4}. \quad (2.12)$$

In particular, if $\langle x \rangle = 0$ and $\langle p_x \rangle = 0$,¹ then according to Eq. (1.33), Eq. (12) takes the form

¹ Eq. (13) may be proved even if $\langle x \rangle$ and $\langle p_x \rangle$ are not equal to zero, by making the following replacements: $x \rightarrow x - \langle x \rangle$ and $\partial/\partial x \rightarrow \partial/\partial x + i\langle p \rangle/\hbar$ in Eq. (7), and then repeating all the calculations – which in this case become somewhat bulky. In Chapter 4, equipped with the bra-ket formalism, we will derive a more general uncertainty relation, which includes the Heisenberg's relation (13) as a particular case, in a more efficient way.

Heisenberg's
uncertainty
relation

$$\langle \tilde{x}^2 \rangle \langle \tilde{p}_x^2 \rangle \geq \frac{\hbar^2}{4}, \quad (2.13)$$

which, according to the definition (1.34) of the r.m.s. uncertainties, is equivalent to Eq. (1.35).

Now let us notice that the Heisenberg's uncertainty relation looks very similar to the *commutation relation* between the corresponding operators:

$$[\hat{x}, \hat{p}_x] \Psi \equiv (\hat{x}\hat{p}_x - \hat{p}_x\hat{x})\Psi = x \left(-i\hbar \frac{\partial \Psi}{\partial x} \right) - \left(-i\hbar \frac{\partial}{\partial x} \right) (x\Psi) = i\hbar\Psi. \quad (2.14a)$$

Coordinate/
momentum
operators'
commutator

Since this relation is valid for any wavefunction $\Psi(x, t)$, it may be represented as an operator equality:

$$[\hat{x}, \hat{p}_x] = i\hbar \neq 0. \quad (2.14b)$$

In Sec. 4.5 we will see that the relation between Eqs. (13) and (14) is just a particular case of a general relation between the expectation values of non-commuting operators, and their commutators.

2.2. Free particle: Wave packets

Let us start our discussion of particular problems with the free 1D motion, i.e. with $U(x, t) = 0$. From Eq. (1.29), it is evident that in the 1D case, a similar “fundamental” (i.e. a particular but the most important) solution of the Schrödinger equation (1) is a sinusoidal (“monochromatic”) wave

$$\Psi_0(x, t) = \text{const} \times \exp\{i(k_0 x - \omega_0 t)\}. \quad (2.15)$$

According to Eqs. (1.32), it describes a particle with definite momentum² $p_0 = \hbar k_0$ and energy $E_0 = \hbar\omega_0 = \hbar^2 k_0^2 / 2m$. However, for this wavefunction, the product $\Psi^* \Psi$ does not depend on either x or t , so that the particle is completely delocalized, i.e. the probability to find it the same along all axis x , at all times.

In order to describe a space-localized state, let us form, at the initial moment of time ($t = 0$), a wave packet of the type shown in Fig. 1.6, by multiplying the sinusoidal waveform (15) by some smooth *envelope function* $A(x)$. As the most important particular example, consider the *Gaussian wave packet*

$$\Psi(x, 0) = A(x) e^{ik_0 x}, \quad \text{with } A(x) = \frac{1}{(2\pi)^{1/4} (\delta x)^{1/2}} \exp\left\{-\frac{x^2}{(2\delta x)^2}\right\}. \quad (2.16)$$

Gaussian
wave
packet:
 $t = 0$

(By the way, Fig. 1.6a shows exactly such a packet.) The pre-exponential factor in this envelope function has been selected in the way to have the initial probability density,

$$w(x, 0) \equiv \Psi^*(x, 0)\Psi(x, 0) = A^*(x)A(x) = \frac{1}{(2\pi)^{1/2} \delta x} \exp\left\{-\frac{x^2}{2(\delta x)^2}\right\}, \quad (2.17)$$

normalized as in Eq. (3), for any parameters δx and k_0 .³

² From this point on to the end of this chapter, I will drop the index x in the x -components of the vectors \mathbf{k} and \mathbf{p} .

³ This fact may be readily proven using the well-known integral of the Gaussian function (17), in infinite limits – see, e.g., MA Eq. (6.9b). It is also straightforward to use MA Eq. (6.9c) to prove that for the wave packet (16), the parameter δx is indeed the r.m.s. uncertainty (1.34) of the coordinate x , thus justifying its notation.

To explore the evolution of this wave packet in time, we could try to solve Eq. (1) with the initial condition (16) directly, but in the spirit of the discussion in Sec. 1.5, it is easier to proceed differently. Let us first represent the initial wavefunction (16) as a sum (1.67) of the eigenfunctions $\psi_k(x)$ of the corresponding stationary 1D Schrödinger equation (1.60), in our current case

$$-\frac{\hbar^2}{2m} \frac{d^2\psi_k}{dx^2} = E_k \psi_k, \quad \text{with } E_k \equiv \frac{\hbar^2 k^2}{2m}, \quad (2.18)$$

which are simply monochromatic waves,

$$\psi_k = a_k e^{ikx}. \quad (2.19)$$

Since (as was discussed in Sec. 1.7) at the unconstrained motion the spectrum of possible wave numbers k is continuous, the sum (1.67) should be replaced with an integral:⁴

$$\Psi(x,0) = \int a_k e^{ikx} dk. \quad (2.20)$$

Now let us notice that from the point of view of mathematics, Eq. (20) is just the usual Fourier transform from the variable k to the “conjugate” variable x , and we can use the well-known formula of the reciprocal Fourier transform to write

$$a_k = \frac{1}{2\pi} \int \Psi(x,0) e^{-ikx} dx = \frac{1}{2\pi} \frac{1}{(2\pi)^{1/4} (\delta x)^{1/2}} \int \exp\left\{-\frac{x^2}{(2\delta x)^2} - i\tilde{k}x\right\} dx, \quad \text{where } \tilde{k} \equiv k - k_0. \quad (2.21)$$

This *Gaussian integral* may be worked out by the following standard method, which will be used many times in this course. Let us complement the exponent to the full square of a linear combination of x and k , adding a compensating term independent of x :

$$-\frac{x^2}{(2\delta x)^2} - i\tilde{k}x \equiv -\frac{1}{(2\delta x)^2} [x + 2i(\delta x)^2 \tilde{k}]^2 - \tilde{k}^2 (\delta x)^2. \quad (2.22)$$

Since the integration in the right-hand side of Eq. (21) should be performed at constant \tilde{k} , in the infinite limits of x , its result would not change if we replace dx by $dx' \equiv d[x + 2i(\delta x)^2 \tilde{k}]$. As a result, we get:⁵

$$\begin{aligned} a_k &= \frac{1}{2\pi} \frac{1}{(2\pi)^{1/4} (\delta x)^{1/2}} \exp\left\{-\tilde{k}^2 (\delta x)^2\right\} \int \exp\left\{-\frac{x'^2}{(2\delta x)^2}\right\} dx' \\ &= \left(\frac{1}{2\pi}\right)^{1/2} \frac{1}{(2\pi)^{1/4} (\delta k)^{1/2}} \exp\left\{-\frac{\tilde{k}^2}{(2\delta k)^2}\right\}, \end{aligned} \quad (2.23)$$

so that a_k also has a Gaussian distribution, now along the k -axis, centered to the value k_0 (Fig. 1.6b), with the constant δk defined as

⁴ For the notation brevity, from this point on the infinite limit signs will be dropped in all 1D integrals.

⁵ The fact that the argument's shift is imaginary is not important. Indeed, since the function under the integral tends to zero at $\text{Re } x' \equiv \text{Re } x \rightarrow \pm\infty$, the difference between infinite integrals of this function along axes of x and x' is equal to its contour integral around the rectangular area $x \leq \text{Im} z \leq x'$. Since the function is also analytical, it obeys the Cauchy theorem MA Eq. (15.1), which says that this contour integral equals zero.

$$\delta k \equiv 1/2\delta x. \quad (2.24)$$

Thus we may represent the initial wave packet (16) as

$$\Psi(x,0) = \left(\frac{1}{2\pi}\right)^{1/2} \frac{1}{(2\pi)^{1/4}(\delta k)^{1/2}} \int \exp\left\{-\frac{(k-k_0)^2}{(2\delta k)^2}\right\} e^{ikx} dk. \quad (2.25)$$

From the comparison of this formula with Eq. (16), it is evident that the r.m.s. uncertainty of the wave number k in this packet is indeed equal to δk defined by Eq. (24), thus justifying the notation. The comparison of the last relation with Eq. (1.35) shows that the Gaussian packet represents the ultimate case in which the product $\delta x \delta p = \delta x (\hbar \delta k)$ has the lowest possible value ($\hbar/2$); for any other envelope's shape, the uncertainty product may only be larger. We could of course get the same result for δk from Eq. (16) using the definitions (1.23), (1.33), and (1.34); the real advantage of Eq. (25) is that it can be readily generalized to $t > 0$. Indeed, we already know that the time evolution of the wavefunction is always given by Eq. (1.69), for our current case⁶

Gaussian
wave
packet:
arbitrary
time

$$\Psi(x,t) = \left(\frac{1}{2\pi}\right)^{1/2} \frac{1}{(2\pi)^{1/4}(\delta k)^{1/2}} \int \exp\left\{-\frac{(k-k_0)^2}{(2\delta k)^2}\right\} e^{ikx} \exp\left\{-i\frac{\hbar k^2}{2m}t\right\} dk. \quad (2.26)$$

Fig. 1 shows several snapshots of the real part of the wavefunction (26), for a particular case $\delta k = 0.1 k_0$.

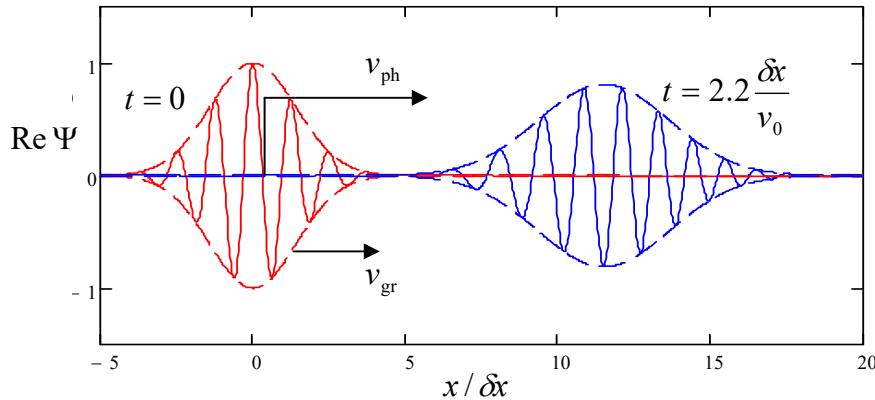

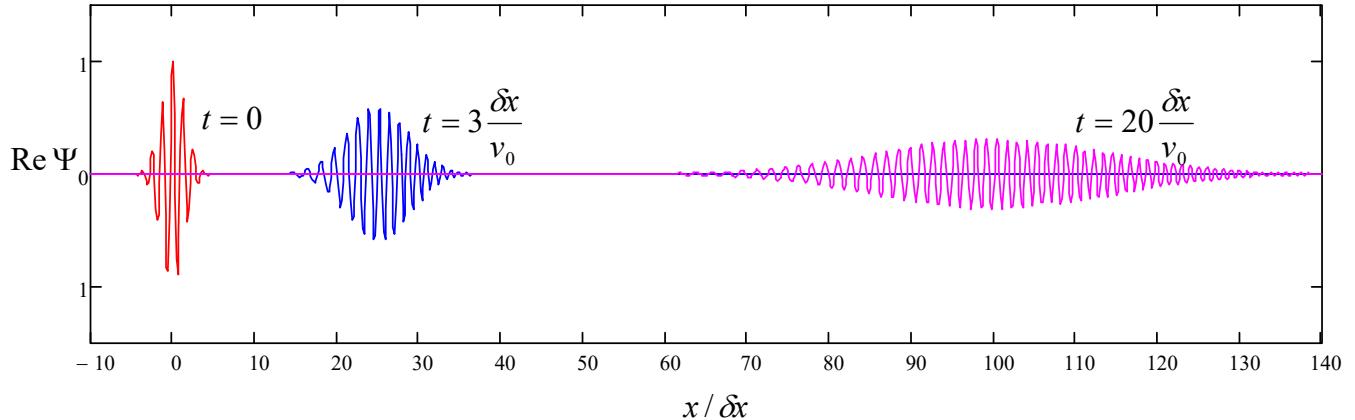

Fig. 2.1. Typical time evolution of a 1D wave packet on (a) smaller and (b) larger time scales. The dashed lines show the packet envelopes, i.e. $\pm |\Psi|$.

⁶ Note that Eq. (26) differs from Eq. (16) only by an exponent of a purely imaginary number, and hence this wavefunction is also properly normalized to 1 – see Eq. (3). Hence the wave packet introduction offers a natural solution to the problem of traveling de Broglie wave's normalization, which was mentioned in Sec. 1.2.

The plots clearly show the following effects:

- (i) the wave packet as a whole (as characterized by its envelope) moves along the x -axis with a certain *group velocity* v_{gr} ,
- (ii) the “carrier” quasi-sinusoidal wave inside the packet moves with a different, *phase velocity* v_{ph} , which may be defined as the velocity of the spatial points where the wave’s phase $\varphi(x, t) \equiv \arg \Psi$ takes a certain fixed value (say, $\varphi = \pi/2$, where $\text{Re} \Psi$ vanishes), and
- (iii) the wave packet’s spatial width gradually increases with time – the packet *spreads*.

All these effects are common for waves of any physical nature.⁷ Indeed, let us consider a 1D wave packet of the type (26), but more general:

$$\Psi(x, t) = \int a_k e^{i(kx - \omega t)} dk, \quad (2.27)$$

Arbitrary
1D wave
packet

propagating in a medium with an arbitrary (but smooth!) dispersion relation $\omega(k)$, and assume that the wave number distribution a_k is narrow: $\delta k \ll \langle k \rangle \equiv k_0$ – see Fig. 1.6b. Then we may expand the function $\omega(k)$ into the Taylor series near the central wave number k_0 , and keep only three of its leading terms:

$$\omega(k) \approx \omega_0 + \frac{d\omega}{dk} \tilde{k} + \frac{1}{2} \frac{d^2\omega}{dk^2} \tilde{k}^2, \quad \text{where } \tilde{k} \equiv k - k_0, \quad \omega_0 \equiv \omega(k_0), \quad (2.28)$$

where both derivatives have to be evaluated at the point $k = k_0$. In this approximation,⁸ the expression in the parentheses on the right-hand side of Eq. (27) may be rewritten as

$$\begin{aligned} kx - \omega(k)t &\approx k_0 x + \tilde{k}x - \left(\omega_0 + \frac{d\omega}{dk} \tilde{k} + \frac{1}{2} \frac{d^2\omega}{dk^2} \tilde{k}^2 \right) t \\ &\equiv (k_0 x - \omega_0 t) + \tilde{k} \left(x - \frac{d\omega}{dk} t \right) - \frac{1}{2} \frac{d^2\omega}{dk^2} \tilde{k}^2 t, \end{aligned} \quad (2.29)$$

so that Eq. (27) becomes

$$\Psi(x, t) \approx e^{i(k_0 x - \omega_0 t)} \int a_k \exp \left\{ i \left[\tilde{k} \left(x - \frac{d\omega}{dk} t \right) - \frac{1}{2} \frac{d^2\omega}{dk^2} \tilde{k}^2 t \right] \right\} d\tilde{k}. \quad (2.30)$$

First, let neglect the last term in square brackets (which is much smaller than the first term if the dispersion relation is smooth enough and/or the time interval t is sufficiently small), and compare the result with the initial form of the wave packet (27):

$$\Psi(x, 0) = \int a_k e^{ikx} dk = A(x) e^{ik_0 x}, \quad \text{with } A(x) \equiv \int a_k e^{i\tilde{k}x} d\tilde{k}. \quad (2.31)$$

The comparison shows that in this approximation, Eq. (30) is reduced to

$$\Psi(x, t) = A(x - v_{\text{gr}} t) e^{ik_0(x - v_{\text{ph}} t)}, \quad (2.32)$$

where v_{gr} and v_{ph} are two constants with the dimension of velocity:

⁷ See, e.g., brief discussions in CM Sec. 6.3 and EM Sec. 7.2.

⁸ By the way, in the particular case of de Broglie waves described by the dispersion relation (1.30), Eq. (28) is exact, because $\omega = E/\hbar$ is a quadratic function of $k = p/\hbar$, and all higher derivatives of ω over k vanish for any k_0 .

Group
and phase
velocities

$$v_{\text{gr}} \equiv \frac{d\omega}{dk} \Big|_{k=k_0}, \quad v_{\text{ph}} \equiv \frac{\omega}{k} \Big|_{k=k_0}. \quad (2.33a)$$

Clearly, Eq. (32) describes the effects (i) and (ii) listed above. For the particular case of the de Broglie waves, whose dispersion law is given by Eq. (1.30),

$$v_{\text{gr}} \equiv \frac{d\omega}{dk} \Big|_{k=k_0} = \frac{\hbar k_0}{m} \equiv v_0, \quad v_{\text{ph}} \equiv \frac{\omega}{k} \Big|_{k=k_0} = \frac{\hbar k_0}{2m} = \frac{v_{\text{gr}}}{2}. \quad (2.33b)$$

We see that (very fortunately :-) the velocity of the wave packet's envelope is equal to v_0 – the classical velocity of the same particle.

Next, the last term in the square brackets of Eq. (30) describes the effect (iii), the wave packet's spread. It may be readily evaluated if the packet (27) is initially Gaussian, as in our example (25):

$$a_k = \text{const} \times \exp \left\{ -\frac{\tilde{k}^2}{(2\delta k)^2} \right\}. \quad (2.34)$$

In this case the integral (30) is Gaussian, and may be worked out exactly as the integral (21), i.e. by representing the merged exponents under the integral as a full square of a linear combination of x and k :

$$\begin{aligned} & -\frac{\tilde{k}^2}{(2\delta k)^2} + i\tilde{k}(x - v_{\text{gr}}t) - \frac{i}{2} \frac{d^2\omega}{dk^2} \tilde{k}^2 t \\ & \equiv -\Delta(t) \left(\tilde{k} + i \frac{x - v_{\text{gr}}t}{2\Delta(t)} \right)^2 - \frac{(x - v_{\text{gr}}t)^2}{4\Delta(t)} + ik_0 x - \frac{i}{2} \frac{d^2\omega}{dk^2} k_0^2 t, \end{aligned} \quad (2.35)$$

where I have introduced the following complex function of time:

$$\Delta(t) \equiv \frac{1}{4(\delta k)^2} + \frac{i}{2} \frac{d^2\omega}{dk^2} t = (\delta x)^2 + \frac{i}{2} \frac{d^2\omega}{dk^2} t, \quad (2.36)$$

and used Eq. (24). Now integrating over \tilde{k} , we get

$$\Psi(x, t) \propto \exp \left\{ -\frac{(x - v_{\text{gr}}t)^2}{4\Delta(t)} + i \left(k_0 x - \frac{1}{2} \frac{d^2\omega}{dk^2} k_0^2 t \right) \right\}. \quad (2.37)$$

The imaginary part of the ratio $1/\Delta(t)$ in this exponent gives just an additional contribution to the wave's phase and does not affect the resulting probability distribution

$$w(x, t) = \Psi^* \Psi \propto \exp \left\{ -\frac{(x - v_{\text{gr}}t)^2}{2} \operatorname{Re} \frac{1}{\Delta(t)} \right\}. \quad (2.38)$$

This is again a Gaussian distribution over axis x , centered to point $\langle x \rangle = v_{\text{gr}}t$, with the r.m.s. width

$$(\delta x')^2 \equiv \left\{ \operatorname{Re} \left[\frac{1}{\Delta(t)} \right] \right\}^{-1} = (\delta x)^2 + \left(\frac{1}{2} \frac{d^2\omega}{dk^2} t \right)^2 \frac{1}{(\delta x)^2}. \quad (2.39a)$$

In the particular case of de Broglie waves, $d^2\omega/dk^2 = \hbar/m$, so that

$$(\delta x')^2 = (\delta x)^2 + \left(\frac{\hbar t}{2m} \right)^2 \frac{1}{(\delta x)^2}. \quad (2.39b)$$

Wave packet's spread

The physics of the packet spreading is very simple: if $d^2\omega/dk^2 \neq 0$, the group velocity $d\omega/dk$ of each small group dk of the monochromatic components of the wave is different, resulting in the gradual (eventually, linear) accumulation of the differences of the distances traveled by the groups. The most curious feature of Eq. (39) is that the packet width at $t > 0$ depends on its initial width $\delta x'(0) = \delta x$ in a non-monotonic way, tending to infinity at both $\delta x \rightarrow 0$ and $\delta x \rightarrow \infty$. Because of that, for a given time interval t , there is an optimal value of δx that minimizes $\delta x'$:

$$(\delta x')_{\min} = \sqrt{2} (\delta x)_{\text{opt}} = \left(\frac{\hbar t}{m} \right)^{1/2}. \quad (2.40)$$

This expression may be used for estimates of the spreading effect. Due to the smallness of the Planck constant \hbar on the human scale of things, for macroscopic bodies this effect is extremely small even for very long time intervals; however, for light particles it may be very noticeable: for an electron ($m = m_e \approx 10^{-30}$ kg), and $t = 1$ s, Eq. (40) yields $(\delta x')_{\min} \sim 1$ cm.

Note also that for any $t \neq 0$, the wave packet retains its Gaussian envelope, but the ultimate relation (24) is *not* satisfied, $\delta x' \delta p > \hbar/2$ – due to a gradually accumulated phase shift between the component monochromatic waves. The last remark on this topic: in quantum mechanics, the wave packet spreading is *not* a ubiquitous effect! For example, in Chapter 5 we will see that in a quantum oscillator, the spatial width of a Gaussian packet (for that system, called the *Glauber state* of the oscillator) does not grow monotonically but rather either stays constant or oscillates in time.

Now let us briefly discuss the case when the initial wave packet is not Gaussian but is described by an arbitrary initial wavefunction. To make the forthcoming result more aesthetically pleasing, it is beneficial to generalize our calculations to an arbitrary initial time t_0 ; it is evident that if U does not depend on time explicitly, it is sufficient to replace t with $(t - t_0)$ in all above formulas. With this replacement, Eq. (27) becomes

$$\Psi(x, t) = \int a_k e^{i[kx - \omega(t - t_0)]} dk, \quad (2.41)$$

and the reciprocal transform (21) reads

$$a_k = \frac{1}{2\pi} \int \Psi(x, t_0) e^{-ikx} dx. \quad (2.42)$$

If we want to express these two formulas with one relation, i.e. plug Eq. (42) into Eq. (41), we should give the integration variable x some other name, e.g., x_0 . (Such notation is appropriate because this variable describes the coordinate argument in the initial wave packet.) The result is

$$\Psi(x, t) = \frac{1}{2\pi} \int dk \int dx_0 \Psi(x_0, t_0) e^{i[k(x-x_0) - \omega(t-t_0)]}. \quad (2.43)$$

Changing the order of integration, this expression may be rewritten in the following general form:

$$\Psi(x, t) = \int G(x, t; x_0, t_0) \Psi(x_0, t_0) dx_0, \quad (2.44)$$

1D propagator: definition

where the function G , usually called *kernel* in mathematics, in quantum mechanics is called the *propagator*.⁹ Its physical sense may be understood by considering the following special initial condition:¹⁰

$$\Psi(x_0, t_0) = \delta(x_0 - x'), \quad (2.45)$$

where x' is a certain point within the domain of particle's motion. In this particular case, Eq. (44) gives

$$\Psi(x, t) = G(x, t; x', t_0). \quad (2.46)$$

Hence, the propagator, considered as a function of its arguments x and t only, is just the wavefunction of the particle, at the δ -functional initial conditions (45). Thus just as Eq. (41) may be understood as a mathematical expression of the linear superposition principle in the momentum (i.e., reciprocal) space domain, Eq. (44) is an expression of this principle in the direct space domain: the system's "response" $\Psi(x, t)$ to an arbitrary initial condition $\Psi(x_0, t_0)$ is just a sum of its responses to its elementary spatial "slices" of this initial function, with the propagator $G(x, t; x_0, t_0)$ representing the weight of each slice in the final sum.

According to Eqs. (43) and (44), in the particular case of a free particle the propagator is equal to

$$G(x, t; x_0, t_0) = \frac{1}{2\pi} \int e^{i[k(x-x_0)-\omega(t-t_0)]} dk, \quad (2.47)$$

Calculating this integral, one should remember that here ω is not a constant but a function of k , given by the dispersion relation for the partial waves. In particular, for the de Broglie waves, with $\hbar\omega = \hbar^2 k^2 / 2m$,

$$G(x, t; x_0, t_0) \equiv \frac{1}{2\pi} \int \exp\left\{i\left[k(x-x_0) - \frac{\hbar k^2}{2m}(t-t_0)\right]\right\} dk. \quad (2.48)$$

This is a Gaussian integral again, and may be readily calculated just it was done (twice) above, by completing the exponent to the full square. The result is

$$G(x, t; x_0, t_0) = \left(\frac{m}{2\pi i\hbar(t-t_0)} \right)^{1/2} \exp\left\{-\frac{m(x-x_0)^2}{2i\hbar(t-t_0)}\right\}. \quad (2.49)$$

Free
particle's
propagator

Please note the following features of this complex function (plotted in Fig. 2):

(i) It depends only on the differences $(x - x_0)$ and $(t - t_0)$. This is natural because the free-particle propagation problem is *translation-invariant* both in space and time.

(ii) The function's shape does not depend on its arguments – they just rescale the same function: its snapshot (Fig. 2), if plotted as a function of un-normalized x , just becomes broader and lower with time. It is curious that the spatial broadening scales as $(t - t_0)^{1/2}$ – just as at the classical diffusion, as a result of a deep mathematical analogy between quantum mechanics and classical statistics – to be discussed further in Chapter 7.

⁹ Its standard notation by letter G stems from the fact that the propagator is essentially the spatial-temporal *Green's function*, defined very similarly to Green's functions of other ordinary and partial differential equations describing various physics systems – see, e.g., CM Sec. 5.1 and/or EM Sec. 2.7 and 7.3.

¹⁰ Note that such initial condition is mathematically *not* equivalent to a δ -functional initial probability density (3).

(iii) In accordance with the uncertainty relation, the ultimately compressed wave packet (45) has an infinite width of momentum distribution, and the quasi-sinusoidal tails of the free-particle propagator, clearly visible in Fig. 2, are the results of the free propagation of the fastest (highest-momentum) components of that distribution, in both directions from the packet center.

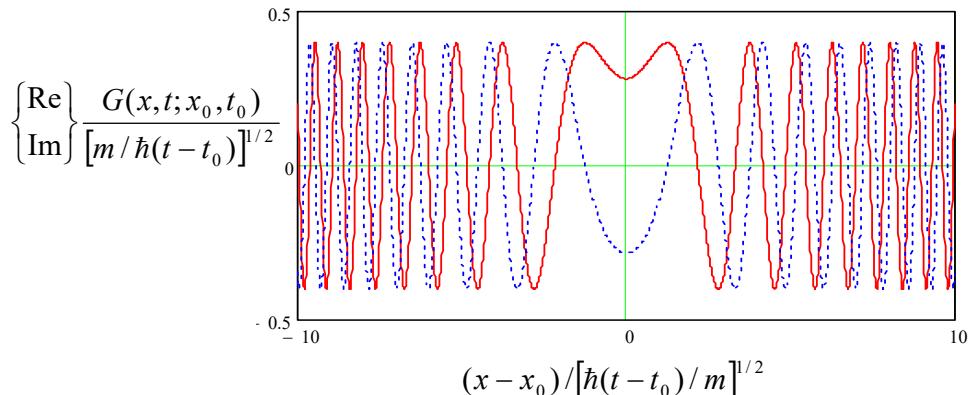

Fig. 2.2. The real (solid line) and imaginary (dotted line) parts of the 1D free particle's propagator (49).

In the following sections, I will mostly focus on monochromatic wavefunctions (that, for unconfined motion, may be interpreted as wave packets of a very large spatial width δx), and only rarely discuss wave packets. My best excuse is the linear superposition principle, i.e. our conceptual ability to restore the general solution from that of monochromatic waves of all possible energies. However, the reader should not forget that, as the above discussion has illustrated, mathematically such restoration is not always trivial.

2.3. Particle reflection and tunneling

Now, let us proceed to the cases when a 1D particle moves in various potential profiles $U(x)$ that are constant in time. Conceptually, the simplest of such profiles is a potential step – see Fig. 3.

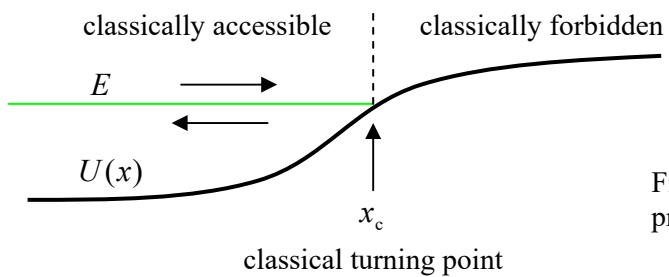

Fig. 2.3. Classical 1D motion in a potential profile $U(x)$.

As I am sure the reader knows, in classical mechanics the particle's kinetic energy $p^2/2m$ cannot be negative, so if the particle is incident on such a step (in Fig. 3, from the left), it can only travel through the *classically accessible* region, where its (conserved) full energy,

$$E = \frac{p^2}{2m} + U(x), \quad (2.50)$$

is larger than the local value $U(x)$. Let the initial velocity $v = p/m$ be positive, i.e. directed toward the step. Before it has reached the *classical turning point* x_c , defined by equality

$$U(x_c) = E, \quad (2.51)$$

the particle's kinetic energy $p^2/2m$ is positive, so that it continues to move in the initial direction. On the other hand, a classical particle cannot penetrate that *classically forbidden region* $x > x_c$, because there its kinetic energy would be negative. Hence when the particle reaches the point $x = x_c$, its velocity has to change its sign, i.e. the particle is reflected back from the classical turning point.

In order to see what does the wave mechanics say about this situation, let us start from the simplest, sharp potential step shown with the bold black line in Fig. 4:

$$U(x) = U_0 \theta(x) \equiv \begin{cases} 0, & \text{at } x < 0, \\ U_0, & \text{at } 0 < x. \end{cases} \quad (2.52)$$

For this choice, and any energy within the interval $0 < E < U_0$, the classical turning point is $x_c = 0$.

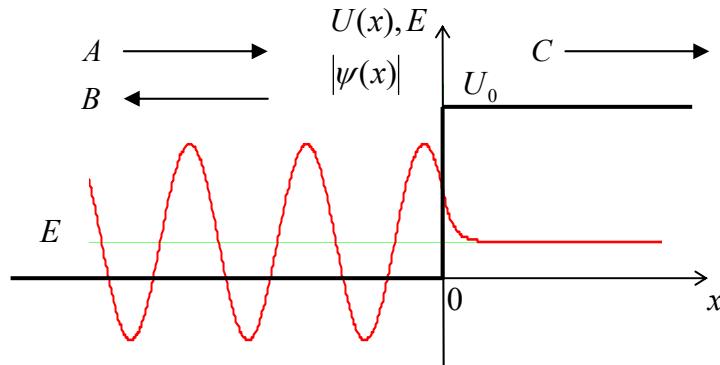

Fig. 2.4. The reflection of a monochromatic wave from a potential step $U_0 > E$. (This particular wavefunction's shape is for $U_0 = 5E$.) The wavefunction is plotted with the same schematic vertical offset by E as those in Fig. 1.8.

Let us represent an incident particle with a wave packet so long that the spread $\delta k \sim 1/\delta x$ of its wave-number spectrum is sufficiently small to make the energy uncertainty $\delta E = \hbar\delta\omega = \hbar(d\omega/dk)\delta k$ negligible in comparison with its average value $E < U_0$, as well as with $(U_0 - E)$. In this case, E may be considered as a given constant, the time dependence of the wavefunction is given by Eq. (1.62), and we can calculate its spatial factor $\psi(x)$ from the 1D version of the stationary Schrödinger equation (1.65):¹¹

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + U(x)\psi = E\psi. \quad (2.53)$$

At $x < 0$, i.e. at $U = 0$, the equation is reduced to the Helmholtz equation (1.78), and may be satisfied with either of two traveling waves, proportional to $\exp\{+ikx\}$ and $\exp\{-ikx\}$ correspondingly, with k satisfying the dispersion equation (1.30):

$$k^2 \equiv \frac{2mE}{\hbar^2}. \quad (2.54)$$

Thus the general solution of Eq. (53) in this region may be represented as

$$\psi_-(x) = Ae^{+ikx} + Be^{-ikx}. \quad (2.55)$$

Incident
and
reflected
waves

¹¹ Note that this is *not* the eigenproblem like the one we have solved in Sec. 1.4 for a potential well. Indeed, now the energy E is considered given – e.g., by the initial conditions that launch a long wave packet upon the potential step – in Fig. 4, from the left.

The second term on the right-hand side of Eq. (55) evidently describes a (formally, infinitely long) wave packet traveling to the left, arising because of the particle's reflection from the potential step. If $B = -A$, this solution is reduced to Eq. (1.84) for the potential well with infinitely high walls, but for our current case of a finite step height U_0 , the relation between the coefficients B and A may be different.

To show this, let us solve Eq. (53) for $x > 0$, where $U = U_0 > E$. In this region the equation may be rewritten as

$$\frac{d^2\psi_+}{dx^2} = \kappa^2 \psi_+, \quad (2.56)$$

where κ is a real and positive constant defined by a formula similar in structure to Eq. (54):

$$\kappa^2 \equiv \frac{2m(U_0 - E)}{\hbar^2} > 0. \quad (2.57)$$

The general solution of Eq. (56) is the sum of $\exp\{+\kappa x\}$ and $\exp\{-\kappa x\}$, with arbitrary coefficients. However, in our particular case the wavefunction should be finite at $x \rightarrow +\infty$, so only the latter exponent is acceptable:

$$\psi_+(x) = Ce^{-\kappa x}. \quad (2.58)$$

Decay in classically forbidden region

Such penetration of the wavefunction to the classically forbidden region, and hence a non-zero probability to find the particle there, is one of the most fascinating predictions of quantum mechanics, and has been repeatedly observed in experiment – e.g., via tunneling experiments – see the next section.¹² From Eq. (58), it is evident that the constant κ , defined by Eqs. (57), may be interpreted as the reciprocal penetration depth. Even for the lightest particles, this depth is usually very small. Indeed, for $E \ll U_0$ that relation yields

$$\delta \equiv \frac{1}{\kappa} \Big|_{E \rightarrow 0} = \frac{\hbar}{(2mU_0)^{1/2}}. \quad (2.59)$$

For example, let us consider a conduction electron in a typical metal, which runs, at the metal's surface, into a sharp potential step whose height is equal to metal's workfunction $U_0 \approx 5$ eV – see the discussion of the photoelectric effect in Sec. 1.1. In this case, according to Eq. (59), δ is close to 0.1 nm, i.e. is close to a typical size of an atom. For heavier elementary particles (e.g., protons) the penetration depth is correspondingly lower, and for macroscopic bodies, it is hardly measurable.

Returning to Eqs. (55) and (58), we still should relate the coefficients B and C to the amplitude A of the incident wave, using the boundary conditions at $x = 0$. Since E is a finite constant, and $U(x)$ is a finite function, Eq. (53) says that $d^2\psi/dx^2$ should be finite as well. This means that the first derivative should be continuous:

$$\lim_{\varepsilon \rightarrow 0} \left(\frac{d\psi}{dx} \Big|_{x=+\varepsilon} - \frac{d\psi}{dx} \Big|_{x=-\varepsilon} \right) = \lim_{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d^2\psi}{dx^2} dx = \frac{2m}{\hbar^2} \lim_{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} [U(x) - E] \psi dx = 0. \quad (2.60)$$

Repeating such calculation for the wavefunction $\psi(x)$ itself, we see that it also should be continuous at all points, including the border point $x = 0$, so that the boundary conditions in our problem are

¹² Note that this effect is pertinent to waves of any type, including mechanical waves (see, e.g., CM Secs. 6.4 and 7.7) and electromagnetic waves (see, e.g., EM Secs. 7.3-7.7).

$$\psi_-(0) = \psi_+(0), \quad \frac{d\psi_-}{dx}(0) = \frac{d\psi_+}{dx}(0). \quad (2.61)$$

Plugging Eqs. (55) and (58) into Eqs. (61), we get a system of two linear equations

$$A + B = C, \quad ikA - ikB = -\kappa C, \quad (2.62)$$

whose (easy :-) solution allows us to express B and C via A :

$$B = A \frac{k - i\kappa}{k + i\kappa}, \quad C = A \frac{2k}{k + i\kappa}. \quad (2.63)$$

We immediately see that the numerator and denominator in the first of these fractions have equal moduli, so that $|B| = |A|$. This means that, as we could expect, a particle with energy $E < U_0$ is totally reflected from the step – just as in classical mechanics. As a result, at $x < 0$ our solution (55) may be represented as a standing wave

$$\psi_- = 2iAe^{i\theta} \sin(kx - \theta), \quad \text{with } \theta \equiv \tan^{-1} \frac{k}{\kappa}. \quad (2.64)$$

Note that the shift $\Delta x \equiv \theta/k = (\tan^{-1} k/\kappa)/k$ of the standing wave to the right, due to the partial penetration of the wavefunction under the potential step, is commensurate with, but generally not equal to the penetration depth $\delta \equiv 1/\kappa$. The red line in Fig. 4 shows the exact behavior of the wavefunction, for a particular case $E = U_0/5$, at which $k/\kappa \equiv [E/(U_0-E)]^{1/2} = 1/2$.

According to Eq. (59), as the particle's energy E is increased to approach U_0 , the penetration depth $1/\kappa$ diverges. This raises an important issue: what happens at $E > U_0$, i.e. if there is no classically forbidden region in the problem? In classical mechanics, the incident particle would continue to move to the right, though with a reduced velocity, corresponding to the new kinetic energy $E - U_0$, so there would be no reflection. In quantum mechanics, however, the situation is different. To analyze it, it is not necessary to re-solve the whole problem; it is sufficient to note that all our calculations, and hence Eqs. (63) are still valid if we take¹³

$$\kappa = -ik', \quad \text{with} \quad k'^2 \equiv \frac{2m(E - U_0)}{\hbar^2} > 0. \quad (2.65)$$

With this replacement, Eq. (63) becomes¹⁴

$$B = A \frac{k - k'}{k + k'}, \quad C = A \frac{2k}{k + k'}. \quad (2.66)$$

The most important result of this change is that now the particle's reflection is *not* total: $|B| < |A|$. To evaluate this effect quantitatively, it is fairer to use not the B/A or C/A ratios, but rather that of the probability currents (5) carried by the de Broglie waves traveling to the right, with amplitudes C and A , in the corresponding regions (respectively, for $x > 0$ and $x < 0$):

¹³ Our earlier discarding of the particular solution $\exp\{\kappa x\}$, now becoming $\exp\{-ik'x\}$, is still valid, but now on different grounds: this term would describe a wave packet incident on the potential step from the right, and this is not the problem under our current consideration.

¹⁴ These formulas are completely similar to those describing the partial reflection of classical waves from a sharp interface between two uniform media, at normal incidence (see, e.g., CM Sec. 6.4 and EM Sec. 7.4), with the effective impedance Z of de Broglie waves being proportional to their wave number k .

$$\mathcal{T} \equiv \frac{I_C}{I_A} = \frac{k' |C|^2}{k |A|^2} = \frac{4kk'}{(k+k')^2} \equiv \frac{4[E(E-U_0)]^{1/2}}{[E^{1/2} + (E-U_0)^{1/2}]^2}. \quad (2.67)$$

Potential
step's
transparency

(The parameter \mathcal{T} so defined is called the *transparency* of the system, in our current case of the potential step of height U_0 , at particle's energy E .) The result given by Eq. (67) is plotted in Fig. 5a as a function of the U_0/E ratio. Note its most important features:

- (i) At $U_0 = 0$, the transparency is full, $\mathcal{T} = 1$ – naturally, because there is no step at all.
- (ii) At $U_0 \rightarrow E$, the transparency drops to zero, giving a proper connection to the case $E < U_0$.
- (iii) Nothing in our solution's procedure prevents us from using Eq. (67) even for $U_0 < 0$, i.e. for the *step-down* (or “cliff”) potential profile – see Fig. 5b. Very counter-intuitively, the particle is (partly) reflected even from such a cliff, and the transmission diminishes (though rather slowly) at $U_0 \rightarrow -\infty$.

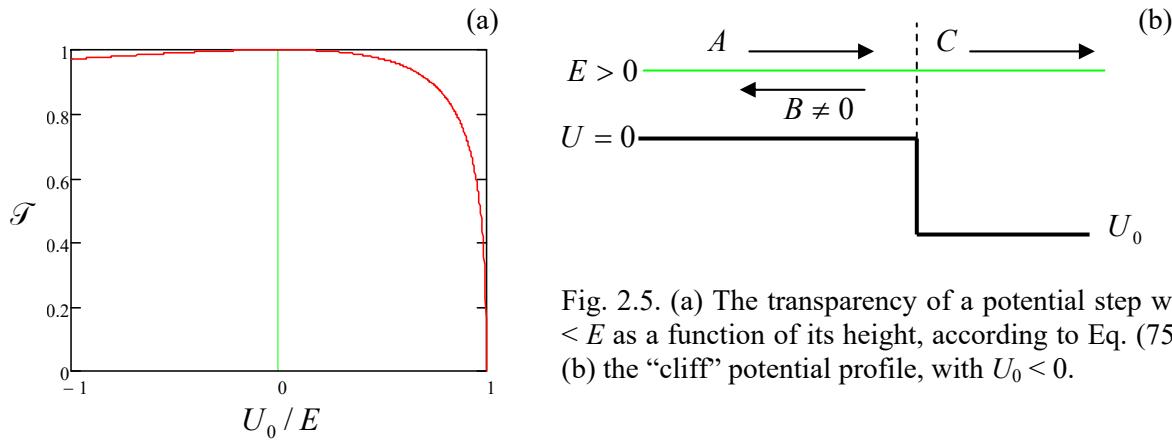

Fig. 2.5. (a) The transparency of a potential step with $U_0 < E$ as a function of its height, according to Eq. (75), and (b) the “cliff” potential profile, with $U_0 < 0$.

The most important conceptual conclusion of this analysis is that the quantum particle is *partly reflected* from a potential step with $U_0 < E$, in the sense that there is a non-zero probability $\mathcal{T} < 1$ to find it passed over the step, while there is also some probability, $(1 - \mathcal{T}) > 0$, to have it reflected.

The last property is exhibited, but for *any* relation between E and U_0 , by another simple potential profile $U(x)$, the famous *potential* (or “tunnel”) *barrier*. Fig. 6 shows its simple, “rectangular” version:

$$U(x) = \begin{cases} 0, & \text{for } x < -d/2, \\ U_0, & \text{for } -d/2 < x < +d/2, \\ 0, & \text{for } +d/2 < x. \end{cases} \quad (2.68)$$

To analyze this problem, it is sufficient to look for the solution to the Schrödinger equation in the form (55) at $x \leq -d/2$. At $x > +d/2$, i.e., behind the barrier, we may use the arguments presented above (no wave source on the right!) to keep just one traveling wave, now with the same wave number:

$$\psi_+(x) = Fe^{ikx}. \quad (2.69)$$

However, under the barrier, i.e. at $-d/2 \leq x \leq +d/2$, we should generally keep both exponential terms,

$$\psi_b(x) = Ce^{-kx} + De^{+kx}, \quad (2.70)$$

because our previous argument, used in the potential step problem's solution, is no longer valid. (Here k and κ are still defined, respectively, by Eqs. (54) and (57).) In order to express the coefficients B , C , D , and F via the amplitude A of the incident wave, we need to plug these solutions into the boundary conditions similar to Eqs. (61), but now at two boundary points, $x = \pm d/2$.

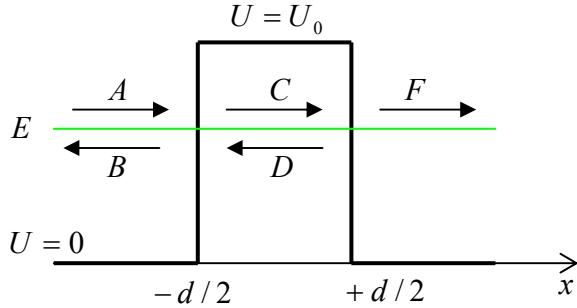

Fig. 2.6. A rectangular potential barrier, and the de Broglie waves taken into account in its analysis.

Solving the resulting system of 4 linear equations, we get four ratios B/A , C/A , etc.; in particular,

$$\frac{F}{A} = \left[\cosh \kappa d + \frac{i}{2} \left(\frac{\kappa}{k} - \frac{k}{\kappa} \right) \sinh \kappa d \right]^{-1} e^{-ikd}, \quad (2.71a)$$

and hence the barrier's transparency

$$\mathcal{T} \equiv \left| \frac{F}{A} \right|^2 = \left[\cosh^2 \kappa d + \left(\frac{\kappa^2 - k^2}{2\kappa k} \right)^2 \sinh^2 \kappa d \right]^{-1}. \quad (2.71b)$$

So, quantum mechanics indeed allows particles with energies $E < U_0$ to pass “through” the potential barrier – see Fig. 6 again. This is the famous effect of *quantum-mechanical tunneling*. Fig. 7a shows the barrier transparency as a function of the particle energy E , for several characteristic values of its thickness d , or rather of the ratio d/δ , with δ defined by Eq. (59).

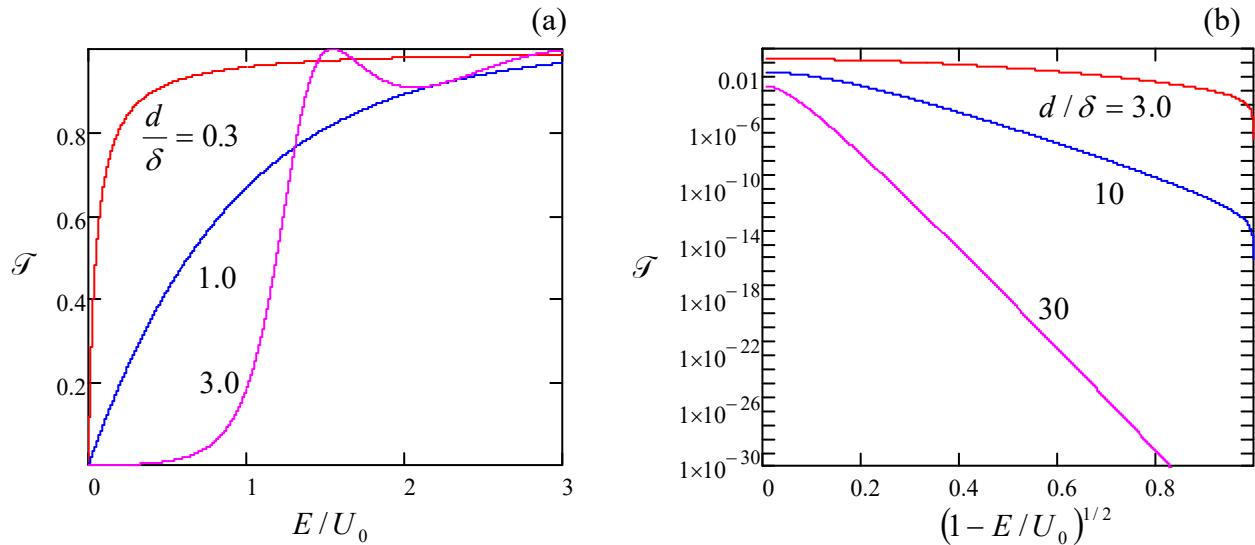

Fig. 2.7. The transparency of a rectangular potential barrier as a function of the particle's energy E .

The plots show that generally, the transparency grows gradually with the particle's energy. This growth is natural because the penetration constant κ decreases with the growth of E , i.e., the wavefunction penetrates more and more into the barrier, so that more and more of it is “picked up” at the second interface ($x = +d/2$) and transferred into the wave $F \exp\{ikx\}$ propagating behind the barrier.

Now let us consider the important limit of a very thin and high rectangular barrier, $d \ll \delta, E \ll U_0$, giving $k \ll \kappa \ll 1/d$. In this limit, Eq. (71) yields

$$\mathcal{T} \equiv \left| \frac{F}{A} \right|^2 \rightarrow \frac{1}{|1+i\alpha|^2} = \frac{1}{1+\alpha^2}, \quad \text{where } \alpha \equiv \frac{1}{2} \left(\frac{\kappa^2 - k^2}{\kappa k} \right) \kappa d \approx \frac{1}{2} \frac{\kappa^2 d}{k} \approx \frac{m}{\hbar^2 k} U_0 d, \quad (2.72)$$

The last product, $U_0 d$, is just the “energy area” (or the “weight”)

$$w \equiv \int_{U(x)>E} U(x) dx \quad (2.73)$$

of the barrier. This fact implies that the very simple result (72) may be correct for a barrier of any shape, provided that it is sufficiently thin and high.

To confirm this guess, let us consider the tunneling problem for a very thin barrier with $\kappa d, kd \ll 1$, approximating it with the Dirac's δ -function (Fig. 8):

$$U(x) = w\delta(x), \quad (2.74)$$

so that the parameter w satisfies Eq. (73).

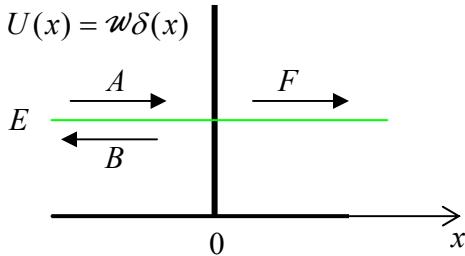

Fig. 2.8. A delta-functional potential barrier.

The solutions of the tunneling problem at all points but $x = 0$ still may be taken in the form of Eqs. (55) and (69), so we only need to analyze the boundary conditions at that point. However, due to the special character of the δ -function, we should be careful here. Indeed, instead of Eq. (60) we now get

$$\begin{aligned} \lim_{\varepsilon \rightarrow 0} \left(\frac{d\psi}{dx} \Big|_{x=+\varepsilon} - \frac{d\psi}{dx} \Big|_{x=-\varepsilon} \right) &= \lim_{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d^2\psi}{dx^2} dx = \lim_{\varepsilon \rightarrow 0} \frac{2m}{\hbar^2} \int_{-\varepsilon}^{+\varepsilon} [U(x) - E] \psi dx \\ &= \frac{2m}{\hbar^2} w \psi(0). \end{aligned} \quad (2.75)$$

According to this relation, at a finite w , the derivatives $d\psi/dx$ are also finite, so that the wavefunction itself is still continuous:

$$\lim_{\varepsilon \rightarrow 0} (\psi \Big|_{x=+\varepsilon} - \psi \Big|_{x=-\varepsilon}) = \lim_{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d\psi}{dx} dx = 0. \quad (2.76)$$

Using these two boundary conditions, we readily get the following system of two linear equations,

$$A + B = F, \quad ikF - (ikA - ikB) = \frac{2m\omega}{\hbar^2} F, \quad (2.77)$$

whose solution yields

$$\frac{B}{A} = \frac{-i\alpha}{1+i\alpha}, \quad \frac{F}{A} = \frac{1}{1+i\alpha}, \quad \text{where } \alpha \equiv \frac{m\omega}{\hbar^2 k}. \quad (2.78)$$

(Taking Eq. (73) into account, this definition of α coincides with that in Eq. (72).) For the barrier transparency $\mathcal{T} \equiv |F/A|^2$, this result again gives the first of Eqs. (72), which is therefore general for such thin barriers. That formula may be recast to give the following simple expression (valid only for $E \ll U_{\max}$):

Thin barrier:
transparency

$$\boxed{\mathcal{T} = \frac{1}{1+\alpha^2} \equiv \frac{E}{E+E_0}, \quad \text{where } E_0 \equiv \frac{m\omega^2}{2\hbar^2 k},} \quad (2.79)$$

which shows that as energy becomes larger than the constant E_0 , the transparency approaches 1.

Now proceeding to another important limit of thick barriers ($d \gg \delta$), Eq. (71) shows that in this case, the transparency is dominated by what is called the *tunnel exponent*:

Thick barrier:
transparency

$$\boxed{\mathcal{T} = \left(\frac{4k\kappa}{k^2 + \kappa^2} \right)^2 e^{-2\kappa d}} \quad (2.80)$$

– the behavior which may be clearly seen as the straight-line segments in semi-log plots (Fig. 7b) of \mathcal{T} as a function of the combination $(1 - E/U_0)^{1/2}$, which is proportional to κ – see Eq. (57). This exponential dependence on the barrier thickness is the most important factor for various applications of quantum-mechanical tunneling – from the field emission of electrons to vacuum¹⁵ to the scanning tunneling microscopy.¹⁶ Note also very substantial negative implications of the effect for the electronic technology progress, most importantly imposing limits on the so-called *Dennard scaling* of field-effect transistors in semiconductor integrated circuits (which is the technological basis of the well-known *Moore's law*), due to the increase of tunneling both through the gate oxide and along the channel of the transistors, from source to drain.¹⁷

Finally, one more feature visible in Fig. 7a (for case $d = 3\delta$) are the oscillations of the transparency as a function of energy, at $E > U_0$, with $\mathcal{T} = 1$, i.e. the reflection completely vanishing, at some points.¹⁸ This is our first glimpse at one more interesting quantum effect: *resonant tunneling*. This effect will be discussed in more detail in Sec. 5 below, using another potential profile where it is more clearly pronounced.

¹⁵ See, e.g., G. Fursey, *Field Emission in Vacuum Microelectronics*, Kluwer, New York, 2005.

¹⁷ See, e.g., V. Sverdlov *et al.*, *IEEE Trans. on Electron Devices* **50**, 1926 (2003), and references therein. (A brief discussion of the field-effect transistors, and literature for further reading, may be found in SM Sec. 6.4.)

¹⁸ Let me mention in passing the curious case of the potential well $U(x) = -(\hbar^2/2m)\nu(\nu+1)/\cosh^2(x/a)$, with any positive integer ν and any real a , which is reflection-free ($\mathcal{T} = 1$) for the incident de Broigle wave of *any* energy E , and hence for any incident wave packet. Unfortunately, a proof of this fact would require more time/space than I can afford. (Note that it was first described in a 1930 paper by Paul Sophus Epstein, before the 1933 publication by G. Pöschl and E. Teller, which is responsible for the common name of this *Pöschl-Teller potential*.)

2.4. Motion in soft potentials

Before moving on to exploring other quantum-mechanical effects, let us see how the results discussed in the previous section are modified in the opposite limit of the so-called *soft* (also called “smooth”) potential profiles, like the one sketched in Fig. 3.¹⁹ The most efficient analytical tool to study this limit is the so-called *WKB* (or “JWKB”, or “quasiclassical”) *approximation* developed by H. Jeffrey, G. Wentzel, A. Kramers, and L. Brillouin in 1925-27. In order to derive its 1D version, let us rewrite the Schrödinger equation (53) in a simpler form

$$\frac{d^2\psi}{dx^2} + k^2(x)\psi = 0, \quad (2.81)$$

where the local wave number $k(x)$ is defined similarly to Eq. (65),

$$k^2(x) \equiv \frac{2m[E - U(x)]}{\hbar^2}; \quad (2.82)$$

Local
wave
number

besides that now it may be a function of x . We already know that for $k(x) = \text{const}$, the fundamental solutions of this equation are $A\exp\{+ikx\}$ and $B\exp\{-ikx\}$, which may be represented in a single form

$$\psi(x) = e^{i\Phi(x)}, \quad (2.83)$$

where $\Phi(x)$ is a complex function, in these two simplest cases being equal, respectively, to $(kx - i\ln A)$ and $(-kx - i\ln B)$. This is why we may try use Eq. (83) to look for solution of Eq. (81) even in the general case, $k(x) \neq \text{const}$. Differentiating Eq. (83) twice, we get

$$\frac{d\psi}{dx} = i \frac{d\Phi}{dx} e^{i\Phi}, \quad \frac{d^2\psi}{dx^2} = \left[i \frac{d^2\Phi}{dx^2} - \left(\frac{d\Phi}{dx} \right)^2 \right] e^{i\Phi}. \quad (2.84)$$

Plugging the last expression into Eq. (81) and requiring the factor before $\exp\{i\Phi(x)\}$ to vanish, we get

$$i \frac{d^2\Phi}{dx^2} - \left(\frac{d\Phi}{dx} \right)^2 + k^2(x) = 0. \quad (2.85)$$

This is still an exact, general equation. At the first sight, it looks harder to solve than the initial equation (81), because Eq. (85) is nonlinear. However, it is ready for simplification in the limit when the potential profile is very soft, $dU/dx \rightarrow 0$. Indeed, for a uniform potential, $d^2\Phi/dx^2 = 0$. Hence, in the so-called 0^{th} *approximation*, $\Phi(x) \rightarrow \Phi_0(x)$, we may try to keep that result, so that Eq. (85) is reduced to

$$\left(\frac{d\Phi_0}{dx} \right)^2 = k^2(x), \quad \text{i.e. } \frac{d\Phi_0}{dx} = \pm k(x), \quad \Phi_0(x) = \pm i \int_x^x k(x') dx', \quad (2.86)$$

so that its general solution is a linear superposition of two functions (83), with Φ replaced with Φ_0 :

$$\psi_0(x) = A \exp \left\{ +i \int_x^x k(x') dx' \right\} + B \exp \left\{ -i \int_x^x k(x') dx' \right\}, \quad (2.87)$$

¹⁹ Quantitative conditions of the “softness” will be formulated later in this section.

where the choice of the lower limits of integration affects only the constants A and B . The physical sense of this result is simple: it is a sum of the forward- and back-propagating de Broglie waves, with the coordinate-dependent local wave number $k(x)$ that self-adjusts to the potential profile.

Let me emphasize the non-trivial nature of this approximation.²⁰ First, any attempt to address the problem with the standard perturbation approach (say, $\psi = \psi_0 + \psi_1 + \dots$, with ψ_n proportional to the n^{th} power of some small parameter) would fail for most potentials, because as Eq. (86) shows, even a slight but persisting deviation of $U(x)$ from a constant leads to a gradual accumulation of the phase Φ_0 , impossible to describe by any small perturbation of ψ . Second, the dropping of the term $d^2\Phi/dx^2$ in Eq. (85) is not too easy to justify. Indeed, since we are committed to the “soft potential limit” $dU/dx \rightarrow 0$, we should be ready to assume the characteristic length a of the spatial variation of Φ to be large, and neglect the terms that are the smallest ones in the limit $a \rightarrow \infty$. However, both first terms in Eq. (85) are apparently of the same order in a , namely $O(a^{-2})$; why have we neglected just one of them?

The price we have paid for such a “sloppy” treatment is substantial: Eq. (87) does *not* satisfy the fundamental property of the Schrödinger equation solutions, the probability current’s conservation. Indeed, since Eq. (81) describes a fixed-energy (stationary) spatial part of the general Schrödinger equation, its probability density $w = \Psi\Psi^* = \psi\psi^*$, and should not depend on time. Hence, according to Eq. (6), we should have $I(x) = \text{const}$. However, this is not true for any component of Eq. (87); for example for the first, forward-propagating component on its right-hand side, Eq. (5) yields

$$I_0(x) = \frac{\hbar}{m} |A|^2 k(x), \quad (2.88)$$

evidently not a constant if $k(x) \neq \text{const}$. The brilliance of the WKB theory is that the problem may be fixed without a full revision of the 0th approximation, just by amending it. Indeed, let us explore the next, 1st approximation:

$$\Phi(x) \rightarrow \Phi_{\text{WKB}}(x) \equiv \Phi_0(x) + \Phi_1(x), \quad (2.89)$$

where Φ_0 still obeys Eq. (86), while Φ_1 describes a 0th approximation’s correction that is small in the following sense:²¹

$$\left| \frac{d\Phi_1}{dx} \right| \ll \left| \frac{d\Phi_0}{dx} \right| = k(x). \quad (2.90)$$

Plugging Eq. (89) into Eq. (85), with the account of the definition (86), we get

$$i \left(\frac{d^2\Phi_0}{dx^2} + \frac{d^2\Phi_1}{dx^2} \right) - \frac{d\Phi_1}{dx} \left(2 \frac{d\Phi_0}{dx} + \frac{d\Phi_1}{dx} \right) = 0. \quad (2.91)$$

Using the condition (90), we may neglect $d^2\Phi_1/dx^2$ in comparison with $d^2\Phi_0/dx^2$ inside the first parentheses, and $d\Phi_1/dx$ in comparison with $2d\Phi_0/dx$ inside the second parentheses. As a result, we get the following (still approximate!) result:

²⁰ Philosophically, this space-domain method is very close to the time-domain *van der Pol method* in classical mechanics, and the very similar *rotating wave approximation* (RWA) in quantum mechanics – see, e.g., CM Secs. 5.2-5.5, and also Secs. 6.5, 7.6, 9.2, and 9.4 of this course.

²¹ For certainty, I will use the discretion given by Eq. (82) to define $k(x)$ as the *positive* root of its right-hand side.

$$\frac{d\Phi_1}{dx} = \frac{i}{2} \frac{d^2\Phi_0}{dx^2} / \frac{d\Phi_0}{dx} = \frac{i}{2} \frac{d}{dx} \left(\ln \frac{d\Phi_0}{dx} \right) = \frac{i}{2} \frac{d}{dx} [\ln k(x)] = i \frac{d}{dx} [\ln k^{1/2}(x)], \quad (2.92)$$

$$i\Phi|_{\text{WKB}} \equiv i\Phi_0 + i\Phi_1 = \pm i \int^x k(x') dx' + \ln \frac{1}{k^{1/2}(x)}, \quad (2.93)$$

$$\psi_{\text{WKB}}(x) = \frac{a}{k^{1/2}(x)} \exp \left\{ i \int^x k(x') dx' \right\} + \frac{b}{k^{1/2}(x)} \exp \left\{ -i \int^x k(x') dx' \right\}. \quad \text{for } k^2(x) > 0. \quad (2.94)$$

WKB
wave-
function

(Again, the lower integration limit is arbitrary, because its choice may be incorporated into the complex constants a and b .) This modified approximation overcomes the problem of current continuity; for example, for the forward-propagating wave, Eq. (5) gives

$$I_{\text{WKB}}(x) = \frac{\hbar}{m} |a|^2 = \text{const.} \quad (2.95)$$

WKB
probability
current

Physically, the factor $k^{1/2}$ in the denominator of the WKB wavefunction's pre-exponent is easy to understand. The smaller the local group velocity (32) of the wave packet, $v_{\text{gr}}(x) = \hbar k(x)/m$, the "easier" (more probable) it should be to find the particle within a certain interval dx . This is exactly the result that the WKB approximation gives: $w(x) = \psi\psi^* \propto 1/k(x) \propto 1/v_{\text{gr}}$. Another value of the 1st approximation is a clarification of the WKB theory's validity condition: it is given by Eq. (90). Plugging into this relation the first form of Eq. (92), and estimating $|d^2\Phi_0/dx^2|$ as $|d\Phi_0/dx|/a$, where a is the spatial scale of a substantial change of $|d\Phi_0/dx| = k(x)$, we may write the condition as

$$ka \gg 1. \quad (2.96)$$

WKB:
first
condition
of validity

In plain English, this means that the region where $U(x)$, and hence $k(x)$, change substantially should contain many de Broglie wavelengths $\lambda = 2\pi/k$.

So far I have implied that $k^2(x) \propto E - U(x)$ is positive, i.e. particle moves in the classically accessible region. Now let us extend the WKB approximation to situations where the difference $E - U(x)$ may change sign, for example to the reflection problem sketched in Fig. 3. Just as we did for the sharp potential step, we first need to find the appropriate solution in the classically forbidden region, in this case for $x > x_c$. For that, there is again no need to redo our calculations, because they are still valid if we, just as in the sharp-step problem, take $k(x) = i\kappa(x)$, where

$$\kappa^2(x) \equiv \frac{2m[U(x) - E]}{\hbar^2} > 0, \quad \text{for } x > x_c, \quad (2.97)$$

and keep just one of two possible solutions (with $\kappa > 0$), in analogy with Eq. (58). The result is

$$\psi_{\text{WKB}}(x) = \frac{c}{\kappa^{1/2}(x)} \exp \left\{ - \int^x \kappa(x') dx' \right\}, \quad \text{for } k^2 < 0, \text{ i.e. } \kappa^2 > 0, \quad (2.98)$$

with the lower limit at some point with $\kappa^2 > 0$ as well. This is a really wonderful formula! It describes the quantum-mechanical penetration of the particle into the classically forbidden region and provides a natural generalization of Eq. (58) – leaving intact our estimates of the depth $\delta \sim 1/\kappa$ of such penetration.

Now we have to do what we have done for the sharp-step problem in Sec. 2: use the boundary conditions at classical turning point $x = x_c$ to relate the constants a , b , and c . However, now this operation is a tad more complex, because both WKB functions (94) and (98) diverge, albeit weakly, at the point, because here both $k(x)$ and $\kappa(x)$ tend to zero. This *connection problem* may be solved in the following way.²²

Let us use our commitment of the potential's "softness", assuming that it allows us to keep just two leading terms in the Taylor expansion of the function $U(x)$ at the point x_c :

$$U(x) \approx U(x_c) + \frac{dU}{dx} \Big|_{x=x_c} (x - x_c) \equiv E + \frac{dU}{dx} \Big|_{x=x_c} (x - x_c). \quad (2.99)$$

Using this truncated expansion, and introducing the following dimensionless variable for the coordinate's deviation from the classical turning point,

$$\zeta \equiv \frac{x - x_c}{x_0}, \quad \text{with } x_0 \equiv \left[\frac{\hbar^2}{2m(dU/dx)_{x=x_c}} \right]^{1/3}, \quad (2.100)$$

we reduce the Schrödinger equation (81) to the so-called *Airy equation*

Airy equation

$$\frac{d^2\psi}{d\zeta^2} - \zeta \psi = 0. \quad (2.101)$$

This simple linear, ordinary, homogenous differential equation of the second order has been very well studied. Its general solution may be represented as a linear combination of two fundamental solutions, the *Airy functions* $\text{Ai}(\zeta)$ and $\text{Bi}(\zeta)$, shown in Fig. 9a.²³

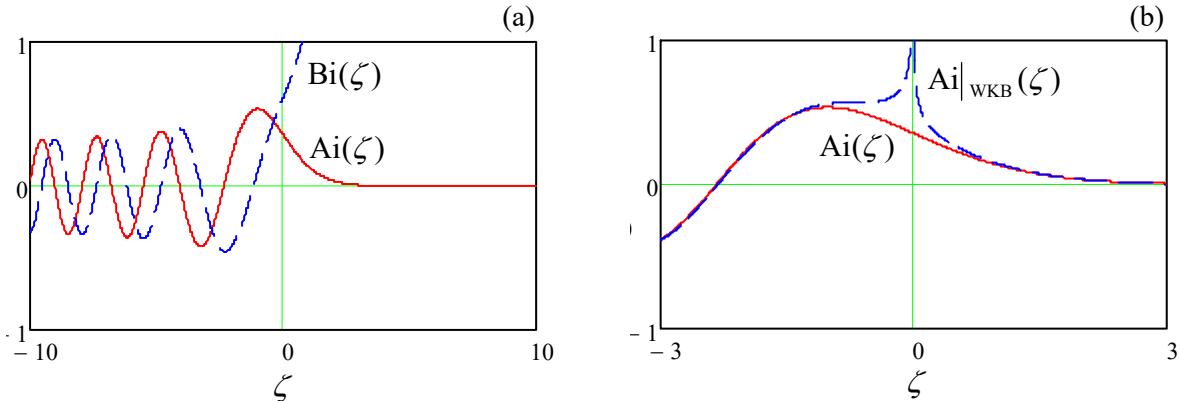

Fig. 2.9. (a) The Airy functions Ai and Bi , and (b) the WKB approximation for the function $\text{Ai}(\zeta)$.

²² An alternative way to solve the connection problem, without involving the Airy functions but using an analytical extension of WKB formulas to the complex-argument plane, may be found, e.g., in Sec. 47 of the textbook by L. Landau and E. Lifshitz, *Quantum Mechanics, Non-Relativistic Theory*, 3rd ed. Pergamon, 1977.

²³ Note the following (exact) integral formulas,

$$\text{Ai}(\zeta) = \frac{1}{\pi} \int_0^\infty \cos\left(\frac{\xi^3}{3} + \zeta\xi\right) d\xi, \quad \text{Bi}(\zeta) = \frac{1}{\pi} \int_0^\infty \left[\exp\left(-\frac{\xi^3}{3} + \zeta\xi\right) + \sin\left(\frac{\xi^3}{3} + \zeta\xi\right) \right] d\xi,$$

frequently more convenient for practical calculations of the Airy functions than the differential equation (101).

The latter function diverges at $\zeta \rightarrow +\infty$, and thus is not suitable for our current problem (Fig. 3), while the former function has the following asymptotic behaviors at $|\zeta| \gg 1$:

$$\text{Ai}(\zeta) \rightarrow \frac{1}{\pi^{1/2} |\zeta|^{1/4}} \times \begin{cases} \frac{1}{2} \exp\left\{-\frac{2}{3} \zeta^{3/2}\right\}, & \text{for } \zeta \rightarrow +\infty, \\ \sin\left\{\frac{2}{3}(-\zeta)^{3/2} + \frac{\pi}{4}\right\}, & \text{for } \zeta \rightarrow -\infty. \end{cases} \quad (2.102)$$

Now let us apply the WKB approximation to the Airy equation (101). Taking the classical turning point ($\zeta = 0$) for the lower limit, for $\zeta > 0$ we get

$$\kappa^2(\zeta) = \zeta, \quad \kappa(\zeta) = \zeta^{1/2}, \quad \int_0^\zeta \kappa(\zeta') d\zeta' = \frac{2}{3} \zeta^{3/2}, \quad (2.103)$$

i.e. exactly the exponent in the top line of Eq. (102). Making a similar calculation for $\zeta < 0$, with the natural assumption $|b| = |a|$ (full reflection from the potential step), we arrive at the following result:

$$\text{Ai}_{\text{WKB}}(\zeta) = \frac{1}{|\zeta|^{1/4}} \times \begin{cases} c' \exp\left\{-\frac{2}{3} \zeta^{3/2}\right\}, & \text{for } \zeta > 0, \\ a' \sin\left\{\frac{2}{3}(-\zeta)^{3/2} + \varphi\right\}, & \text{for } \zeta < 0. \end{cases} \quad (2.104)$$

This approximation differs from the exact solution at small values of ζ , i.e. close to the classical turning point – see Fig. 9b. However, at $|\zeta| \gg 1$, Eqs. (104) describe the Airy function exactly, provided that

$$\varphi = \frac{\pi}{4}, \quad c' = \frac{a'}{2}. \quad (2.105)$$

WKB:
connection
formulas

These *connection formulas* may be used to rewrite Eq. (104) as

$$\text{Ai}_{\text{WKB}}(\zeta) = \frac{a'}{2|\zeta|^{1/4}} \times \begin{cases} \exp\left\{-\frac{2}{3} \zeta^{3/2}\right\}, & \text{for } \zeta > 0, \\ \frac{1}{i} \left[\exp\left\{i \frac{2}{3} \zeta^{3/2} + i \frac{\pi}{4}\right\} - \exp\left\{-i \frac{2}{3} \zeta^{3/2} - i \frac{\pi}{4}\right\} \right], & \text{for } \zeta < 0, \end{cases} \quad (2.106)$$

and hence may be described by the following two simple mnemonic rules:

(i) If the classical turning point is taken for the lower limit in the WKB integrals in the classically allowed and the classically forbidden regions, then the moduli of the quasi-amplitudes of the exponents are equal.

(ii) Reflecting from a “soft” potential step, the wavefunction acquires an additional phase shift $\Delta\varphi = \pi/2$, if compared with its reflection from a “hard”, infinitely high potential wall located at point x_c (for which, according to Eq. (63) with $\kappa = 0$, we have $B = -A$).

In order for the connection formulas (105)-(106) to be valid, deviations from the linear approximation (99) of the potential profile should be relatively small within the region where the WKB approximation differs from the exact Airy function: $|\zeta| \sim 1$, i.e. $|x - x_c| \sim x_0$. These deviations may be estimated using the next term of the Taylor expansion, dropped in Eq. (99): $(d^2 U / d^2 x)(x - x_c)^2 / 2$. As a result, the condition of validity of the connection formulas (i.e. of the “softness” of the reflecting

potential profile) may be expressed as $|d^2U/dx^2| \ll |dU/dx|$ at $x \approx x_c$ – meaning the $\sim x_0$ -wide vicinity of the point x_c). With the account of Eq. (100) for x_0 , this condition becomes

$$\left| \frac{d^2U}{dx^2} \right|_{x \approx x_c}^3 \ll \frac{2m}{\hbar^2} \left(\frac{dU}{dx} \right)_{x \approx x_c}^4. \quad (2.107)$$

Connection formulas' validity

As an example of a very useful application of the WKB approximation, let us use the connection formulas to calculate the energy spectrum of a 1D particle in a soft 1D potential well (Fig. 10).

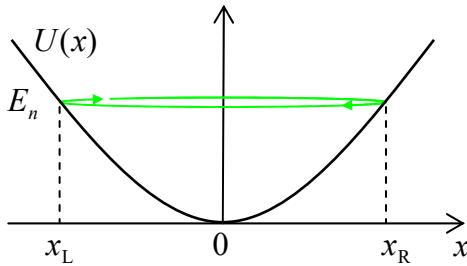

Fig. 2.10. The WKB treatment of an eigenstate of a particle in a soft 1D potential well.

As was discussed in Sec. 1.7, we may consider the standing wave describing an eigenfunction ψ_n (corresponding to an eigenenergy E_n) as a sum of two traveling de Broglie waves going back and forth between the walls, being sequentially reflected from each of them. Let us apply the WKB approximation to such traveling waves. First, according to Eq. (94), propagating from the left classical turning point x_L to the right such point x_R , it acquires the phase change

$$\Delta\varphi_{\rightarrow} = \int_{x_L}^{x_R} k(x) dx. \quad (2.108)$$

At the reflection from the soft wall at x_R , according to the mnemonic rule (ii), the wave acquires an additional shift $\pi/2$. Now, traveling back from x_R to x_L , the wave gets a shift similar to one given by Eq. (108): $\Delta\varphi_{\leftarrow} = \Delta\varphi_{\rightarrow}$. Finally, at the reflection from x_L it gets one more $\pi/2$ -shift. Summing up all these contributions at the wave's roundtrip, we may write the self-consistency condition (that the wavefunction “catches its own tail with its teeth”) in the form

$$\Delta\varphi_{\text{total}} \equiv \Delta\varphi_{\rightarrow} + \frac{\pi}{2} + \Delta\varphi_{\leftarrow} + \frac{\pi}{2} \equiv 2 \int_{x_L}^{x_R} k(x) dx + \pi = 2\pi n, \quad \text{with } n = 1, 2, \dots \quad (2.109)$$

Rewriting this result in terms of the particle's momentum $p(x) = \hbar k(x)$, we arrive at the so-called *Wilson-Sommerfeld* (or “Bohr-Sommerfeld”) *quantization rule*

$$\oint_C p(x) dx = 2\pi\hbar \left(n - \frac{1}{2} \right), \quad (2.110)$$

Wilson-Sommerfeld quantization rule

where the closed path C means the full period of classical motion.²⁴

²⁴ Note that at the motion in more than one dimension, a closed classical trajectory may have no classical turning points. In this case, the constant $1/2$, arising from the turns, should be dropped from Eqs. (110) written for the scalar product $\mathbf{p}(\mathbf{r}) \cdot d\mathbf{r}$ – the so-called *Bohr quantization rule*. It was suggested by N. Bohr as early as 1913 as an interpretation of Eq. (1.8) for the circular motion of the electron around the proton, while its 1D modification (110) is due to W. Wilson (1915) and A. Sommerfeld (1916).

Let us see what does this quantization rule give for the very important particular case of a quadratic potential profile of a harmonic oscillator of frequency ω_0 . In this case,

$$U(x) = \frac{m}{2} \omega_0^2 x^2, \quad (2.111)$$

and the classical turning points (where $U(x) = E$) are the roots of a simple equation

$$\frac{m}{2} \omega_0^2 x_c^2 = E_n, \quad \text{so that } x_R = \frac{1}{\omega_0} \left(\frac{2E_n}{m} \right)^{1/2} > 0, \quad x_L = -x_R < 0. \quad (2.112)$$

Due to the potential's symmetry, the integration required by Eq. (110) is also simple:

$$\begin{aligned} \int_{x_L}^{x_R} p(x) dx &= \int_{x_L}^{x_R} \{2m[E_n - U(x)]\}^{1/2} dx \equiv (2mE_n)^{1/2} 2 \int_0^{x_R} \left(1 - \frac{x^2}{x_R^2}\right)^{1/2} dx \\ &\equiv (2mE_n)^{1/2} 2x_R \int_0^1 (1 - \xi^2)^{1/2} d\xi = (2mE_n)^{1/2} 2x_R \frac{\pi}{4} \equiv \frac{\pi E_n}{\omega_0}, \end{aligned} \quad (2.113)$$

so that Eq. (110) yields

$$E_n = \hbar\omega_0 \left(n' + \frac{1}{2} \right), \quad \text{with } n' \equiv n - 1 = 0, 1, 2, \dots. \quad (2.114)$$

To estimate the validity of this result, we have to check the condition (96) at all points of the classically allowed region, and Eq. (107) at the turning points. The checkup shows that both conditions are valid only for $n \gg 1$. However, we will see in Sec. 9 below that Eq. (114) is actually exactly correct for *all* energy levels – thanks to special properties of the potential profile (111).

Now let us use the mnemonic rule (i) to examine particle's penetration into the classically forbidden region of an abrupt potential step of a height $U_0 > E$. For this case, the rule, i.e. the second of Eqs. (105), yields the following relation of the quasi-amplitudes in Eqs. (94) and (98): $|c| = |a|/2$. If we now naively applied this relation to the sharp step sketched in Fig. 4, forgetting that it does not satisfy Eq. (107), we would get the following relation of the full amplitudes, defined by Eqs. (55) and (58):

$$\left| \frac{C}{\kappa} \right| = \frac{1}{2} \left| \frac{A}{k} \right|. \quad (\text{WRONG!}) \quad (2.115)$$

This result differs from the correct Eq. (63), and hence we may expect that the WKB approximation's prediction for more complex potentials, most importantly for tunneling through a soft potential barrier (Fig. 11) should be also different from the exact result (71) for the rectangular barrier shown in Fig. 6.

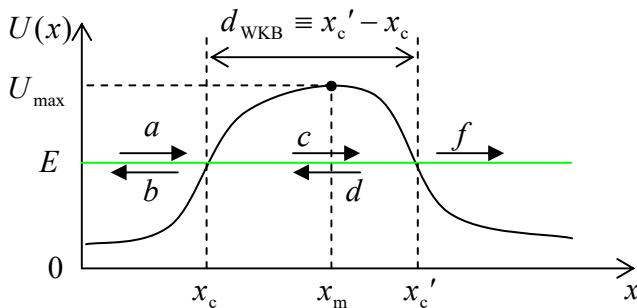

Fig. 2.11. Tunneling through a soft 1D potential barrier.

In order to analyze tunneling through such a soft barrier, we need (just as in the case of a rectangular barrier) to take unto consideration five partial waves, but now they should be taken in the WKB form:

$$\psi_{\text{WKB}} = \begin{cases} \frac{a}{k^{1/2}(x)} \exp\left\{i \int_{x'}^x k(x') dx'\right\} + \frac{b}{k^{1/2}(x)} \exp\left\{-i \int_{x'}^x k(x') dx'\right\}, & \text{for } x < x_c, \\ \frac{c}{\kappa^{1/2}(x)} \exp\left\{- \int_{x_c}^x \kappa(x') dx'\right\} + \frac{d}{\kappa^{1/2}(x)} \exp\left\{\int_{x_c}^x \kappa(x') dx'\right\}, & \text{for } x_c < x < x_c', \\ \frac{f}{k^{1/2}(x)} \exp\left\{i \int_{x_c}^x k(x') dx'\right\}, & \text{for } x_c' < x, \end{cases} \quad (2.116)$$

where the lower limits of integrals are arbitrary (each within the corresponding range of x). Since on the right of the left classical point, we have two exponents rather than one, and on the right of the second point, one traveling waves rather than two, the connection formulas (105) have to be generalized, using asymptotic formulas not only for $\text{Ai}(\zeta)$, but also for the second Airy function, $\text{Bi}(\zeta)$. The analysis, absolutely similar to that carried out above (though naturally a bit bulkier),²⁵ gives a remarkably simple result:

Soft potential barrier:
transparency

$$\mathcal{T}_{\text{WKB}} \equiv \left| \frac{f}{a} \right|^2 = \exp\left\{ -2 \int_{x_c}^{x_c'} \kappa(x) dx \right\} \equiv \exp\left\{ -\frac{2}{\hbar} \int_{x_c}^{x_c'} (2m[U(x) - E])^{1/2} dx \right\}, \quad (2.117)$$

with the pre-exponential factor equal to 1 – the fact which might be readily expected from the mnemonic rule (i) of the connection formulas.

This formula is broadly used in applied quantum mechanics, despite the approximate character of its pre-exponential coefficient for insufficiently soft barriers that do not satisfy Eq. (107). For example, Eq. (80) shows that for a rectangular barrier with thickness $d \gg \delta$, the WKB approximation (117) with $d_{\text{WKB}} = d$ underestimates \mathcal{T} by a factor of $[4k\kappa/(k^2 + \kappa^2)]^2$ – equal, for example, 4, if $k = \kappa$, i.e. if $U_0 = 2E$. However, on the appropriate logarithmic scale (see Fig. 7b), such a factor, smaller than an order of magnitude, is just a small correction.

Note also that when E approaches the barrier's top U_{\max} (Fig. 11), the points x_c and x_c' merge, so that according to Eq. (117), $\mathcal{T}_{\text{WKB}} \rightarrow 1$, i.e. the particle reflection vanishes at $E = U_{\max}$. So, the WKB approximation does not describe the effect of the over-barrier reflection at $E > U_{\max}$. (This fact could be noticed already from Eq. (95): in the absence of the classical turning points, the WKB probability current is constant for any barrier profile.) This conclusion is incorrect even for apparently smooth barriers where one could naively expect the WKB approximation to work perfectly. Indeed, near the point $x = x_m$ where the potential reaches maximum (i.e. $U(x_m) = U_{\max}$), we may always approximate any smooth function $U(x)$ with the quadratic term of the Taylor expansion, i.e. with an inverted parabola:

$$U(x) \approx U_{\max} - \frac{m\omega_0^2(x - x_m)^2}{2}. \quad (2.118)$$

²⁵ For the most important case $\mathcal{T}_{\text{WKB}} \ll 1$, Eq. (117) may be simply derived from Eqs. (105)-(106) – the exercise left for the reader.

Calculating derivatives dU/dx and d^2U/dx^2 of this function and plugging them into the condition (107), we may see that the WKB approximation is only valid if $|U_{\max} - E| \gg \hbar\omega_0$. Just for the reader's reference, an exact analysis of tunneling through the barrier (118) gives the following *Kemble formula*:²⁶

$$\mathcal{T} = \frac{1}{1 + \exp\{-2\pi(E - U_{\max})/\hbar\omega_0\}}, \quad (2.119)$$

Kemble formula

valid for any sign of the difference $(E - U_{\max})$. This formula describes a gradual approach of \mathcal{T} to 1, i.e. a *gradual* reduction of reflection, at the particle energy's increase, with $\mathcal{T} = \frac{1}{2}$ at $E = U_{\max}$.

The last remark of this section: the WKB approximation opens a straight way toward an alternative formulation of quantum mechanics, based on the *Feynman path integral*. However, I will postpone its discussion until a more compact notation has been introduced in Chapter 4.

2.5. Resonant tunneling, and metastable states

Now let us move to other, conceptually different quantum effects, taking place in more elaborate potential profiles. Neither piecewise-constant nor smooth-potential models of $U(x)$ are convenient for their quantitative description because they both require "stitching" partial de Broglie waves at each classical turning point, which may lead to cumbersome calculations. However, we may get a very good insight of the physics of quantum effects that may take place in such profiles, using their approximation by sets of Dirac's delta functions.

Additional help in studying such effects is provided by the notions of the *scattering* and *transfer matrices*, very useful for other cases as well. Consider an arbitrary but finite-length potential "bump" (formally called a *scatterer*), localized somewhere between points x_1 and x_2 , on the flat potential background, say $U = 0$ (Fig. 12).

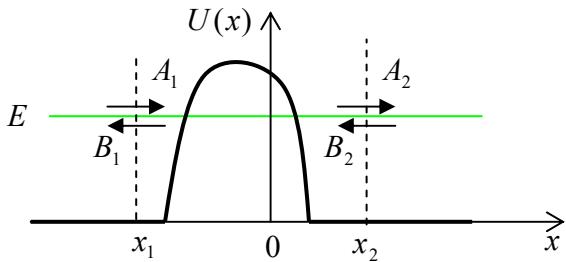

Fig. 2.12. De Broglie wave amplitudes near a single 1D scatterer.

From Sec. 2, we know that the general solutions of the stationary Schrödinger equation, with a certain energy E , outside the interval $[x_1, x_2]$ are sets of two sinusoidal waves, traveling in the opposite directions. Let us represent them in the form

$$\psi_j = A_j e^{ik(x-x_j)} + B_j e^{-ik(x-x_j)}, \quad (2.120)$$

²⁶ This formula was derived (in a more general form, valid for an arbitrary soft potential barrier) by E. Kemble in 1935. In some communities, it is known as the "Hill-Wheeler formula", after D. Hill and J. Wheeler's 1953 paper in that the Kemble formula was spelled out for the quadratic profile (118). Note that mathematically Eq. (119) is similar to the Fermi distribution in statistical physics, with an effective temperature $T_{\text{ef}} = \hbar\omega_0/2\pi k_B$. This coincidence has some curious implications for the Fermi particle tunneling statistics.

where the index j (for now) is equal to either 1 or 2, and $(\hbar k)^2/2m = E$. Note that each of the two wave pairs (129) has, in this notation, its own reference point x_j , because this is very convenient for what follows. As we have already discussed, if the de Broigle wave/particle is incident from the left (i.e. $B_2 = 0$), the solution of the linear Schrödinger equation within the scatterer range ($x_1 < x < x_2$) can provide only linear expressions for the transmitted (A_2) and reflected (B_1) wave amplitudes via the incident wave amplitude A_1 :

$$A_2 = S_{21}A_1, \quad B_1 = S_{11}A_1, \quad (2.121)$$

where S_{11} and S_{21} are certain (generally, complex) coefficients. Alternatively, if a wave, with amplitude B_2 , is incident on the scatterer from the right (i.e. if $A_1 = 0$), it can induce a transmitted wave (B_1) and a reflected wave (A_2), with amplitudes

$$B_1 = S_{12}B_2, \quad A_2 = S_{22}B_2, \quad (2.122)$$

where the coefficients S_{22} and S_{12} are generally different from S_{11} and S_{21} . Now we can use the linear superposition principle to argue that if the waves A_1 and B_2 are simultaneously incident on the scatterer (say, because the wave B_2 has been partly reflected back by some other scatterer located at $x > x_2$), the resulting *scattered wave* amplitudes A_2 and B_1 are just the sums of their values for separate incident waves:

$$\begin{aligned} B_1 &= S_{11}A_1 + S_{12}B_2, \\ A_2 &= S_{21}A_1 + S_{22}B_2. \end{aligned} \quad (2.123)$$

These linear relations may be conveniently represented using the so-called *scattering matrix* S :

Scattering
matrix:
definition

$$\begin{pmatrix} B_1 \\ A_2 \end{pmatrix} = S \begin{pmatrix} A_1 \\ B_2 \end{pmatrix}, \quad \text{with } S \equiv \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix}. \quad (2.124)$$

Scattering matrices, duly generalized, are an important tool for the analysis of wave scattering in more dimensions than one; for 1D problems, however, another matrix is often more convenient to represent the same linear relations (123). Indeed, let us solve this system for A_2 and B_2 . The result is

Transfer
matrix:
definition

$$\begin{aligned} A_2 &= T_{11}A_1 + T_{12}B_1, \quad \text{i.e. } \begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = T \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}, \\ B_2 &= T_{21}A_1 + T_{22}B_1, \end{aligned} \quad (2.125)$$

where T is the *transfer matrix*, with the following elements:

$$T_{11} = S_{21} - \frac{S_{11}S_{22}}{S_{12}}, \quad T_{12} = \frac{S_{22}}{S_{12}}, \quad T_{21} = -\frac{S_{11}}{S_{21}}, \quad T_{22} = \frac{1}{S_{12}}. \quad (2.126)$$

The matrices S and T have some universal properties, valid for an arbitrary (but time-independent) scatterer; they may be readily found from the probability current conservation and the time-reversal symmetry of the Schrödinger equation. Let me leave finding these relations for the reader's exercise. The results show, in particular, that the scattering matrix may be rewritten in the following form:

$$S = e^{i\theta} \begin{pmatrix} re^{i\varphi} & t \\ t & -re^{-i\varphi} \end{pmatrix}, \quad (2.127a)$$

where four real parameters r , t , θ , and φ satisfy the following universal relation:

$$r^2 + t^2 = 1, \quad (2.127b)$$

so that only 3 of these parameters are independent. As a result of this symmetry, T_{11} may be also represented in a simpler form, similar to T_{22} : $T_{11} = \exp\{i\theta\}/t = 1/S_{12}^* = 1/S_{21}^*$. The last form allows a ready expression of the scatterer's transparency via just one coefficient of the transfer matrix:

$$\mathcal{T} \equiv \left| \frac{A_2}{A_1} \right|_{B_2=0}^2 = |S_{21}|^2 = |T_{11}|^{-2}. \quad (2.128)$$

In our current context, the most important property of the 1D transfer matrices is that to find the total transfer matrix T of a system consisting of several (say, N) sequential arbitrary scatterers (Fig. 13), it is sufficient to multiply their matrices.

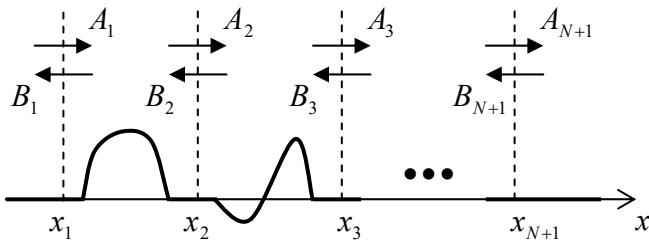

Fig. 2.13. A sequence of several 1D scatterers.

Indeed, extending the definition (125) to other points x_j ($j = 1, 2, \dots, N+1$), we can write

$$\begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = T_1 \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}, \quad \begin{pmatrix} A_3 \\ B_3 \end{pmatrix} = T_2 \begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = T_2 T_1 \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}, \quad \text{etc.} \quad (2.129)$$

(where the matrix indices correspond to the scatterers' order on the x -axis), so that

$$\begin{pmatrix} A_{N+1} \\ B_{N+1} \end{pmatrix} = T_N T_{N-1} \dots T_1 \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}. \quad (2.130)$$

But we can also define the *total transfer matrix* similarly to Eq. (125), i.e. as

$$\begin{pmatrix} A_{N+1} \\ B_{N+1} \end{pmatrix} \equiv T \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}, \quad (2.131)$$

so that comparing Eqs. (130) and (131) we get

$$T = T_N T_{N-1} \dots T_1. \quad (2.132)$$

This formula is valid even if the flat-potential gaps between component scatterers are shrunk to zero, so that it may be applied to a scatterer with an arbitrary profile $U(x)$, by fragmenting its length into many small segments $\Delta x = x_{j+1} - x_j$, and treating each fragment as a rectangular barrier of the average height $(U_j)_{\text{ef}} = [U(x_{j+1}) - U(x_j)]/2$ – see Fig. 14. Since very efficient numerical algorithms are readily available for fast multiplication of matrices (especially as small as 2×2 in our case), this approach is broadly used in practice for the computation of transparency of potential barriers with complicated profiles $U(x)$. (Computationally, this procedure is much more efficient than the direct numerical solution of the stationary Schrödinger equation.)

Transfer matrix:
composite scatterer

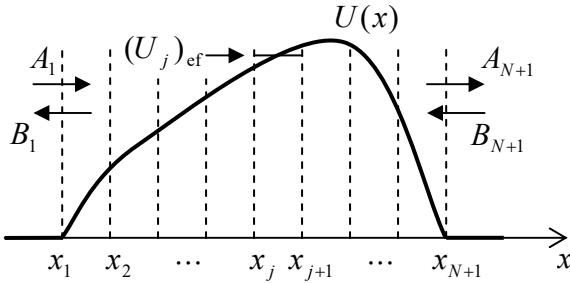

Fig. 2.14. The transfer matrix approach to a potential barrier with an arbitrary profile.

In order to apply this approach to several particular, conceptually important systems, let us calculate the transfer matrices for a few elementary scatterers, starting from the delta-functional barrier located at $x = 0$ – see Fig. 8. Taking $x_1, x_2 \rightarrow 0$, we can merely change the notation of the wave amplitudes in Eq. (78) to get

$$S_{11} = \frac{-i\alpha}{1+i\alpha}, \quad S_{21} = \frac{1}{1+i\alpha}. \quad (2.133)$$

An absolutely similar analysis of the wave incidence from the left yields

$$S_{22} = \frac{-i\alpha}{1+i\alpha}, \quad S_{12} = \frac{1}{1+i\alpha}, \quad (2.134)$$

and using Eqs. (126), we get

$$T_\alpha = \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix}. \quad (2.135)$$

As a sanity check, Eq. (128) applied to this result, immediately brings us back to Eq. (79).

The next example may seem strange at the first glance: what if there is no scatterer at all between the points x_1 and x_2 ? If the points coincide, the answer is indeed trivial and can be obtained, e.g., from Eq. (135) by taking $w=0$, i.e. $\alpha=0$:

$$T_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \equiv I \quad (2.136)$$

- the so-called *identity matrix*. However, we are free to choose the reference points $x_{1,2}$ participating in Eq. (120) as we wish. For example, what if $x_2 - x_1 = a$? Let us first take the forward-propagating wave alone: $B_2 = 0$ (and hence $B_1 = 0$); then

$$\psi_2 = \psi_1 = A_1 e^{ik(x-x_1)} \equiv A_1 e^{ik(x_2-x_1)} e^{ik(x-x_2)}. \quad (2.137)$$

The comparison of this expression with the definition (120) for $j=2$ shows that $A_2 = A_1 \exp\{ik(x_2-x_1)\} = A_1 \exp\{ika\}$, i.e. $T_{11} = \exp\{ika\}$. Repeating the calculation for the back-propagating wave, we see that $T_{22} = \exp\{-ika\}$, and since the space interval provides no particle reflection, we finally get

$$T_a = \begin{pmatrix} e^{ika} & 0 \\ 0 & e^{-ika} \end{pmatrix}, \quad (2.138)$$

independently of a common shift of points x_1 and x_2 . At $a=0$, we naturally recover the special case (136).

Transfer matrix:
short scatterer

Identity matrix

Transfer matrix:
spatial interval

Now let us use these simple results to analyze the *double-barrier system* shown in Fig. 15. We could of course calculate its properties as before, writing down explicit expressions for all five traveling waves shown by arrows in Fig. 15, then using the boundary conditions (124) and (125) at each of points $x_{1,2}$ to get a system of four linear equations, and finally, solving it for four amplitude ratios.

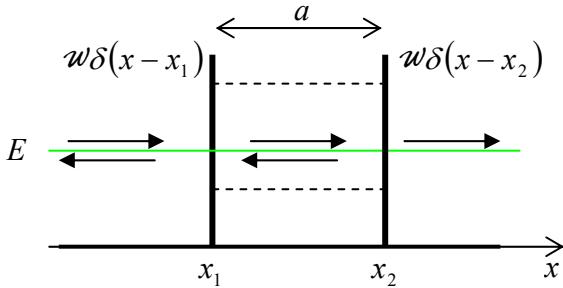

Fig. 2.15. The double-barrier system. The dashed lines show (schematically) the quasi-levels of the metastable-state energies.

However, the transfer matrix approach simplifies the calculations, because we may immediately use Eqs. (132), (135), and (138) to write

$$T = T_\alpha T_a T_\alpha = \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix} \begin{pmatrix} e^{ika} & 0 \\ 0 & e^{-ika} \end{pmatrix} \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix}. \quad (2.139)$$

Let me hope that the reader remembers the “row by column” rule of the multiplication of square matrices;²⁷ using it for the last two matrices, we may reduce Eq. (139) to

$$T = \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix} \begin{pmatrix} (1-i\alpha)e^{ika} & -i\alpha e^{ika} \\ i\alpha e^{-ika} & (1+i\alpha)e^{-ika} \end{pmatrix}. \quad (2.140)$$

Now there is no need to calculate all elements of the full product T , because, according to Eq. (128), for the calculation of barrier’s transparency T we need only one its element, T_{11} :

$$\mathcal{T} = \frac{1}{|T_{11}|^2} = \frac{1}{|\alpha^2 e^{-ika} + (1-i\alpha)^2 e^{ika}|^2}. \quad (2.141)$$

Double barrier: transparency

This result is somewhat similar to that following from Eq. (71) for $E > U_0$: the transparency is a π -periodic function of the product ka , reaching its maximum ($\mathcal{T} = 1$) at some point of each period – see Fig. 16a. However, Eq. (141) is different in that for $\alpha \gg 1$, the resonance peaks of the transparency are very narrow, reaching their maxima at $ka \approx k_n a \equiv n\pi$, with $n = 1, 2, \dots$

The physics of this *resonant tunneling* effect²⁸ is the so-called *constructive interference*, absolutely similar to that of electromagnetic waves (for example, light) in a *Fabry-Perot resonator* formed by two parallel semi-transparent mirrors.²⁹ Namely, the incident de Broglie wave may either

²⁷ In an analytical form: $(AB)_{jj'} = \sum_{j''=1}^N A_{jj''} B_{j''j'}$, where N is the matrix rank (in our current case, $N = 2$).

²⁸ In older literature, it is sometimes called the *Townsend* (or “Ramsauer-Townsend”) effect. However, it is more common to use that term only for a similar effect at 3D scattering – to be discussed in Chapter 3.

²⁹ See, e.g., EM Sec. 7.9.

tunnel through the two barriers or undertake, on its way, several sequential reflections from these semi-transparent walls. At $k = k_n$, i.e. at $2ka = 2k_n a = 2\pi n$, the phase differences between all these partial waves are multiples of 2π , so that they add up in phase – “constructively”. Note that the same constructive interference of numerous reflections from the walls may be used to interpret the standing-wave eigenfunctions (1.84), so that the resonant tunneling at $\alpha \gg 1$ may be also considered as a result of the incident wave’s resonance induction of such a standing wave, with a very large amplitude, in the space between the barriers, with the transmitted wave’s amplitude proportionately increased.

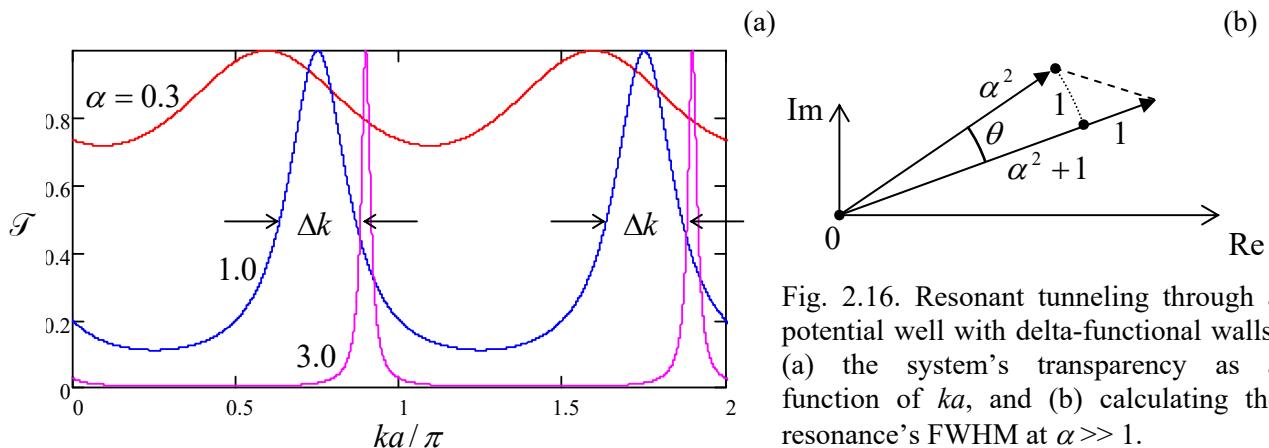

Fig. 2.16. Resonant tunneling through a potential well with delta-functional walls: (a) the system’s transparency as a function of ka , and (b) calculating the resonance’s FWHM at $\alpha \gg 1$.

As a result of this resonance, the maximum transparency of the system is *perfect* ($\mathcal{T}_{\max} = 1$) even at $\alpha \rightarrow \infty$, i.e. in the case of very *low* transparency of each of the two component barriers. Indeed, the denominator in Eq. (141) may be interpreted as the squared length of the difference between two 2D vectors, one of length α^2 , and another of length $|1 - i\alpha|^2 = 1 + \alpha^2$, with the angle $\theta = 2ka + \text{const}$ between them – see Fig. 16b. At the resonance, the vectors are aligned, and their difference is smallest (equal to 1) so that $\mathcal{T}_{\max} = 1$. (This result is exact only if the two barriers are exactly equal.)

The same vector diagram may be used to calculate the so-called FWHM, a common acronym for the *Full Width* [of the resonance curve at its] *Half-Maximum*. By definition, this is the difference $\Delta k = k_+ - k_-$ between such two values of k , on the opposite slopes of the same resonance, at that $\mathcal{T} = \mathcal{T}_{\max}/2$ – see the arrows in Fig. 16a. Let the vectors in Fig. 16b, drawn for $\alpha \gg 1$, be misaligned by a small angle $\theta \sim 1/\alpha^2 \ll 1$, so that the length of the difference vector is much smaller than the length of each vector. To double its length squared, and hence to reduce \mathcal{T} by a factor of two in comparison with its maximum value 1, the arc between the vectors, equal to $\alpha^2\theta$, should also become equal to ± 1 , i.e. $\alpha^2(2k_{\pm}a + \text{const}) = \pm 1$. Subtracting these two equalities from each other, we get

$$\Delta k \equiv k_+ - k_- = \frac{1}{a\alpha^2} \ll k_{\pm}. \quad (2.142)$$

Now let us use the simple system shown in Fig. 15 to discuss an issue of large conceptual significance. For that, consider what would happen if at some initial moment (say, $t = 0$) we have placed a 1D quantum particle inside the double-barrier well with $\alpha \gg 1$, and left it there alone, without any incident wave. To simplify the analysis, let us assume that the initial state of the particle coincides with one of the stationary states of the infinite-wall well of the same size – see Eq. (1.84):

$$\Psi(x,0) = \psi_n(x) = \left(\frac{2}{a}\right)^{1/2} \sin[k_n(x - x_1)], \quad \text{where } k_n = \frac{\pi n}{a}, \quad n = 1, 2, \dots \quad (2.143)$$

At $\alpha \rightarrow \infty$, this is just an eigenstate of the system, and from our analysis in Sec. 1.5 we know the time evolution of its wavefunction:

$$\Psi(x,t) = \psi_n(x) \exp\{-i\omega_n t\} = \left(\frac{2}{a}\right)^{1/2} \sin[k_n(x - x_1)] \exp\{-i\omega_n t\}, \quad \text{with } \omega_n = \frac{E_n}{\hbar} = \frac{\hbar k_n^2}{2m}, \quad (2.144)$$

telling us that the particle remains in the well at all times with constant probability $W(t) = W(0) = 1$.

However, if the parameter α is large but finite, the de Broglie wave would slowly “leak out” from the well, so that $W(t)$ would slowly decrease. Such a state is called *metastable*. Let us derive the law of its time evolution, assuming that at the slow leakage, with a characteristic time $\tau \gg 1/\omega_n$, does not affect the instant wave distribution inside the well, besides the gradual, slow reduction of W .³⁰ Then we can generalize Eq. (144) as

$$\Psi(x,t) = \left(\frac{2W}{a}\right)^{1/2} \sin[k_n(x - x_1)] \exp\{-i\omega_n t\} \equiv A \exp\{i(k_n x - \omega_n t)\} + B \exp\{-i(k_n x + \omega_n t)\}, \quad (2.145)$$

making the probability of finding the particle in the well equal to $W \leq 1$. As the last form of Eq. (145) shows, this function is the sum of two traveling waves, with equal magnitudes of their amplitudes and equal but opposite probability currents (5):

$$|A| = |B| = \left(\frac{W}{2a}\right)^{1/2}, \quad I_A = \frac{\hbar}{m} |A|^2 k_n = \frac{\hbar W}{m 2a} \frac{\pi n}{a}, \quad I_B = -I_A. \quad (2.146)$$

But we already know from Eq. (79) that at $\alpha \gg 1$, the delta-functional wall’s transparency \mathcal{T} equals $1/\alpha^2$, so that the wave carrying current I_A , incident on the right wall from the inside, induces an outgoing wave outside of the well (Fig. 17) with the following probability current:

$$I_R = \mathcal{T} I_A = \frac{1}{\alpha^2} I_A = \frac{1}{\alpha^2} \frac{\pi n \hbar W}{2ma^2}. \quad (2.147)$$

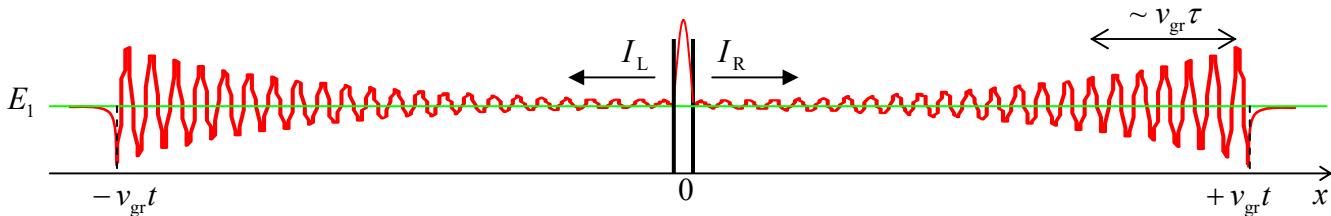

Fig. 2.17. Metastable state’s decay in the simple model of a 1D potential well formed by two low-transparent walls – schematically.

Absolutely similarly,

$$I_L = \frac{1}{\alpha^2} I_B = -I_R. \quad (2.148)$$

³⁰ This virtually evident assumption finds its formal justification in the perturbation theory to be discussed in Chapter 6.

Now we may combine the 1D version (6) of the probability conservation law for the well's interior:

$$\frac{dW}{dt} + I_R - I_L = 0, \quad (2.149)$$

with Eqs. (147)-(148) to write

$$\frac{dW}{dt} = -\frac{1}{\alpha^2} \frac{\pi n \hbar}{ma^2} W. \quad (2.150)$$

This is just the standard differential equation,

$$\boxed{\frac{dW}{dt} = -\frac{1}{\tau} W}, \quad (2.151)$$

of the exponential decay, $W(t) = W(0)\exp\{-t/\tau\}$, where the constant τ , in our case equal to

$$\tau = \frac{ma^2}{\pi n \hbar} \alpha^2, \quad (2.152)$$

is called the *metastable state's lifetime*. Using Eq. (2.33b) for the de Broglie waves' group velocity, for our particular wave vector giving $v_{gr} = \hbar k_n/m = \pi n \hbar / ma$, Eq. (152) may be rewritten in a more general form,

$$\boxed{\tau = \frac{t_a}{\mathcal{T}}}, \quad (2.153)$$

where the *attempt time* t_a is equal to a/v_{gr} , and (in our particular case) $\mathcal{T} = 1/\alpha^2$, in which it is valid for a broad class of similar metastable systems.³¹ Equality may be interpreted in the following semi-classical way. The particle travels back and forth between the confining potential barriers, with the time interval t_a between the sequential moments of incidence, each time attempting to leak through the wall, with the success probability equal to \mathcal{T} , so the reduction of W per each incidence is $\Delta W = -W\mathcal{T}$, in the limit $\alpha \gg 1$ (i.e. $\mathcal{T} \ll 1$) immediately leading to the decay equation (151) with the lifetime (153).

Another useful look at Eq. (152) may be taken by returning to the resonant tunneling problem in the same system, and expressing the resonance width (142) in terms of the incident particle's energy:

$$\Delta E = \Delta \left(\frac{\hbar^2 k^2}{2m} \right) \approx \frac{\hbar^2 k_n}{m} \Delta k = \frac{\hbar^2 k_n}{m} \frac{1}{a \alpha^2} = \frac{\pi n \hbar^2}{m a^2 \alpha^2}. \quad (2.154)$$

Comparing Eqs. (152) and (154), we get a remarkably simple, parameter-independent formula³²

$$\boxed{\Delta E \cdot \tau = \hbar}. \quad (2.155)$$

³¹ Essentially the only requirement is to have the attempt time Δt_A to be much longer than the effective time (the *instanton time*, see Sec. 5.3 below) of tunneling through the barrier. In the delta-functional approximation for the barrier, the latter time is equal to zero, so that this requirement is always fulfilled.

³² Note that the metastable state's decay (2.151) may be formally obtained from the basic Schrödinger equation (1.61) by adding an imaginary part, equal to $(-\Delta E/2)$, to its eigenenergy E_n . Indeed, in this case Eq. (1.62) becomes $a_n(t) = \text{const} \times \exp\{-i(E_n - i\Delta E/2)t/\hbar\} \equiv \text{const} \times \exp\{-iE_n t/\hbar\} \times \exp\{-\Delta E t/2\hbar\} = \text{const} \times \exp\{-iE_n t/\hbar\} \times \exp\{-t/2\tau\}$, so that $W(t) \propto |a_n(t)|^2 \propto \exp\{-t/\tau\}$. Such formalism, which hides the physical origin of the state's decay, may be convenient for some calculations, but misleading in other cases, and I will not use it in this course.

This *energy-time uncertainty relation* is certainly *more* general than our simple model; for example, it is valid for the lifetime and resonance tunneling width of any metastable state in the potential profile of any shape. This seems very natural, since because of the energy identification with frequency, $E = \hbar\omega$, typical for quantum mechanics, Eq. (155) may be rewritten as $\Delta\omega\tau = 1$ and seems to follow directly from the Fourier transform in time, just as the Heisenberg's uncertainty relation (1.35) follows from the Fourier transform in space. In some cases, these two relations are indeed interchangeable; for example, Eq. (24) for the Gaussian wave packet width may be rewritten as $\delta E \cdot \Delta t = \hbar$, where $\delta E = \hbar(d\omega/dk)\delta k = \hbar v_{\text{gr}}\delta k$ is the r.m.s. spread of energies of monochromatic components of the packet, while $\Delta t \equiv \delta x/v_{\text{gr}}$ is the time scale of packet's passage through a fixed observation point x .

However, Eq. (155) is much *less* general than Heisenberg's uncertainty relation (1.35). Indeed, in the non-relativistic quantum mechanics we are studying now, the Cartesian coordinates of a particle, the Cartesian components of its momentum, and the energy E are regular observables, represented by operators. In contrast, time is treated as a *c*-number argument, and is *not* represented by an operator, so that Eq. (155) cannot be derived in such general assumptions as Eq. (1.35). Thus the time-energy uncertainty relation should be used with caution. Unfortunately, not everybody is so careful. One can find, for example, wrong claims that due to this relation, the energy dissipated by any system performing an elementary (single-bit) calculation during a time interval Δt has to be larger than $\hbar/\Delta t$.³³ Another incorrect statement is that the energy of a system cannot be measured, during a time interval Δt , with an accuracy better than $\hbar/\Delta t$.³⁴

Now that we have a quantitative mathematical description of the metastable state's decay (valid, again, only if $\alpha \gg 1$, i.e. if $\tau \gg t_a$), we may use it for discussion of two important conceptual issues of quantum mechanics. First, this is one of the simplest examples of systems that may be considered, from two different points of view, as either Hamiltonian (and hence *time-reversible*), or open (and hence *irreversible*). Indeed, from the former point of view, our particular system is certainly described by a time-independent Hamiltonian of the type (1.41), with the potential energy

$$U(x) = w[\delta(x - x_1) + \delta(x - x_2)] \quad (2.156)$$

- see Fig. 15 again. In this point of view, the total probability of finding the particle *somewhere* on the axis x remains equal to 1, and the full system's energy, calculated from Eq. (1.23),

$$\langle E \rangle = \int_{-\infty}^{+\infty} \Psi^*(x, t) \hat{H} \Psi(x, t) d^3x, \quad (2.157)$$

remains constant and completely definite ($\delta E = 0$). On the other hand, since the "emitted" wave packets would never return to the potential well,³⁵ it makes sense to look at the well's region alone. For such a

³³ On this issue, I dare to refer the reader to my own old work K. Likharev, *Int. J. Theor. Phys.* **21**, 311 (1982), which provided a constructive proof (for a particular system) that at *reversible computation*, whose idea had been put forward in 1973 by C. Bennett (see, e.g., SM Sec. 2.3), energy dissipation may be lower than this apparent "quantum limit".

³⁴ See, e.g., a discussion of this issue in the monograph by V. Braginsky and F. Khalili, *Quantum Measurement*, Cambridge U. Press, 1992.

³⁵ For more realistic 2D and 3D systems, this statement is true even if the system as a whole is confined inside some closed volume, much larger than the potential well housing the metastable states. Indeed, if the walls

truncated, *open* system (for which the space beyond the interval $[x_1, x_2]$ serves as its *environment*), the probability W of finding the particle inside this interval, and hence its energy $\langle E \rangle = WE_n$, decay exponentially per Eq. (151) – the decay equation typical for irreversible systems. We will return to the discussion of the dynamics of such open quantum systems in Chapter 7.

Second, the same model enables a preliminary discussion of one important aspect of quantum measurements. As Eq. (151) and Fig. 17 show, at $t \gg \tau$, the well becomes virtually empty ($W \approx 0$), and the whole probability is localized in two clearly separated wave packets with equal amplitudes, moving from each other with the speed v_{gr} , each “carrying the particle away” with a probability of 50%. Now assume that an experiment has detected the particle on the left side of the well. Though the formalisms suitable for quantitative analysis of the detection process will not be discussed until Chapter 7, due to the wide separation $\Delta x = 2v_{\text{gr}}t \gg 2v_{\text{gr}}\tau$ of the packets, we may safely assume that such detection may be done without any actual physical effect on the counterpart wave packet.³⁶ But if we know that the particle has been found on the left side, there is no chance to find it on the right side. If we attributed the full wavefunction to all stages of this particular experiment, this situation might be rather confusing. Indeed, that would mean that the wavefunction at the right packet’s location should instantly turn into zero – the so-called *wave packet reduction* (or “collapse”) – a hypothetical, irreversible process that cannot be described by the Schrödinger equation for this system, even including the particle detectors.

However, if (as was already discussed in Sec. 1.3) we attribute the wavefunction to a certain statistical ensemble of similar experiments, there is no need to involve such an artificial notion. The two-packet picture we have calculated (Fig. 17) describes the full ensemble of experiments with all systems prepared in the initial state (143), i.e. does not depend on the particle detection results. On the other hand, the “reduced packet” picture (with no wave packet on the right of the well) describes only a sub-ensemble of such experiments, in which the particles have been detected on the left side. As was discussed on classical examples in Sec. 1.3, for such redefined ensemble the probability distribution is rather different. So, the “wave packet reduction” is just a result of a purely accounting decision of the observer.³⁷ I will return to this important discussion in Sec. 10.1 – on the basis of the forthcoming discussion of open systems in Chapters 7 and 8.

2.6. Localized state coupling, and quantum oscillations

Now let us discuss one more effect specific to quantum mechanics. Its mathematical description may be simplified using a model potential consisting of two very short and deep potential wells. For that, let us first analyze the properties of a single well of this type (Fig. 18), which may be modeled similarly to the short and high potential barrier – see Eq. (74), but with a negative “weight”:

$$U(x) = -w\delta(x), \quad \text{with } w > 0. \quad (2.158)$$

providing such confinement are even slightly uneven, the emitted plane-wave packets will be reflected from them, but would never return to the well intact. (See SM Sec. 2.1 for a more detailed discussion of this issue.)

³⁶ This argument is especially convincing if the particle’s detection time is much shorter than the time $t_c = 2v_{\text{gr}}t/c$, where c is the speed of light in vacuum, i.e. the maximum velocity of any information transfer.

³⁷ “The collapse of the wavefunction after measurement represents nothing more than the updating of that scientist’s expectations.” N. D. Mermin, *Phys. Today*, **72**, 53 (Jan. 2013).

In contrast to its tunnel-barrier counterpart (74), such potential sustains a stationary state with a negative eigenenergy $E < 0$, and a *localized* eigenfunction ψ , with $|\psi| \rightarrow 0$ at $x \rightarrow \pm\infty$.

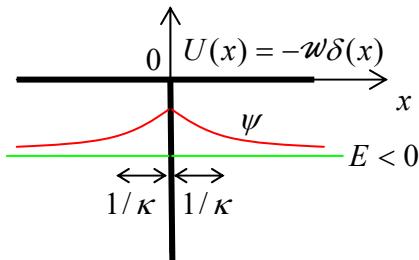

Fig. 2.18. Delta-functional potential well and its localized eigenstate (schematically).

Indeed, at $x \neq 0$, $U(x) = 0$, so the 1D Schrödinger equation is reduced to the Helmholtz equation (1.83), whose localized solutions with $E < 0$ are single exponents, vanishing at large distances:³⁸

$$\psi(x) = \psi_0(x) \equiv \begin{cases} Ae^{-\kappa x}, & \text{for } x > 0, \\ Ae^{+\kappa x}, & \text{for } x < 0, \end{cases} \quad \text{with } \frac{\hbar^2 \kappa^2}{2m} = -E, \quad \kappa > 0. \quad (2.159)$$

(The coefficients before the exponents have been selected equal to satisfy the boundary condition (76) of the wavefunction's continuity at $x = 0$.) Plugging Eq. (159) into the second boundary condition, given by Eq. (75), but now with the negative sign before w , we get

$$(-\kappa A) - (+\kappa A) = -\frac{2m w}{\hbar^2} A, \quad (2.160)$$

in which the common factor $A \neq 0$ may be canceled. This equation³⁹ has one solution for any $w > 0$:

$$\kappa = \kappa_0 \equiv \frac{m w}{\hbar^2}, \quad (2.161)$$

and hence the system has only one (ground) localized state, with the following eigenenergy:⁴⁰

$$E = E_0 \equiv -\frac{\hbar^2 \kappa_0^2}{2m} = -\frac{m w^2}{2\hbar^2}. \quad (2.162)$$

Now we are ready to analyze localized states of the two-well potential shown in Fig. 19:

$$U(x) = -w \left[\delta\left(x - \frac{a}{2}\right) + \delta\left(x + \frac{a}{2}\right) \right], \quad \text{with } w > 0. \quad (2.163)$$

Here we may still use the single-exponent solutions, similar to Eq. (159), for the wavefunction outside the interval $[-a/2, +a/2]$, but inside the interval, we need to take into account both possible exponents:

$$\psi = C_+ e^{\kappa x} + C_- e^{-\kappa x} \equiv C_A \sinh \kappa x + C_S \cosh \kappa x, \quad \text{for } -\frac{a}{2} \leq x \leq +\frac{a}{2}, \quad (2.164)$$

³⁸ See Eqs. (56)-(58), with $U_0 = 0$.

³⁹ Such algebraic equations for linear differential equations are frequently called *characteristic*.

⁴⁰ Note that this E_0 is equal, by magnitude, to the constant E_0 that participates in Eq. (79). Note also that this result was actually already obtained, “backward”, in the solution of Problem 1.12(ii), but that solution did not address the issue of whether the calculated potential (158) could sustain any other localized eigenstates.

with the parameter κ defined as in Eq. (159). The last of these equivalent expressions is more convenient because due to the symmetry of the potential (163) to the central point $x = 0$, the system's eigenfunctions should be either symmetric (even) or antisymmetric (odd) functions of x (see Fig. 19), so that they may be analyzed separately, only for one half of the system, say $x \geq 0$, and using just one of the hyperbolic function (164) in each case.

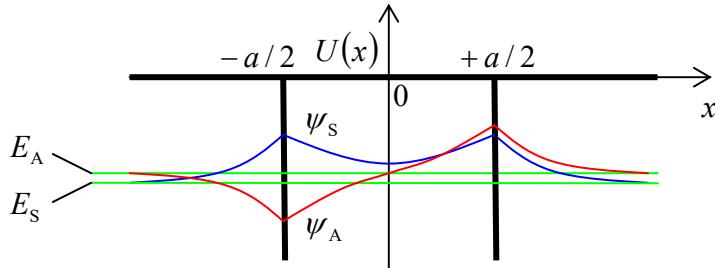

Fig. 2.19. A system of two coupled potential wells, and its localized eigenstates (schematically).

For the *antisymmetric* eigenfunction, Eqs. (159) and (164) yield

$$\psi_A \equiv C_A \times \begin{cases} \sinh \kappa x, & \text{for } 0 \leq x \leq \frac{a}{2}, \\ \sinh \frac{\kappa a}{2} \exp\left\{-\kappa\left(x - \frac{a}{2}\right)\right\}, & \text{for } \frac{a}{2} \leq x, \end{cases} \quad (2.165)$$

where the front coefficient in the lower line has been selected to satisfy the condition (76) of the wavefunction's continuity at $x = +a/2$ – and hence at $x = -a/2$. What remains is to satisfy the condition (75), with a negative sign before w , for the derivative's jump at that point. This condition yields the following characteristic equation:

$$\sinh \frac{\kappa a}{2} + \cosh \frac{\kappa a}{2} = \frac{2m w}{\hbar^2 \kappa} \sinh \frac{\kappa a}{2}, \quad \text{i.e. } 1 + \coth \frac{\kappa a}{2} = 2 \frac{(\kappa_0 a)}{(\kappa a)}, \quad (2.166)$$

where κ_0 , given by Eq. (161), is the value of κ for a single well, i.e. the reciprocal spatial width of its localized eigenfunction – see Fig. 18.

Figure 20a shows both sides of Eq. (166) as functions of the dimensionless product κa , for several values of the parameter $\kappa_0 a$, i.e. of the normalized distance between the two wells. The plots show, first of all, that as the parameter $\kappa_0 a$ is decreased, the LHS and RHS plots cross (i.e. Eq. (166) has a solution) at lower and lower values of κa . At $\kappa a \ll 1$, the left-hand side of the last form of this equation may be approximated as $2/\kappa a$. Comparing this expression with the right-hand side of the characteristic equation, we see that this transcendental equation has a solution (i.e. the system has an antisymmetric localized state) only if $\kappa_0 a > 1$, i.e. if the distance a between the two narrow potential wells is larger than the following value,

$$a_{\min} = \frac{1}{\kappa_0} \equiv \frac{\hbar^2}{m w}, \quad (2.167)$$

which is equal to the characteristic spread of the wavefunction in a single well – see Fig. 18. (At $a \rightarrow a_{\min}$, $\kappa a \rightarrow 0$, meaning that the state's localization becomes weaker and weaker.)

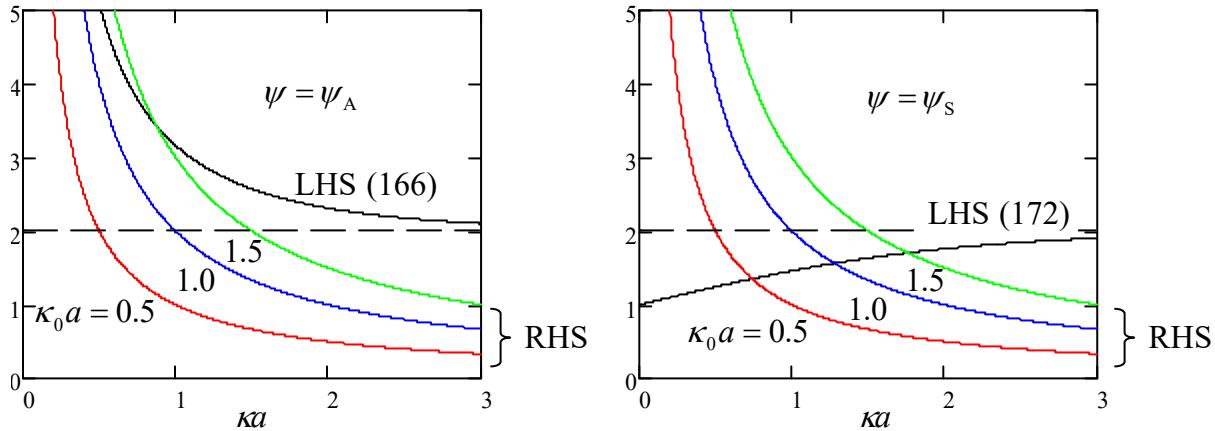

Fig. 2.20. Graphical solutions of the characteristic equations of the two-well system, for:
(a) the antisymmetric eigenstate (165), and (b) the symmetric eigenstate (171).

In the opposite limit of large distances between the potential wells, i.e. $\kappa_0 a \gg 1$, Eq. (166) shows that $\kappa a \gg 1$ as well, so that its left-hand side may be approximated as $2(1 + \exp\{-\kappa a\})$, and the equation yields

$$\kappa \approx \kappa_0 (1 - \exp\{-\kappa_0 a\}) \approx \kappa_0 . \quad (2.168)$$

This result means that the eigenfunction is an antisymmetric superposition of two virtually unperturbed wavefunctions (159) of each partial potential well:

$$\psi_A(x) \approx \frac{1}{\sqrt{2}} [\psi_R(x) - \psi_L(x)], \quad \text{where } \psi_R(x) \equiv \psi_0\left(x - \frac{a}{2}\right), \quad \psi_L(x) \equiv \psi_0\left(x + \frac{a}{2}\right), \quad (2.169)$$

and the front coefficient is selected in such a way that if the eigenfunction ψ_0 of each well is normalized, so is ψ_A . Plugging the middle (more exact) form of Eq. (168) into the last of Eqs. (159), we can see that in this limit the antisymmetric state's energy is only slightly higher than the eigenenergy E_0 of a single well, given by Eq. (162):

$$E_A \approx E_0 (1 - 2 \exp\{-\kappa_0 a\}) \equiv E_0 + \delta, \quad \text{where } \delta \equiv \frac{2m\omega^2}{\hbar^2} \exp\{-\kappa_0 a\} > 0 . \quad (2.170)$$

The *symmetric* eigenfunction has a form reminding Eq. (165), but still different from it:

$$\psi = \psi_S \equiv C_S \times \begin{cases} \cosh \kappa x, & \text{for } 0 \leq x \leq \frac{a}{2}, \\ \cosh \frac{\kappa a}{2} \exp\left\{-\kappa\left(x - \frac{a}{2}\right)\right\}, & \text{for } \frac{a}{2} \leq x, \end{cases} \quad (2.171)$$

giving a characteristic equation similar in structure to Eq. (166), but with a different left-hand side:

$$1 + \tanh \frac{\kappa a}{2} = 2 \frac{(\kappa_0 a)}{(\kappa a)} . \quad (2.172)$$

Figure 20b shows both sides of this equation for several values of the parameter $\kappa_0 a$. It is evident that in contrast to Eq. (166), Eq. (172) has a unique solution (and hence the system has a localized symmetric

eigenstate) for *any* value of the parameter $\kappa_0 a$, i.e. for any distance between the partial wells. In the limit of very close wells (i.e. their strong coupling), $\kappa_0 a \ll 1$, we get $\kappa a \ll 1$, $\tanh(\kappa a/2) \rightarrow 0$, and Eq. (172) yields $\kappa \rightarrow 2\kappa_0$, leading to a four-fold increase of the eigenenergy's magnitude in comparison with that of the single well:

$$E_S \approx 4E_0 \equiv -\frac{m(2w)^2}{2\hbar^2}, \quad \text{for } \kappa_0 a \ll 1. \quad (2.173)$$

The physical meaning of this result is very simple: two very close potential wells act (on the symmetric eigenfunction only!) together, so that their “weights” $w \equiv \int U(x)dx$ just add up.

In the opposite, weak coupling limit, i.e. $\kappa_0 a \gg 1$, Eq. (172) shows that $\kappa a \gg 1$ as well, so that its left-hand side may be approximated as $2(1 - \exp\{-\kappa a\})$, and the equation yields

$$\kappa \approx \kappa_0 (1 + \exp\{-\kappa_0 a\}) \approx \kappa_0. \quad (2.174)$$

In this limit, the eigenfunction is a symmetric superposition of two virtually unperturbed wavefunctions (159) of each partial potential well:

$$\psi_S(x) \approx \frac{1}{\sqrt{2}} [\psi_R(x) + \psi_L(x)], \quad (2.175)$$

and the eigenenergy is also close to the energy E_0 of a partial well, but is slightly lower:

$$E_S \approx E_0 (1 + 2 \exp\{-\kappa_0 a\}) \equiv E_0 - \delta, \quad \text{so that } E_A - E_S = 2\delta, \quad (2.176)$$

where δ is again given by the last of Eqs. (170).

So, the eigenenergy of the symmetric state is always lower than that of the antisymmetric state. The physics of this effect (which remains qualitatively the same in more complex two-component systems, most importantly in diatomic molecules such as H₂) is evident from the sketch of the wavefunctions ψ_A and ψ_S , given by Eqs. (165) and (171), in Fig. 19. In the antisymmetric mode, the wavefunction has to vanish at the center of the system, so that each its half is squeezed to one half of the system's spatial extension. Such a squeeze increases the function's gradient, and hence its kinetic energy (1.27), and hence its total energy. On the contrary, in the symmetric mode, the wavefunction effectively spreads into the counterpart well. As a result, it changes in space slower, and hence its kinetic energy is also lower.

Even more importantly, the symmetric state's energy decreases as the distance a is decreased, corresponding to the effective attraction of the partial wells. This is a good toy model of the strongest (and most important) type of atomic cohesion – the *covalent* (or “chemical”) *bonding*.⁴¹ In the simplest case of the H₂ molecule, each of two electrons of the system, in its ground state,⁴² reduces its kinetic energy by spreading its wavefunction around both hydrogen nuclei (protons), rather than being confined near one of them – as it had to be in a single atom. The resulting bonding is very strong: in chemical units, 429 kJ/mol, i.e. 18.6 eV per molecule. Perhaps counter-intuitively, this quantum-mechanical

⁴¹ Historically, the development of the quantum theory of such bonding in the H₂ molecule (by Walter Heinrich Heitler and Fritz Wolfgang London in 1927) was the breakthrough decisive for the acceptance of the then-emerging quantum mechanics by the community of chemists.

⁴² Due to the opposite spins of these electrons, the Pauli principle allows them to be in the same orbital ground state – see Chapter 8.

covalent bonding is even stronger than the strongest classical (*ionic*) bonding due to electron transfer between atoms, leading to the Coulomb attraction of the resulting ions. (For example, the atomic cohesion in the NaCl molecule is just 3.28 eV.)

Now let us analyze the dynamic properties of our model system (Fig. 19) because such a pair of weakly coupled potential wells is our first example of the very important class of *two-level systems*.⁴³ It is easiest to do in the weak-coupling limit $\kappa_0 a \gg 1$, when the simple results (168)-(170) and (174)-(176) are quantitatively valid. In particular, Eqs. (169) and (175) enable us to represent the quasi-localized states of the particle in each partial well as linear combinations of its two eigenstates:

$$\psi_R(x) = \frac{1}{\sqrt{2}} [\psi_S(x) + \psi_A(x)], \quad \psi_L(x) = \frac{1}{\sqrt{2}} [\psi_S(x) - \psi_A(x)]. \quad (2.177)$$

Let us perform the following thought (“gedanken”) experiment: place a particle, at $t = 0$, into one of these quasi-localized states, say $\psi_R(x)$, and leave the system alone to evolve, so that

$$\Psi(x, 0) = \psi_R(x) = \frac{1}{\sqrt{2}} [\psi_S(x) + \psi_A(x)]. \quad (2.178)$$

According to the general solution (1.69) of the time-independent Schrödinger equation, the time dynamics of this wavefunction may be obtained simply by multiplying each eigenfunction by the corresponding complex-exponential time factor:

$$\Psi(x, t) = \frac{1}{\sqrt{2}} \left[\psi_S(x) \exp\left\{-i \frac{E_S}{\hbar} t\right\} + \psi_A(x) \exp\left\{-i \frac{E_A}{\hbar} t\right\} \right]. \quad (2.179)$$

From here, using Eqs. (170) and (176), and then Eqs. (169) and (175) again, we get

$$\begin{aligned} \Psi(x, t) &= \frac{1}{\sqrt{2}} \left(\psi_S(x) \exp\left\{\frac{i\delta t}{\hbar}\right\} + \psi_A(x) \exp\left\{-\frac{i\delta t}{\hbar}\right\} \right) \exp\left\{-\frac{iE_0 t}{\hbar}\right\} \\ &= \left(\psi_R(x) \cos \frac{\delta t}{\hbar} + i \psi_L(x) \sin \frac{\delta t}{\hbar} \right) \exp\left\{-i \frac{E_0 t}{\hbar}\right\}. \end{aligned} \quad (2.180)$$

This result implies, in particular, that the probabilities W_R and W_L to find the particle, respectively, in the right and left wells change with time as

$$W_R = \cos^2 \frac{\delta t}{\hbar}, \quad W_L = \sin^2 \frac{\delta t}{\hbar},$$

(2.181)

Quantum oscillations

mercifully leaving the total probability constant: $W_R + W_L = 1$. (If our calculation had not passed this sanity check, we would be in big trouble.)

This is the famous effect of *quantum oscillations*⁴⁴ of the particle’s wavefunction between two similar, coupled subsystems, with the frequency

⁴³ As we will see later in Chapter 4, these properties are similar to those of spin-½ particles; hence two-level systems are frequently called the *spin-½-like* systems.

⁴⁴ Sometimes they are called the *Bloch oscillations*, but more commonly the last term is reserved for a related but different effect in spatially-periodic systems – to be discussed in Sec. 8 below.

$$\omega = \frac{2\delta}{\hbar} \equiv \frac{E_A - E_S}{\hbar}. \quad (2.182)$$

In its last form, this result does not depend on the assumption of weak coupling, though the simple form (181) of the oscillations, with its 100% probability variations, does. (Indeed, at a strong coupling of two subsystems, the very notion of the quasi-localized states ψ_R and ψ_L is ambiguous.) Qualitatively, this effect may be interpreted as follows: the particle, placed into one of the potential wells, tries to escape from it via tunneling through the potential barrier separating the wells. (In our particular system, shown in Fig. 17, the barrier is formed by the spatial segment of length a , which has the potential energy, $U = 0$, higher than the eigenstate energy $-E_0$.) However, in the two-well system, the particle can only escape into the adjacent well. After the tunneling into that counterpart well, the particle tries to escape from it, and hence comes back, etc. – very much as a classical 1D oscillator, initially deflected from its equilibrium position, at negligible damping.

Some care is required at using such interpretation for quantitative conclusions. In particular, let us compare the period $\mathcal{T} \equiv 2\pi/\omega$ of the oscillations (181) with the metastable state's lifetime discussed in the previous section. For our particular model, we may use the second of Eqs. (170) to write

$$\omega = \frac{4|E_0|}{\hbar} \exp\{-\kappa_0 a\}, \quad \mathcal{T} = \frac{\pi\hbar}{\delta} = \frac{\pi\hbar}{2|E_0|} \exp\{\kappa_0 a\} \equiv \frac{t_a}{2} \exp\{\kappa_0 a\}, \quad \text{for } \kappa_0 a \gg 1, \quad (2.183)$$

where $t_a \equiv 2\pi/\omega_0 \equiv 2\pi\hbar/|E_0|$ is the effective attempt time. On the other hand, according to Eq. (80), the transparency \mathcal{T} of our potential barrier, in this limit, scales as $\exp\{-2\kappa_0 a\}$,⁴⁵ so that according to the general relation (153), the lifetime τ is of the order of $t_a \exp\{2\kappa_0 a\} \gg \mathcal{T}$. This is a rather counter-intuitive result: the speed of particle tunneling into a similar adjacent well is much higher than that, through a similar barrier, to the free space!

In order to show that this important result is not an artifact of our delta-functional model of the potential barrier, and also compare \mathcal{T} and τ more directly, let us analyze the quantum oscillations between two weakly coupled wells, now assuming that the (symmetric) potential profile $U(x)$ is sufficiently soft (Fig. 21), so that all its eigenfunctions ψ_S and ψ_A are at least differentiable at all points.⁴⁶ If the barrier's transparency is low, the quasi-localized wavefunctions $\psi_R(x)$ and $\psi_L(x) = \psi_R(-x)$ and their eigenenergies may be found approximately by solving the Schrödinger equations in one of the wells, neglecting the tunneling through the barrier, but the calculation of δ requires a little bit more care. Let us write the stationary Schrödinger equations for the symmetric and antisymmetric solutions in the form

$$[E_A - U(x)]\psi_A = -\frac{\hbar^2}{2m} \frac{d^2\psi_A}{dx^2}, \quad [E_S - U(x)]\psi_S = -\frac{\hbar^2}{2m} \frac{d^2\psi_S}{dx^2}, \quad (2.184)$$

⁴⁵ It is hard to use Eq. (80) for a more exact evaluation of \mathcal{T} in our current system, with its infinitely deep potential wells, because the meaning of the wave number k is not quite clear. However, this is not too important, because in the limit $\kappa_0 a \gg 1$, the tunneling exponent makes the dominant contribution into the transparency – see, again, Fig. 2.7b.

⁴⁶ Such a smooth well may have more than one quasi-localized eigenstate, so that the proper state (and energy) index n is implied in all remaining formulas of this section.

multiply the former equation by ψ_S and the latter one by ψ_A , subtract them from each other, and then integrate the result from 0 to ∞ . The result is

$$(E_A - E_S) \int_0^\infty \psi_S \psi_A dx = \frac{\hbar^2}{2m} \int_0^\infty \left(\frac{d^2 \psi_S}{dx^2} \psi_A - \frac{d^2 \psi_A}{dx^2} \psi_S \right) dx. \quad (2.185)$$

If $U(x)$, and hence $d^2 \psi_{A,S}/dx^2$, are finite for all x , we may integrate the right-hand side by parts to get

$$(E_A - E_S) \int_0^\infty \psi_S \psi_A dx = \frac{\hbar^2}{2m} \left(\frac{d\psi_S}{dx} \psi_A - \frac{d\psi_A}{dx} \psi_S \right)_0^\infty. \quad (2.186)$$

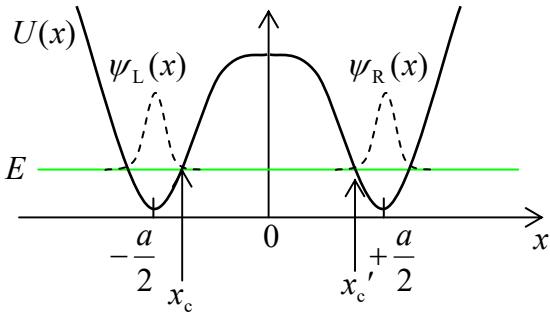

Fig. 2.21. Weak coupling between two similar, soft potential wells.

So far, this result is exact (provided that the derivatives participating in it are finite at each point); for *weakly* coupled wells, it may be further simplified. Indeed, in this case, the left-hand side of Eq. (186) may be approximated as

$$(E_A - E_S) \int_0^\infty \psi_S \psi_A dx \approx \frac{E_A - E_S}{2} \equiv \delta, \quad (2.187)$$

because this integral is dominated by the vicinity of point $x = a/2$, where the second terms in each of Eqs. (169) and (175) are negligible, and the integral is equal to $1/2$, assuming the proper normalization of the function $\psi_R(x)$. On the right-hand side of Eq. (186), the substitution at $x = \infty$ vanishes (due to the wavefunction's decay in the classically forbidden region), and so does the first term at $x = 0$, because for the antisymmetric solution, $\psi_A(0) = 0$. As a result, the energy half-split δ may be expressed in any of the following (equivalent) forms:

$$\delta = \frac{\hbar^2}{2m} \psi_S(0) \frac{d\psi_A}{dx}(0) = \frac{\hbar^2}{m} \psi_R(0) \frac{d\psi_R}{dx}(0) = -\frac{\hbar^2}{m} \psi_L(0) \frac{d\psi_L}{dx}(0). \quad (2.188)$$

It is straightforward (and hence left for the reader's exercise) to show that within the limits of the WKB approximation's validity, Eq. (188) may be reduced to

$$\delta = \frac{\hbar}{t_a} \exp \left\{ - \int_{x_c}^{x_c'} \kappa(x') dx' \right\}, \quad \text{so that } \tau \equiv \frac{\pi \hbar}{\delta} = \frac{t_a}{2} \exp \left\{ \int_{x_c}^{x_c'} \kappa(x') dx' \right\}, \quad (2.189)$$

where t_a is the time period of the classical motion of the particle, with the energy $E \approx E_A \approx E_S$, inside each well, the function $\kappa(x)$ is defined by Eq. (82), and x_c and x_c' are the classical turning points limiting the potential barrier at the level E of the particle's eigenenergy – see Fig. 21. The result (189) is evidently a natural generalization of Eq. (183), so that the strong relationship between the times of

particle tunneling into the continuum of states and into a discrete eigenstate, is indeed not specific for the delta-functional model. We will return to this fact, in its more general form, at the end of Chapter 6.

2.7. Periodic systems: Energy bands and gaps

Let us now proceed to the discussion of one of the most important issues of wave mechanics: particle motion through a periodic system. As a precursor to this discussion, let us calculate the transparency of the potential profile shown in Fig. 22 (frequently called the *Dirac comb*): a sequence of N similar, equidistant delta-functional potential barriers, separated by $(N - 1)$ potential-free intervals a .

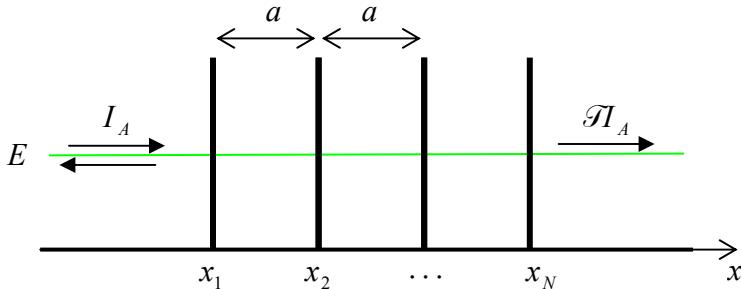

Fig. 2.22. Tunneling through a Dirac comb: a system of N similar, equidistant barriers, i.e. $(N - 1)$ similar coupled potential wells.

According to Eq. (132), its transfer matrix is the following product

$$T = \underbrace{T_\alpha T_a T_\alpha \dots T_a T_\alpha}_{(N-1)+N \text{ terms}}, \quad (2.190)$$

with the component matrices given by Eqs. (135) and (138), and the barrier height parameter α defined by the last of Eqs. (78). Remarkably, this multiplication may be carried out analytically,⁴⁷ giving

$$\mathcal{T} \equiv |T_{11}|^{-2} = \left[(\cos Nqa)^2 + \left(\frac{\sin ka - \alpha \cos ka}{\sin qa} \sin Nqa \right)^2 \right]^{-1}, \quad (2.191a)$$

where q is a new parameter, with the wave number dimensionality, defined by the following relation:

$$\cos qa \equiv \cos ka + \alpha \sin ka. \quad (2.191b)$$

For $N = 1$, Eqs. (191) immediately yield our old result (79), while for $N = 2$ they may be readily reduced to Eq. (141) – see Fig. 16a. Fig. 20 shows its predictions for two larger numbers N , and several values of the dimensionless parameter α .

Let us start the discussion of the plots from the case $N = 3$, when three barriers limit two coupled potential wells between them. Comparison of Fig. 23a and Fig. 16a shows that the transmission patterns, and their dependence on the parameter α , are very similar, besides that in the coupled-well system, each resonant tunneling peak splits into two, with the ka -difference between them scaling as $1/\alpha$. From the discussion in the last section, we may now readily interpret this result: each pair of resonance peaks of transparency corresponds to the alignment of the incident particle's energy E with the pair of energy levels E_A, E_S of the symmetric and antisymmetric states of the system. However, in contrast to the

⁴⁷ This formula will be easier to prove after we have discussed the properties of Pauli matrices in Chapter 4.

system shown in Fig. 19, these states are metastable, because the particle may leak out from these states just as it could in the system studied in Sec. 5 – see Fig. 15 and its discussion. As a result, each of the resonant peaks has a non-zero energy width ΔE , obeying Eq. (155).

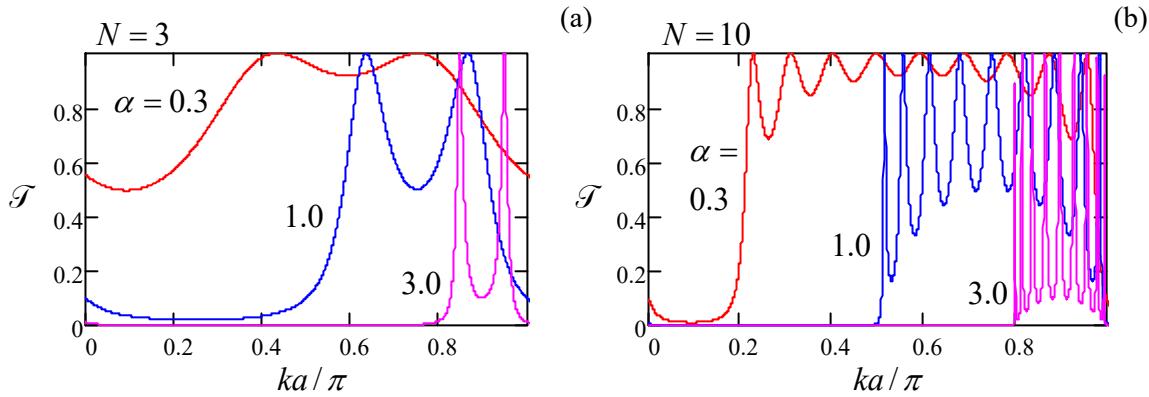

Fig. 2.23. The Dirac comb's transparency as a function of the product ka for three values of α . Since the function $\mathcal{T}(ka)$ is π -periodic (just like it is for $N = 2$, see Fig. 16a), only one period is shown.

A further increase of N (see Fig. 23b) results in the increase of the number of resonant peaks per period to $(N - 1)$, and at $N \rightarrow \infty$ the peaks merge into the so-called *allowed energy bands* (frequently called just the “energy bands”) with average transparency $\mathcal{T} \sim 1$, separated from similar bands in the adjacent periods of function $\mathcal{T}(ka)$ by *energy gaps*⁴⁸ where $\mathcal{T} \rightarrow 0$. Notice the following important features of the pattern:

- (i) at $N \rightarrow \infty$, the band/gap edges become sharp for any α , and tend to fixed positions (determined by α but independent of N);
- (ii) the larger is well coupling (the smaller is α), the broader are the allowed energy bands and the narrower are the gaps between them.

Our previous discussion of the resonant tunneling gives us a clue for a semi-quantitative interpretation of this pattern: if $(N - 1)$ potential wells are weakly coupled by tunneling through the potential barriers separating them, the system's energy spectrum consists of groups of $(N - 1)$ metastable energy levels, each group being close to one of the unperturbed eigenenergies of the well. (According to Eq. (1.84), for our current example shown in Fig. 22, with its rectangular potential wells, these eigenenergies correspond to $k_n a = \pi n$.)

Now let us recall that in the case $N = 2$, analyzed in the previous section, the eigenfunctions (169) and (175) differed only by the phase shift $\Delta\varphi$ between their localized components $\psi_R(x)$ and $\psi_L(x)$, with $\Delta\varphi = 0$ for one of them (ψ_S) and $\Delta\varphi = \pi$ for its counterpart. Hence it is natural to expect that for other N as well, each metastable energy level corresponds to an eigenfunction that is a superposition of similar localized functions in each potential well, but with certain phase shifts $\Delta\varphi$ between them.

Moreover, we may expect that at $N \rightarrow \infty$, i.e. for *periodic structures*,⁴⁹ with

⁴⁸ In solid-state (especially semiconductor) physics and electronics, the term *bandgaps* is more common.

⁴⁹ This is a reasonable 1D model, for example, for solid-state crystals, whose samples may feature up to $\sim 10^9$ similar atoms or molecules in each direction of the crystal lattice.

$$U(x+a) = U(x), \quad (2.192)$$

when the system does not have the ends that could affect its properties, the phase shifts $\Delta\varphi$ between the localized wavefunctions in all couples of adjacent potential wells should be equal, i.e.

$$\psi(x+a) = \psi(x)e^{i\Delta\varphi} \quad (2.193a)$$

for all x .⁵⁰ This equality is the (1D version of the) much-celebrated *Bloch theorem*.⁵¹ Mathematical rigor aside,⁵² it is a virtually evident fact because the particle's density $w(x) = \psi^*(x)\psi(x)$, which has to be periodic in this a -periodic system, may be so only if $\Delta\varphi$ is constant. For what follows, it is more convenient to represent the real constant $\Delta\varphi$ in the form qa , so that the Bloch theorem takes the form

Bloch
theorem:
1D version

$$\psi(x+a) = \psi(x)e^{iqa}. \quad (2.193b)$$

The physical sense of the parameter q will be discussed in detail below, but we may immediately notice that according to Eq. (193b), an addition of $(2\pi/a)$ to this parameter yields the same wavefunction; hence all observables have to be $(2\pi/a)$ -periodic functions of q .⁵³

Now let us use the Bloch theorem to calculate the eigenfunctions and eigenenergies for the infinite version of the system shown in Fig. 22, i.e. for an infinite set of delta-functional potential barriers – see Fig. 24.

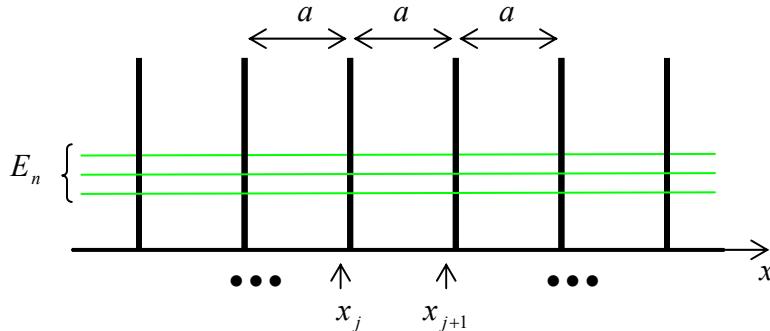

Fig. 2.24. The simplest periodic potential: an infinite Dirac comb.

To start, let us consider two points separated by one period a : one of them, x_j , just left of the position of one of the barriers, and another one, x_{j+1} , just left of the following barrier – see Fig. 24 again.

⁵⁰ A reasonably fair classical image of $\Delta\varphi$ is the geometric angle between similar objects – e.g., similar paper clips – attached at equal distances to a long, uniform rubber band. If the band's ends are twisted, the twist is equally distributed between the structure's periods, representing the constancy of $\Delta\varphi$. (I have to confess that, due to the lack of time, this was the only “lecture demonstration” in my Stony Brook QM courses.)

⁵¹ Named after F. Bloch who applied this concept to the wave mechanics in 1929, i.e. very soon after its formulation. Note, however, that an equivalent statement in mathematics, called the *Floquet theorem*, has been known since at least 1883.

⁵² I will recover this rigor in two steps. Later in this section, we will see that the function obeying Eq. (193) is indeed a solution to the Schrödinger equation. However, to save time/space, it will be better for us to postpone until Chapter 4 the proof that *any* eigenfunction of the equation, with periodic boundary conditions, obeys the Bloch theorem. As a partial reward for this delay, that proof will be valid for an arbitrary spatial dimensionality.

⁵³ The product $\hbar q$, which has the dimensionality of linear momentum, is called either the *quasimomentum* or (especially in solid-state physics) the “crystal momentum” of the particle. Informally, it is very convenient (and common) to use the name “quasimomentum” for the bare q as well, despite its evidently different dimensionality.

The eigenfunctions at each of the points may be represented as linear superpositions of two simple waves $\exp\{\pm ikx\}$, and the amplitudes of their components should be related by a 2×2 transfer matrix T of the potential fragment separating them. According to Eq. (132), this matrix may be found as the product of the matrix (135) of one delta-functional barrier by the matrix (138) of one zero-potential interval a :

$$\begin{pmatrix} A_{j+1} \\ B_{j+1} \end{pmatrix} = T_a T_\alpha \begin{pmatrix} A_j \\ B_j \end{pmatrix} = \begin{pmatrix} e^{ika} & 0 \\ 0 & e^{-ika} \end{pmatrix} \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix} \begin{pmatrix} A_j \\ B_j \end{pmatrix}. \quad (2.194)$$

However, according to the Bloch theorem (193b), the component amplitudes should be also related as

$$\begin{pmatrix} A_{j+1} \\ B_{j+1} \end{pmatrix} = e^{iqa} \begin{pmatrix} A_j \\ B_j \end{pmatrix} \equiv \begin{pmatrix} e^{iqa} & 0 \\ 0 & e^{iqa} \end{pmatrix} \begin{pmatrix} A_j \\ B_j \end{pmatrix}. \quad (2.195)$$

The condition of self-consistency of these two equations gives the following characteristic equation:

$$\left| \begin{pmatrix} e^{ika} & 0 \\ 0 & e^{-ika} \end{pmatrix} \begin{pmatrix} 1-i\alpha & -i\alpha \\ i\alpha & 1+i\alpha \end{pmatrix} - \begin{pmatrix} e^{iqa} & 0 \\ 0 & e^{iqa} \end{pmatrix} \right| = 0. \quad (2.196)$$

In Sec. 5, we have already calculated the matrix product participating in this equation – see the second operand in Eq. (140). Using it, we see that Eq. (196) is reduced to the same simple Eq. (191b) that has jumped at us from the solution of the somewhat different (resonant tunneling) problem. Let us explore that simple result in detail. First of all, the left-hand side of Eq. (191b) is a sinusoidal function of the product qa with unit amplitude, while its right-hand side is a sinusoidal function of the product ka , with amplitude $(1 + \alpha^2)^{1/2} > 1$ – see Fig. 25,

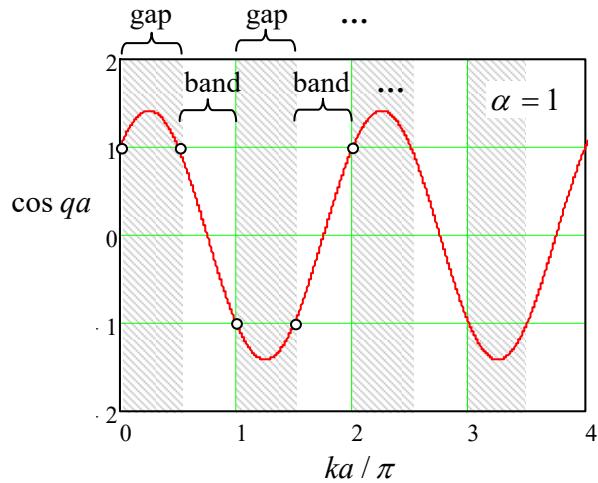

Fig. 2.25. The graphical representation of the characteristic equation (191b) for a fixed value of the parameter α . The ranges of ka that yield $|\cos qa| < 1$, correspond to allowed energy bands, while those with $|\cos qa| > 1$, correspond to energy gaps between them.

As a result, within each half-period $\Delta(ka) = \pi$ of the right-hand side, there is an interval where the magnitude of the right-hand side is larger than 1, so that the characteristic equation does not have a real solution for q . These intervals correspond to the energy gaps (see Fig. 23 again), while the complementary intervals of ka , where a real solution for q exists, correspond to the allowed energy bands. In contrast, the parameter q can take *any* real values, so it is more convenient to plot the eigenenergy $E = \hbar^2 k^2 / 2m$ as the function of the quasimomentum $\hbar q$ (or, even more conveniently, of the

dimensionless parameter qa) rather than ka .⁵⁴ Before doing that, we need to recall that the parameter α , defined by the last of Eqs. (78), depends on the wave vector k as well, so that if we vary q (and hence k), it is better to characterize the structure by another, k -independent dimensionless parameter, for example

$$\beta \equiv (ka)\alpha \equiv \frac{w}{\hbar^2 / ma}, \quad (2.197)$$

so that our characteristic equation (191b) becomes

Dirac comb:
 q vs k

$$\cos qa \equiv \cos ka + \beta \frac{\sin ka}{ka}. \quad (2.198)$$

Fig. 26 shows the plots of k and E , following from Eq. (198), as functions of qa , for a particular, moderate value of the parameter β . The first evident feature of the pattern is the 2π -periodicity of the pattern in the argument qa , which we have already predicted from the general Bloch theorem arguments. (Due to this periodicity, the complete band/gap pattern may be studied, for example, on just one interval $-\pi \leq qa \leq +\pi$, called the *1st Brillouin zone* – the so-called *reduced zone picture*. For some applications, however, it is more convenient to use the *extended zone picture* with $-\infty \leq qa \leq +\infty$ – see, e.g., the next section.)

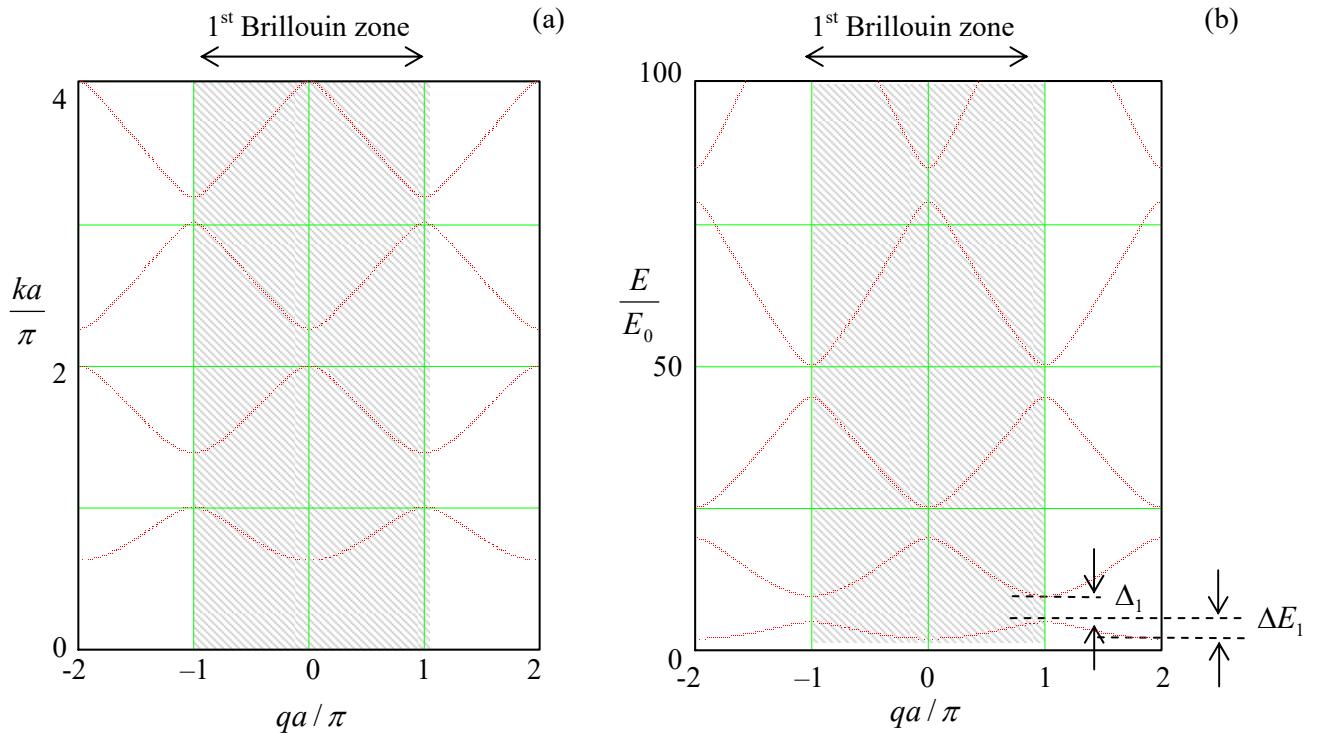

Fig. 2.26. (a) The “genuine” momentum k of a particle in an infinite Dirac comb (Fig. 24), and (b) its energy $E = \hbar^2 k^2 / 2m$ (in the units of $E_0 \equiv \hbar^2 / 2ma^2$), as functions of normalized quasimomentum, for a particular value ($\beta = 3$) of the dimensionless parameter defined by Eq. (197). Arrows in the lower right corner of panel (b) illustrate the definition of energy band (ΔE_n) and energy gap (Δ_n) widths.

⁵⁴ A more important reason for taking q as the argument is that for a general periodic potential $U(x)$, the particle’s momentum $\hbar k$ is not uniquely related to E , while (according to the Bloch theorem) the quasimomentum $\hbar q$ is.

However, maybe the most important fact, clearly visible in Fig. 26, is that there is an infinite number of energy bands, with different energies $E_n(q)$ for the same value of q . Mathematically, it is evident from Eq. (198) – or alternatively from Fig. 25. Indeed, for each value of qa , there is a solution ka to this equation on each half-period $\Delta(ka) = \pi$. Each of such solutions (see Fig. 26a) gives a specific value of particle's energy $E = \hbar^2 k^2 / 2m$. A continuous set of similar solutions for various qa forms a particular energy band.

Since the energy band picture is one of the most practically important results of quantum mechanics, it is imperative to understand its physics. It is natural to describe this physics in two different ways in two opposite potential strength limits. In parallel, we will use this discussion to obtain simpler expressions for the energy band/gap structure in each limit. An important advantage of this approach is that both analyses may be carried out for an arbitrary periodic potential $U(x)$ rather than for the particular model shown in Fig. 24.

(i) Tight-binding approximation. This approximation works well when the eigenenergy E_n of the states quasi-localized at the energy profile minima is much lower than the height of the potential barriers separating them – see Fig. 27. As should be clear from our discussion in Sec. 6, essentially the only role of coupling between these states (via tunneling through the potential barriers separating the minima) is to establish a certain phase shift $\Delta\varphi \equiv qa$ between the adjacent quasi-localized wavefunctions $u_n(x - x_j)$ and $u_n(x - x_{j+1})$.

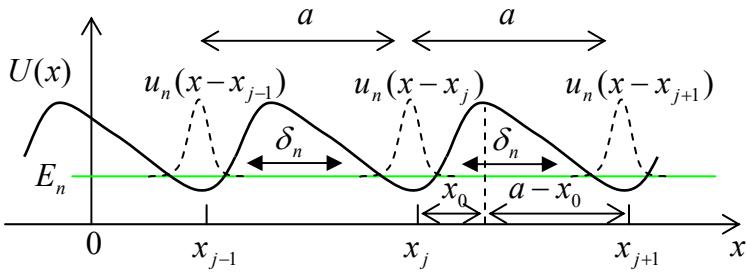

Fig. 2.27. The tight-binding approximation (schematically).

To describe this effect quantitatively, let us first return to the problem of two coupled wells considered in Sec. 6, and recast the result (180), with restored eigenstate index n , as

$$\Psi_n(x, t) = [a_R(t)\psi_R(x) + a_L(t)\psi_L(x)]\exp\left\{-i\frac{E_n}{\hbar}t\right\}, \quad (2.199)$$

where the probability amplitudes a_R and a_L oscillate sinusoidally in time:

$$a_R(t) = \cos\frac{\delta_n}{\hbar}t, \quad a_L(t) = i\sin\frac{\delta_n}{\hbar}t. \quad (2.200)$$

This evolution satisfies the following system of two equations whose structure is similar to Eq. (1.61a):

$$i\hbar\dot{a}_R = -\delta_n a_L, \quad i\hbar\dot{a}_L = -\delta_n a_R. \quad (2.201)$$

Eq. (199) may be readily generalized to the case of many similar coupled wells:

$$\Psi_n(x, t) = \left[\sum_j a_j(t)u_n(x - x_j) \right] \exp\left\{-i\frac{E_n}{\hbar}t\right\}, \quad (2.202)$$

where E_n are the eigenenergies and u_n the eigenfunctions of each well. In the tight-binding limit, only the adjacent wells are coupled, so that instead of Eq. (201) we should write an infinite system of similar equations

$$i\hbar \dot{a}_j = -\delta_n a_{j-1} - \delta_n a_{j+1}, \quad (2.203)$$

for each well number j , where parameters δ_n describe the coupling between two adjacent potential wells. Repeating the calculation outlined at the end of the last section for our new situation, for a smooth potential we may get an expression essentially similar to the last form of Eq. (188):

Tight-binding limit:
coupling energy

$$\delta_n = \frac{\hbar^2}{m} u_n(x_0) \frac{du_n}{dx}(a - x_0), \quad (2.204)$$

where x_0 is the distance between the well bottom and the middle of the potential barrier on the right of it – see Fig. 27. The only substantial new feature of this expression in comparison with Eq. (188) is that the sign of δ_n alternates with the level number n : $\delta_1 > 0$, $\delta_2 < 0$, $\delta_3 > 0$, etc. Indeed, the number of zeros (and hence, “wiggles”) of the eigenfunctions $u_n(x)$ of any potential well increases as n – see, e.g., Fig. 1.8,⁵⁵ so that the difference of the exponential tails of the functions, sneaking under the left and right barriers limiting the well also alternates with n .

The infinite system of ordinary differential equations (203) enables solutions of many important problems (such as the spread of the wavefunction that was initially localized in one well, etc.), but our task right now is just to find its stationary states, i.e. the solutions proportional to $\exp\{-i(\varepsilon_n/\hbar)t\}$, where ε_n is a still unknown, q -dependent addition to the background energy E_n of the n^{th} energy level. To satisfy the Bloch theorem (193) as well, such a solution should have the following form:

$$a_j(t) = a \exp\left\{iqx_j - i\frac{\varepsilon_n}{\hbar}t + \text{const}\right\}. \quad (2.205)$$

Plugging this solution into Eq. (203) and canceling the common exponent, we get

Tight-binding limit:
energy bands

$$E = E_n + \varepsilon_n = E_n - \delta_n (e^{-iqa} + e^{iqa}) \equiv E_n - 2\delta_n \cos qa, \quad (2.206)$$

so that in this approximation, the energy band width ΔE_n (see Fig. 26b) equals $4|\delta_n|$.

The relation (206), whose validity is restricted to $|\delta_n| \ll E_n$, describes the lowest energy bands plotted in Fig. 26b reasonably well. (For larger β , the agreement would be even better.) So, this calculation explains what the energy bands really are: in the tight-binding limit they are best interpreted as isolated well’s energy levels E_n , broadened into bands by the interwell interaction. Also, this result gives clear proof that the energy band extremes correspond to $qa = 2\pi l$ and $qa = 2\pi(l + \frac{1}{2})$, with integer l . Finally, the sign alteration of the coupling coefficient δ_n (204) explains why the energy maxima of one band are aligned, on the qa axis, with energy minima of the adjacent bands – see Fig. 26.

(ii) *Weak-potential limit*. Amazingly, the energy-band structure is also compatible with a completely different physical picture that may be developed in the opposite limit. Let the particle’s energy E be so high that the periodic potential $U(x)$ may be treated as a small perturbation. Naively, in

⁵⁵ Below, we will see several other examples of this behavior. This alternation rule is also described by the Wilson-Sommerfeld quantization condition (110).

this limit we could expect a slightly and smoothly deformed parabolic dispersion relation $E = \hbar^2 k^2 / 2m$. However, if we are plotting the stationary-state energy as a function of q rather than k , we need to add $2\pi l/a$, with an arbitrary integer l , to the argument. Let us show this by expanding all variables into the 1D-spatial Fourier series. For the potential energy $U(x)$ that obeys Eq. (192), such an expansion is straightforward:⁵⁶

$$U(x) = \sum_{l''} U_{l''} \exp\left\{-i \frac{2\pi x}{a} l''\right\}, \quad (2.207)$$

where the summation is over all integers l'' , from $-\infty$ to $+\infty$. However, for the wavefunction we should show due respect to the Bloch theorem (193), which shows that strictly speaking, $\psi(x)$ is *not* periodic.

To overcome this difficulty, let us define another function:

$$u(x) \equiv \psi(x) e^{-iqx}, \quad (2.208)$$

and study its periodicity:

$$u(x+a) = \psi(x+a) e^{-iq(x+a)} = \psi(x) e^{-iqx} = u(x). \quad (2.209)$$

We see that the new function is a -periodic, and hence we can use Eqs. (208)-(209) to rewrite the Bloch theorem in a different form:

$$\psi(x) = u(x) e^{iqx}, \quad \text{with } u(x+a) = u(x). \quad (2.210)$$

1D Bloch theorem:
alternative form

Now it is safe to expand the periodic function $u(x)$ exactly as $U(x)$:

$$u(x) = \sum_{l'} u_{l'} \exp\left\{-i \frac{2\pi x}{a} l'\right\}, \quad (2.211)$$

so that, according to Eq. (210),

$$\psi(x) = e^{iqx} \sum_{l'} u_{l'} \exp\left\{-i \frac{2\pi x}{a} l'\right\} = \sum_{l'} u_{l'} \exp\left\{i\left(q - \frac{2\pi}{a} l'\right)x\right\}. \quad (2.212)$$

The only nontrivial part of plugging Eqs. (207) and (212) into the stationary Schrödinger equation (53) is how to handle the product term,

$$U(x)\psi = \sum_{l', l''} U_{l''} u_{l'} \exp\left\{i\left[q - \frac{2\pi}{a}(l' + l'')\right]x\right\}. \quad (2.213)$$

At fixed l' , we may change the summation over l'' to that over $l \equiv l' + l''$ (so that $l'' \equiv l - l'$), and write:

$$U(x)\psi = \sum_l \exp\left\{i\left(q - \frac{2\pi}{a} l\right)x\right\} \sum_{l'} u_{l'} U_{l-l'}. \quad (2.214)$$

Now plugging Eq. (212) (with the summation index l' replaced with l) and Eq. (214) into the stationary Schrödinger equation (53), and requiring the coefficients of each spatial exponent to match, we get an infinite system of linear equations for u_l :

⁵⁶ The benefits of such an unusual notation of the summation index (l'' instead of, say, l) will be clear in a few lines.

$$\sum_l U_{l-l'} u_{l'} = \left[E - \frac{\hbar^2}{2m} \left(q - \frac{2\pi}{a} l \right)^2 \right] u_l. \quad (2.215)$$

(Note that by this calculation we have essentially proved that the Bloch wavefunction (210) is indeed a solution of the Schrödinger equation, provided that the quasimomentum q is selected in a way to make the system of linear equation (215) compatible, i.e. is a solution of its characteristic equation.)

So far, the system of equations (215) is an equivalent alternative to the initial Schrödinger equation, for any potential's strength.⁵⁷ In the weak-potential limit, i.e. if all Fourier coefficients U_n are small,⁵⁸ we can complete all the calculations analytically.⁵⁹ Indeed, in the so-called 0th approximation we can ignore *all* U_n , so that in order to have at least one u_l different from 0, Eq. (215) requires that

$$E \rightarrow E_l \equiv \frac{\hbar^2}{2m} \left(q - \frac{2\pi l}{a} \right)^2. \quad (2.216)$$

(u_l itself should be obtained from the normalization condition). This result means that in this approximation, the dispersion relation $E(q)$ has an infinite number of similar quadratic branches numbered by integer l – see Fig. 28.

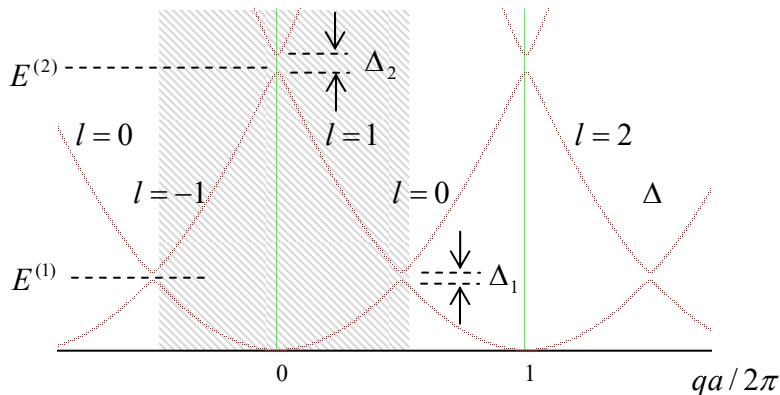

Fig. 2.28. The energy band/gap picture in the weak potential limit ($\Delta_n \ll E^{(n)}$), with the shading showing the 1st Brillouin zone.

On every branch, such eigenfunction has just one Fourier coefficient, i.e. is a monochromatic traveling wave

$$\psi_l \rightarrow u_l e^{ikx} = u_l \exp \left\{ i \left(q - \frac{2\pi l}{a} \right) x \right\}. \quad (2.217)$$

Next, the above definition of E_l allows us to rewrite Eq. (215) in a more transparent form

⁵⁷ By the way, the system is very efficient for fast numerical solution of the stationary Schrödinger equation for any periodic profile $U(x)$, even though to describe potentials with large U_n , this approach may require taking into account a correspondingly large number of Fourier amplitudes u_l .

⁵⁸ Besides, possibly, a constant potential U_0 , which, as was discussed in Chapter 1, may be always taken for the energy reference. As a result, in the following calculations, I will take $U_0 = 0$ to simplify the formulas.

⁵⁹ This method is so powerful that its multi-dimensional version is not much more complex than the 1D version described here – see, e.g., Sec. 3.2 in the classical textbook by J. Ziman, *Principles of the Theory of Solids*, 2nd ed., Cambridge U. Press, 1979.

$$\sum_{l' \neq l} U_{l-l'} u_{l'} = (E - E_l) u_l, \quad (2.218)$$

which may be formally solved for u_l :

$$u_l = \frac{1}{E - E_l} \sum_{l' \neq l} U_{l-l'} u_{l'}. \quad (2.219)$$

This formula shows that if the Fourier coefficients U_n are non-zero but small, the wavefunctions do acquire other Fourier components (besides the main one, with the index corresponding to the branch number), but these additions are all small, besides narrow regions near the points $E_l = E_{l'}$ where two branches (216) of the dispersion relation $E(q)$, with some specific numbers l and l' , cross. According to Eq. (216), this happens when

$$\left(q - \frac{2\pi}{a} l \right) \approx - \left(q - \frac{2\pi}{a} l' \right), \quad (2.220)$$

i.e. at $q \approx q_m \equiv \pi m/a$ (with the integer $m \equiv l + l'$)⁶⁰ corresponding to

$$E_l \approx E_{l'} \approx \frac{\hbar^2}{2ma^2} [\pi(l+l') - 2\pi l]^2 = \frac{\pi^2 \hbar^2}{2ma^2} n^2 \equiv E^{(n)}, \quad (2.221)$$

Weak-potential limit:
energy gap positions

with integer $n \equiv l - l'$. (According to their definitions, the index n is just the number of the branch crossing on the energy scale, while the index m numbers the position of the crossing points on the q -axis – see Fig. 28.) In such a region, E has to be close to both E_l and $E_{l'}$, so that the denominator in just one of the infinite number of terms in Eq. (219) is very small, making the term substantial despite the smallness of U_n . Hence we can take into account only one term in each of the sums (written for l and l'):

$$\begin{aligned} U_n u_{l'} &= (E - E_l) u_l, \\ U_{-n} u_l &= (E - E_{l'}) u_{l'}. \end{aligned} \quad (2.222)$$

Taking into account that for any real function $U(x)$, the Fourier coefficients in its Fourier expansion (207) have to be related as $U_{-n} = U_n^*$, Eq. (222) yields the following simple characteristic equation

$$\begin{vmatrix} E - E_l & -U_n \\ -U_n^* & E - E_{l'} \end{vmatrix} = 0, \quad (2.223)$$

with the following solution:

$$E_{\pm} = E_{\text{ave}} \pm \left[\left(\frac{E_l - E_{l'}}{2} \right)^2 + U_n U_n^* \right]^{1/2}, \quad \text{with } E_{\text{ave}} \equiv \frac{E_l + E_{l'}}{2} = E^{(n)}. \quad (2.224)$$

Weak-potential limit:
level anticrossing

According to Eq. (216), close to the branch crossing point $q_m = \pi(l + l')/a$, the fraction participating in this result may be approximated as⁶¹

$$\frac{E_l - E_{l'}}{2} \approx \gamma \tilde{q}, \quad \text{with } \gamma \equiv \frac{dE_l}{dq} \Big|_{q=q_m} = \frac{\pi \hbar^2 n}{ma} = \frac{2aE^{(n)}}{\pi n}, \quad \text{and } \tilde{q} \equiv q - q_m, \quad (2.225)$$

⁶⁰ Let me hope that the difference between this new integer and the particle's mass, both called m , is absolutely clear from the context.

⁶¹ Physically, $\gamma \hbar \equiv \hbar(\pi n/a)/m = \hbar k^{(n)}/m$ is just the velocity of a free classical particle with energy $E^{(n)}$.

while the parameters $E_{\text{ave}} = E^{(n)}$ and $U_n U_n^* = |U_n|^2$ do not depend on \tilde{q} , i.e. on the distance from the central point q_m . This is why Eq. (224) may be plotted as the famous *level anticrossing* (also called “avoided crossing”, or “intended crossing”, or “non-crossing”) *diagram* (Fig. 29), with the energy gap width Δ_n equal to $2|U_n|$, i.e. just twice the magnitude of the n -th Fourier harmonic of the periodic potential $U(x)$. Such anticrossings are also clearly visible in Fig. 28, which shows the result of the exact solution of Eq. (198) for the particular case $\beta = 0.5$.⁶²

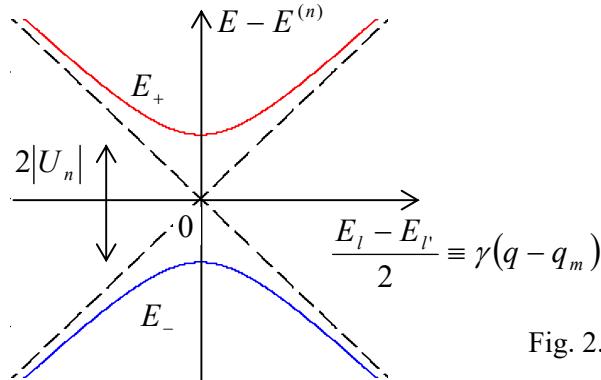

Fig. 2.29. The level anticrossing diagram.

We will run into the anticrossing diagram again and again in the course, notably at the discussion of spin- $\frac{1}{2}$ and other two-level systems. It is also repeatedly met in classical mechanics, for example at the calculation of frequencies of coupled oscillators.^{63,64} In our current case of the weak potential limit of the band theory, the diagram describes the interaction of two traveling de Broglie waves (217), with oppositely directed wave vectors, l and $-l'$, via the $(l - l')$ th (i.e. the n th) Fourier harmonic of the potential profile $U(x)$.⁶⁵ This effect exists also in the classical wave theory and is known as the *Bragg reflection*, describing, for example, the 1D model of the X-wave reflection by a crystal lattice (see, e.g. Fig. 1.5) in the limit of weak interaction between the incident wave and each atom.

The anticrossing diagram shows that rather counter-intuitively, even a weak periodic potential changes the topology of the initially parabolic dispersion relation radically, connecting its different branches, and thus creating the energy gaps. Let me hope that the reader has enjoyed the elegant description of this effect, discussed above, as well as one more illustration of the wonderful ability of physics to give completely different interpretations (and different approximate approaches) to the same effect in opposite limits.

So, we have explained analytically (though only in two limits) the particular band structure shown in Fig. 26. Now we may wonder how general this structure is, i.e. how much of it is independent of the Dirac comb model (Fig. 24). For that, let us represent the band pattern, such as that shown in Fig.

⁶² From that figure, it is also clear that in the weak potential limit, the width ΔE_n of the n th energy band is just $E^{(n)} - E^{(n-1)}$ – see Eq. (221). Note that this is exactly the distance between the adjacent energy levels of the simplest 1D potential well of infinite depth – cf. Eq. (1.85).

⁶³ See, e.g., CM Sec. 6.1 and in particular Fig. 6.2.

⁶⁴ Actually, we could readily obtain this diagram in the previous section, for the system of two weakly coupled potential wells (Fig. 21), if we assumed the wells to be slightly dissimilar.

⁶⁵ In the language of the de Broglie wave scattering, to be discussed in Sec. 3.3, Eq. (220) may be interpreted as the condition that each of these waves, scattered on the n th Fourier harmonic of the potential profile, constructively interferes with its counterpart, leading to a strong enhancement of their interaction.

26b (plotted for a particular value of the parameter β , characterizing the potential barrier strength) in a more condensed form, which would allow us to place the results for a range of β values on a single comprehensible plot. The way to do this should be clear from Fig. 26b: since the dependence of energy on the quasimomentum in each energy band is not too eventful, we may plot just the highest and the smallest values of the particle's energy $E = \hbar^2 k^2 / 2m$ as functions of $\beta \equiv ma\omega/\hbar^2$ – see Fig. 30, which may be obtained from Eq. (198) with $qa = 0$ and $qa = \pi$.

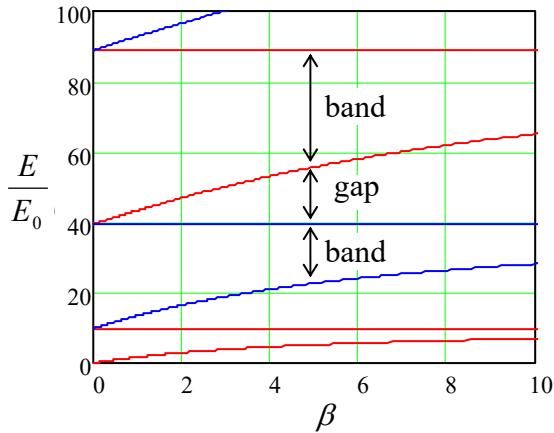

Fig. 2.30. Characteristic curves of the Schrödinger equation for the infinite Dirac comb (Fig. 24).

These plots (in mathematics, commonly called *characteristic curves*, while in applied physics, *band-edge diagrams*) show, first of all, that at small β , all energy gap widths are equal and proportional to this parameter, and hence to ω . This feature is in a full agreement with the main conclusion (224) of our general analysis of the weak-potential limit, because for the Dirac comb potential (Fig. 24),

$$U(x) = \omega \sum_{j=-\infty}^{+\infty} \delta(x - ja + \text{const}), \quad (2.226)$$

all Fourier harmonic amplitudes, defined by Eq. (207), are equal by magnitude: $|U_l| = \omega/a$. As β is further increased, the gaps grow and the allowed energy bands shrink, but rather slowly. This is also natural, because, as Eq. (79) shows, transparency \mathcal{T} of the delta-functional barriers separating the quasi-localized states (and hence the coupling parameters $\delta_n \propto \mathcal{T}^{1/2}$ participating in the general tight-binding limit's theory) decrease with $\omega \propto \beta$ very gradually.

These features may be compared with those for more realistic and relatively simple periodic functions $U(x)$, for example the sinusoidal potential $U(x) = A \cos(2\pi x/a)$ – see Fig. 31a. For this potential, the stationary Schrödinger equation (53) takes the following form:

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + A \cos \frac{2\pi x}{a} \psi = E \psi. \quad (2.227)$$

By introduction of dimensionless variables⁶⁶

$$\xi \equiv \frac{\pi x}{a}, \quad \alpha \equiv \frac{E}{E^{(1)}}, \quad 2\beta \equiv \frac{A}{E^{(1)}}, \quad (2.228)$$

⁶⁶ Note that this definition of β is quantitatively different from that for the Dirac comb (226), but in both cases, this parameter is proportional to the amplitude of the potential modulation.

where $E^{(1)}$ is defined by Eq. (221) with $n = 1$, Eq. (227) is reduced to the canonical form of the well-studied *Mathieu equation*⁶⁷

Mathieu
equation

$$\frac{d^2\psi}{d\xi^2} + (\alpha - 2\beta \cos 2\xi)\psi = 0. \quad (2.229)$$

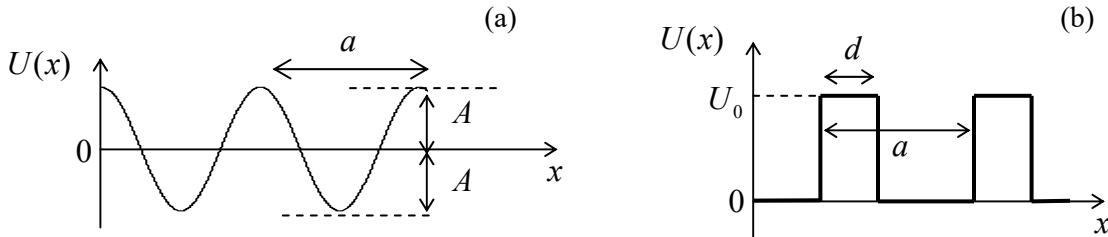

Fig. 2.31. Two other simple periodic potential profiles: (a) the sinusoidal (“Mathieu”) potential and (b) the Kronig-Penney potential.

Figure 32 shows the characteristic curves of this equation. We see that now at small β the first energy gap grows much faster than the higher ones: $\Delta_n \propto \beta^n$. This feature is in accord with the weak-coupling result $\Delta_1 = 2|U_1|$, which is valid only in the linear approximation in U_n , because for the Mathieu potential, $U_l = A(\delta_{l+1} + \delta_{l-1})/2$. Another clearly visible feature is the exponentially fast shrinkage of the allowed energy bands at $2\beta > \alpha$ (in Fig. 32, on the right from the dashed line), i.e. at $E < A$. It may be readily explained by our tight-binding approximation result (206): as soon as the eigenenergy drops significantly below the potential maximum $U_{\max} = A$ (see Fig. 31a), the quantum states in the adjacent potential wells are connected only by tunneling through relatively high potential barriers separating these wells, so that the coupling amplitudes δ_n become exponentially small – see, e.g., Eq. (189).

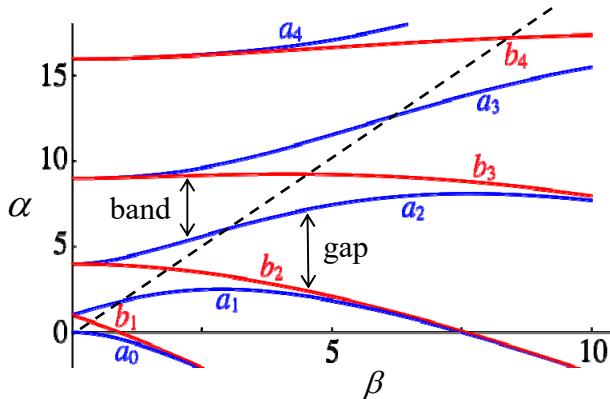

Fig. 2.32. Characteristic curves of the Mathieu equation. The dashed line corresponds to the equality $\alpha = 2\beta$, i.e. $E = A \equiv U_{\max}$, separating the regions of under-barrier tunneling and over-barrier motion. Adapted from Fig. 28.2.1 at <http://dlmf.nist.gov>. (Contribution by US Government, not subject to copyright).

Another simple periodic profile is the *Kronig-Penney potential*, shown in Fig. 31b, which gives relatively simple analytical expressions for the characteristic curves. Its advantage is a more realistic law of the decrease of the Fourier harmonics U_l at $l \gg 1$, and hence of the energy gaps in the weak-potential limit:

⁶⁷ This equation, first studied in the 1860s by É. Mathieu in the context of a rather practical problem of vibrating elliptical drumheads (!), has many other important applications in physics and engineering, notably including the parametric excitation of oscillations – see, e.g., CM Sec. 5.5.

$$\Delta_n \approx 2|U_n| \propto \frac{U_0}{n}, \quad \text{at } E \sim E^{(n)} \gg U_0. \quad (2.230)$$

Leaving a detailed analysis of the Kronig-Penney potential for the reader's exercise, let me conclude this section by addressing the effect of potential modulation on the number of eigenstates in 1D systems of a large but finite length $l \gg a, k^{-1}$. Surprisingly, the Bloch theorem makes the analysis of this problem elementary, for arbitrary $U(x)$. Indeed, let us assume that l is comprised of an integer number of periods a , and its ends are described by similar boundary conditions – both assumptions evidently inconsequential for $l \gg a$. Then, according to Eq. (210), the boundary conditions impose, on the quasimomentum q , exactly the same quantization condition as we had for k for a free 1D motion. Hence, instead of Eq. (1.100), we can write

$$dN = \frac{l}{2\pi} dq, \quad (2.231)$$

1D number
of states

with the corresponding change of the summation rule:

$$\sum_q f(q) \rightarrow \frac{l}{2\pi} \int f(q) dk. \quad (2.232)$$

As a result, the density of states in the 1D *q-space*, $dN/dq = l/2\pi$, does not depend on the potential profile at all! Note, however, that the profile does affect the density of states on the *energy* scale, dN/dE . As an extreme example, on the bottom and at the top of each energy band we have $dE/dq \rightarrow 0$, and hence

$$\frac{dN}{dE} = \frac{dN}{dq} \Big/ \frac{dE}{dq} = \frac{l}{2\pi} \Big/ \frac{dE}{dq} \rightarrow \infty. \quad (2.233)$$

This effect of state concentration at the band/gap edges (which survives in higher spatial dimensionalities as well) has important implications for the operation of several important electronic and optical devices, in particular semiconductor lasers and light-emitting diodes.

2.8. Periodic systems: Particle dynamics

The band structure of the energy spectrum of a particle moving in a periodic potential has profound implications not only for its density of states but also for its dynamics. Indeed, let us consider the simplest case of a wave packet composed of the Bloch functions (210), all belonging to the same (say, n^{th}) energy band. Similarly to Eq. (27) for a free particle, we can describe such a packet as

$$\Psi(x, t) = \int a_q u_q(x) e^{i[qx - \omega(q)t]} dq, \quad (2.234)$$

where the a -periodic functions $u(x)$, defined by Eq. (208), are now indexed to emphasize their dependence on the quasimomentum, and $\omega(q) = E_n(q)/\hbar$ is the function of q describing the shape of the corresponding energy band – see, e.g., Fig. 26b or Fig. 28. If the packet is narrow in the *q-space*, i.e. if the width δq of the distribution a_q is much smaller than all the characteristic *q*-scales of the dispersion relation $\omega(q)$, in particular of π/a , we may simplify Eq. (234) exactly as it was done in Sec. 2 for a free particle, despite the presence of the periodic factors $u_q(x)$ under the integral. In the linear approximation of the Taylor expansion, we get a full analog of Eq. (32), but now with q rather than k , and

$$v_{\text{gr}} = \frac{d\omega}{dq} \Big|_{q=q_0}, \quad \text{and} \quad v_{\text{ph}} = \frac{\omega}{q} \Big|_{q=q_0}, \quad (2.235)$$

where q_0 is the central point of the quasimomentum distribution. Despite the formal similarity with Eqs. (33) for the free particle, this result is much more eventful. For example, as evident from the dispersion relation's topology (see Figs. 26b, 28), the group velocity vanishes not only at $q = 0$, but at all values of q that are multiples of (π/a) , at the bottom and on the top of each energy band. Even more intriguing is that the group velocity's sign changes periodically with q .

This group velocity alternation leads to fascinating, counter-intuitive phenomena if a particle placed in a periodic potential is the subject of an additional external force $F(t)$. (For electrons in a crystal, this may be, for example, the force of the applied electric field.) Let the force be relatively weak, so that the product Fa (i.e. the scale of the energy increment from the additional force per one lattice period) is much smaller than both relevant energy scales of the dispersion relation $E(q)$ – see Fig. 26b:

$$Fa \ll \Delta E_n, \Delta_n. \quad (2.236)$$

This strong relationship allows one to neglect the force-induced interband transitions, so that the wave packet (234) includes the Bloch eigenfunctions belonging to only one (initial) energy band at all times. For the time evolution of its center q_0 , theory yields⁶⁸ an extremely simple equation of motion

$$\dot{q}_0 = \frac{1}{\hbar} F(t). \quad (2.237)$$

Time
evolution
of quasi-
momentum

This equation is physically very transparent: it is essentially the 2nd Newton law for the time evolution of the quasimomentum $\hbar q$ under the effect of the additional force $F(t)$ only, excluding the periodic force $-\partial U(x)/\partial x$ of the background potential $U(x)$. This is very natural, because as Eq. (210) implies, $\hbar q$ is essentially the particle's momentum averaged over the potential's period, and the periodic force effect drops out at such an averaging.

Despite the simplicity of Eq. (237), the results of its solution may be highly nontrivial. First, let us use Eqs. (235) and (237) to find the instant *group acceleration* of the particle (i.e. the acceleration of its wave packet's envelope):

$$a_{\text{gr}} \equiv \frac{dv_{\text{gr}}}{dt} \equiv \frac{d}{dt} \frac{d\omega(q_0)}{dq_0} \equiv \frac{d}{dq_0} \frac{d\omega(q_0)}{dq_0} \frac{dq_0}{dt} = \frac{d^2\omega(q_0)}{dq_0^2} \frac{dq_0}{dt} = \frac{1}{\hbar} \frac{d^2\omega}{dq^2} \Big|_{q=q_0} F(t). \quad (2.238)$$

This means that the second derivative of the dispersion $\omega(q)$ relation (specific for each energy band) plays the role of the effective reciprocal mass of the particle at this particular value of q_0 :

$$m_{\text{ef}} = \frac{\hbar}{d^2\omega/dq^2} \equiv \frac{\hbar^2}{d^2E_n/dq^2}. \quad (2.239)$$

Effective
mass

For the particular case of a free particle, for which Eq. (216) is exact, this expression is reduced to the original (and constant) mass m , but generally, the effective mass depends on the wave packet's

⁶⁸ The proof of Eq. (237) is not difficult, but becomes more compact in the bra-ket formalism, to be discussed in Chapter 4. This is why I recommend to the reader its proof as an exercise after reading that chapter. For a generalization of this theory to the case of essential interband transitions see, e.g., Sec. 55 in E. Lifshitz and L. Pitaevskii, *Statistical Physics, Part 2*, Pergamon, 1980.

momentum. According to Eq. (239), at the bottom of any energy band, m_{ef} is always positive but depends on the strength of the particle's interaction with the periodic potential. In particular, according to Eq. (206), in the tight-binding limit, the effective mass is very large:

$$|m_{\text{ef}}|_{q=(\pi/a)n} = \frac{\hbar^2}{2\delta_n a^2} \equiv m \frac{E^{(1)}}{\pi^2 \delta_n} \gg m . \quad (2.240)$$

On the contrary, in the weak-potential limit, the effective mass is close to m at most points of each energy band, but at the edges of the (narrow) bandgaps, it is much smaller. Indeed, expanding Eq. (224) in the Taylor series near point $q = q_m$, we get

$$E_{\pm}|_{E \approx E^{(n)}} - E_{\text{ave}} \approx \pm |U_n| \pm \frac{1}{2|U_n|} \left(\frac{dE_l}{dq} \right)^2_{q=q_m} \tilde{q}^2 = \pm |U_n| \pm \frac{\gamma^2}{2|U_n|} \tilde{q}^2 , \quad (2.241)$$

where γ and \tilde{q} are defined by Eq. (225), so that

$$|m_{\text{ef}}|_{q=q_m} = |U_n| \frac{\hbar^2}{\gamma^2} \equiv m \frac{|U_n|}{2E^{(n)}} \ll m . \quad (2.242)$$

The effective mass effects in real atomic crystals may be very significant. For example, the charge carriers in silicon have $m_{\text{ef}} \approx 0.19 m_e$ in the lowest, normally-empty energy band (traditionally called the *conduction band*), and $m_{\text{ef}} \approx 0.98 m_e$ in the adjacent lower, normally-filled *valence band*. In some semiconducting compounds, the conduction-band mass may be even smaller – down to $0.0145 m_e$ in InSb!

However, the effective mass' magnitude is not the most surprising effect. A more fascinating corollary of Eq. (239) is that on the top of each energy band the effective mass is *negative* – please revisit Figs. 26b, 28, and 29 again. This means that the particle (or more strictly, its wave packet's envelope) is accelerated in the direction *opposite* to the applied force. This is exactly what electronic engineers, working with electrons in semiconductors, call *holes*, characterizing them by a *positive mass* $|m_{\text{ef}}|$, but compensating this sign change by taking their charge e positive. If the particle stays in close vicinity of the energy band's top (say, due to frequent scattering effects, typical for the semiconductors used in engineering practice), such double sign flip does not lead to an error in calculations of hole's dynamics, because the electric field's force is proportional to the particle's charge, so that the particle's acceleration a_{gr} is proportional to the charge-to-mass ratio.⁶⁹

However, in some phenomena such simple representation is unacceptable.⁷⁰ For example, let us form a narrow wave packet at the bottom of the lowest energy band,⁷¹ and then exert on it a constant force $F > 0$ – say, due to a constant external electric field directed along the x -axis. According to Eq. (237), this force would lead to linear growth of q_0 in time, so that in the quasimomentum space, the

⁶⁹ More discussion of this issue may be found in SM Sec. 6.4.

⁷⁰ The balance of this section describes effects that are not discussed in most quantum mechanics textbooks. Though, in my opinion, every educated physicist should be aware of them, some readers may skip them at the first reading, jumping directly to the next Sec. 9.

⁷¹ Physical intuition tells us (and the theory of open systems, to be discussed in Chapter 7, confirms) that this may be readily done, for example, by weakly coupling the system to a relatively low-temperature environment, and letting it relax to the lowest possible energy.

packet's center would slide, with a constant speed, along the q axis – see Fig. 33a. Close to the energy band's bottom, this motion would correspond to a positive effective mass (possibly, somewhat different than the genuine particle's mass m), and hence be close to the free particle's acceleration. However, as soon as q_0 has reached the inflection point where $d^2E_1/dq^2 = 0$, the effective mass, and hence its acceleration (238) change signs to negative, i.e. the packet starts to slow down (in the direct space), while still moving ahead with the same velocity in the quasimomentum space. Finally, at the energy band's top, the particle stops at a certain x_{\max} , while continuing to move forward in the q -space.

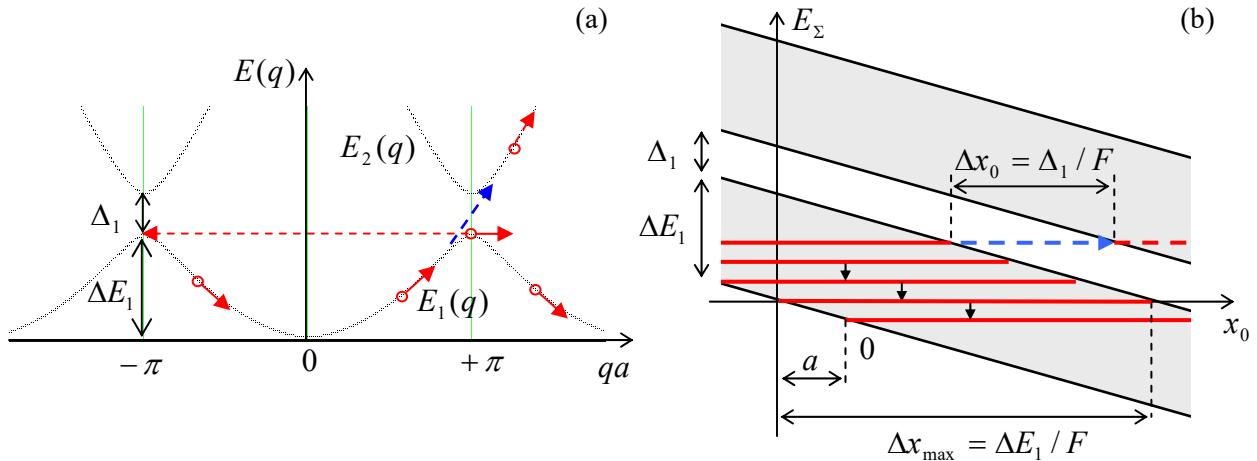

Fig. 2.33. The Bloch oscillations (red lines) and the Landau-Zener tunneling (blue arrows) represented in: (a) the reciprocal space of q , and (b) the direct space. On panel (b), the tilted gray strips show the allowed energy bands, while the bold red lines, the Wannier-Stark ladder's steps.

Now we have two alternative ways to look at the further time evolution of the wave packet along the quasimomentum's axis. From the extended zone picture (which is the simplest for this analysis, see Fig. 33a),⁷² we may say that the particle crosses the 1st Brillouin zone boundary and continues to go forward in q -space, i.e. down the lowest energy band. According to Eq. (235), this region (up to the next energy minimum at $qa = 2\pi$) corresponds to a negative group velocity. After q_0 has reached that minimum, the whole process repeats again – and again, and again.

These are the famous *Bloch oscillations* – the effect which had been predicted, by the same F. Bloch, as early as 1929 but evaded experimental observation until the 1980s (see below) due to the strong scattering effects in real solid-state crystals. The time period of the oscillations may be readily found from Eq. (237):

$$\Delta t_B = \frac{\Delta q}{dq/dt} = \frac{2\pi/a}{F/\hbar} = \frac{2\pi\hbar}{Fa}, \quad (2.243)$$

so that their frequency may be expressed by a very simple formula

⁷² This phenomenon may be also discussed from the point of view of the reduced zone picture, but then it requires the introduction of instant jumps between the Brillouin zone boundary points (see the dashed red line in Fig. 33) that correspond to physically equivalent states of the particle. Evidently, for the description of this particular phenomenon, this language is more artificial.

$$\omega_B \equiv \frac{2\pi}{\Delta t_B} = \frac{Fa}{\hbar}, \quad (2.244)$$

Bloch oscillations: frequency

and hence is independent of any peculiarities of the energy band/gap structure.

The direct-space motion of the wave packet's center $x_0(t)$ during the Bloch oscillation process may be analyzed by integrating the first of Eqs. (235) over some time interval Δt , and using Eq. (237):

$$\Delta x_0(t) \equiv \int_0^{\Delta t} v_{\text{gr}} dt = \int_0^{\Delta t} \frac{d\omega(q_0)}{dq_0} dt \equiv \int_0^{\Delta t} \frac{d\omega(q_0)}{dq_0 / dt} dt = \frac{\hbar}{F} \int_{t=0}^{t=\Delta t} d\omega = \frac{\hbar}{F} \Delta\omega(q_0). \quad (2.245)$$

If the interval Δt is equal to the Bloch oscillation period Δt_B (243), the initial and final values of $E(q_0) = \hbar\omega(q_0)$ are equal, giving $\Delta x_0 = 0$: in the end of the period, the wave packet returns to its initial position in space. However, if we carry out this integration only from the smallest to the largest values of $\omega(q_0)$, i.e. the adjacent points where the group velocity vanishes, we get the following Bloch oscillation swing:

$$\Delta x_{\max} = \frac{\hbar}{F} (\omega_{\max} - \omega_{\min}) \equiv \frac{\Delta E_1}{F}. \quad (2.246)$$

Bloch oscillations: spatial swing

This simple result may be interpreted using an alternative energy diagram (Fig. 33b), which results from the following arguments. The additional force F may be described not only via the 2nd Newton law's version (237), but, alternatively, by its contribution $-Fx$ to the Gibbs potential energy⁷³

$$U_{\Sigma}(x) = U(x) - Fx \quad (2.247)$$

The exact solution of the Schrödinger equation (61) with such a potential may be hard to find directly, but if the force F is sufficiently weak, as we are assuming throughout this discussion, the second term in Eq. (247) may be considered as a constant on the scale of $a \ll \Delta x_{\max}$. In this case, our quantum-mechanical treatment of the periodic potential $U(x)$ is still virtually correct, but with an energy shift depending on the “global” position x_0 of the packet's center. In this approximation, the total energy of the wave packet is

$$E_{\Sigma} = E(q_0) - Fx_0. \quad (2.248)$$

In a plot of such energy as a function of x_0 (Fig. 33b), the energy dependence on q_0 is hidden, but as was discussed above, it is rather uneventful and may be well characterized by the position of band-gap edges on the energy axis.⁷⁴ In this representation, the Bloch oscillations keep the full energy E_{Σ} of the particle constant, i.e. follow a horizontal line in Fig. 33b, limited by the classical turning points corresponding to the bottom and the top of the allowed energy band. The distance Δx_{\max} between these points is evidently given by Eq. (246).

Besides this alternative look at the Bloch oscillation swing, the total energy diagram shown in Fig. 33b enables one more remarkable result. Let a wave packet be so narrow in the momentum space

⁷³ Physically, this is just the relevant part of the potential energy of the total system comprised of our particle (in the periodic potential) and the source of the force F – see, e.g., CM Sec. 1.4.

⁷⁴ In semiconductor physics and engineering, such spatial *band-edge diagrams* are virtually unavoidable components of almost every discussion/publication. In this series, a few more examples of such diagrams may be found in SM Sec. 6.4.

that $\delta x \sim 1/\delta q \gg \Delta x_{\max}$; then it may be well represented by definite energy, i.e. by a horizontal line in Fig. 33b. But Eq. (247) is exactly invariant with respect to the following simultaneous translation of the coordinate and the energy:

$$x \rightarrow x + a, \quad E \rightarrow E - Fa. \quad (2.249)$$

This means that it is satisfied by an infinite set of similar solutions, each corresponding to one of the horizontal red lines shown in Fig. 33b. This is the famous *Wannier-Stark ladder*,⁷⁵ with the step height

$$\Delta E_{\text{ws}} = Fa. \quad (2.250)$$

Wannier-Stark ladder

The importance of this alternative representation of the Bloch oscillations is due to the following fact. In most experimental realizations, the power of the electromagnetic radiation with frequency (244), that may be extracted from the oscillations of a charged particle, is very low, so that their direct detection represents a hard problem.⁷⁶ However, let us apply to a Bloch oscillator an additional ac field at frequency $\omega \approx \omega_B$. As these frequencies are brought close together, the external signal should synchronize (“phase-lock”) the Bloch oscillations,⁷⁷ resulting in certain changes of time-independent observables – for example, a resonant change of absorption of the external radiation. Now let us notice that the combination of Eqs. (244) and (250) yield the following simple relation:

$$\Delta E_{\text{ws}} = \hbar \omega_B. \quad (2.251)$$

This means that the phase-locking at $\omega \approx \omega_B$ allows for an alternative (but equivalent) interpretation – as the result of ac-field-induced quantum transitions⁷⁸ between the steps of the Wannier-Stark ladder. (Again, such occasions when two very different languages may be used for alternative interpretations of the same effect is one of the most beautiful features of physics.)

This phase-locking effect has been used for the first experimental confirmations of the Bloch oscillation theory.⁷⁹ For this purpose, the natural periodic structures, solid-state crystals, are inconvenient due to their very small period $a \sim 10^{-10}$ m. Indeed, according to Eq. (244), such structures require very high forces F (and hence very high electric fields $\mathcal{E} = F/e$) to bring ω_B to an experimentally convenient range. This problem has been overcome using artificial periodic structures (*superlattices*) of certain semiconductor compounds, such as $\text{Ga}_{1-x}\text{Al}_x\text{As}$ with various degrees x of the gallium-to-aluminum atom replacement, whose layers may be grown over each other epitaxially, i.e., with very few crystal structure violations. Such superlattices, with periods $a \sim 10$ nm, have enabled a clear observation of the resonance at $\omega \approx \omega_B$, and hence a measurement of the Bloch oscillation frequency, in particular its proportionality to the applied dc electric field, predicted by Eq. (244).

⁷⁵ This effect was first discussed in detail by Gregory Hugh Wannier in his 1959 monograph on solid-state physics, while the name of Johannes Stark is traditionally associated with virtually any electric field effect on atomic systems, after he had discovered the first of such effects in 1913.

⁷⁶ In systems with many independent particles (such as electrons in semiconductors), the detection problem is exacerbated by the phase incoherence of the Bloch oscillations performed by each particle. This drawback is absent in atomic Bose-Einstein condensates whose Bloch oscillations (in a periodic potential created by standing optical waves) were eventually observed by M. Ben Dahan *et al.*, *Phys. Rev. Lett.* **76**, 4508 (1996).

⁷⁷ A simple analysis of phase locking of a classical oscillator may be found, e.g., in CM Sec. 5.4. (See also the brief discussion of the phase locking of the Josephson oscillations at the end of Sec. 1.6 of this course.)

⁷⁸ A quantitative theory of such transitions will be discussed in Sec. 6.6 and then in Chapter 7.

⁷⁹ E. Mendez *et al.*, *Phys. Rev. Lett.* **60**, 2426 (1988).

Very soon after this discovery, the Bloch oscillations were observed⁸⁰ in small Josephson junctions, where they result from the quantum dynamics of the Josephson phase difference φ in a 2π -periodic potential profile, created by the junction. A straightforward translation of Eq. (244) to this case (left for the reader's exercise) shows that the frequency of such Bloch oscillations is

$$\omega_B = \frac{\pi \bar{I}}{2e}, \quad \text{i.e. } f_B \equiv \frac{\omega_B}{2\pi} = \frac{\bar{I}}{2e}, \quad (2.252)$$

where \bar{I} is the dc current passed through the junction – the effect not to be confused with the “classical” Josephson oscillations with frequency (1.75). It is curious that Eq. (252) may be legitimately interpreted as a result of a periodic transfer, through the Josephson junction, of discrete Cooper pairs (of charge $-2e$), between two coherent Bose-Einstein condensates in the superconducting electrodes of the junction.⁸¹

Next, our discussion of the Bloch oscillations was based on the premise that the wave packet of the particle stays within one (say, the lowest) energy band. However, just one look at Fig. 28 shows that this assumption becomes unrealistic if the energy gap separating this band from the next one becomes very small, $\Delta_1 \rightarrow 0$. Indeed, in the weak-potential approximation, which is adequate in this limit, $|U_1| \rightarrow 0$, the two dispersion curve branches (216) cross without any interaction, so that if our particle (meaning its the wave packet) is driven to approach that point, it should continue to move up in energy – see the dashed blue arrow in Fig. 33a. Similarly, in the real-space representation shown in Fig. 33b, it is intuitively clear that at $\Delta_1 \rightarrow 0$, the particle residing at one of the steps of the Wannier-Stark ladder should be able to somehow overcome the vanishing spatial gap $\Delta x_0 = \Delta_1/F$ and to “leak” into the next band – see the horizontal dashed blue arrow on that panel.

This process, called the *Landau-Zener* (or “interband”, or “band-to-band”) *tunneling*,⁸² is indeed possible. To analyze it, let us first take $F = 0$, and consider what happens if a quantum particle, described by an x -long (i.e. E -narrow) wave packet, is incident from free space upon a periodic structure of a large but finite length $l = Na \gg a$ – see, e.g., Fig. 22. If the packet’s energy E is within one of the energy bands, it may evidently propagate through the structure (though may be partly reflected from its ends). The corresponding quasimomentum may be found by solving the dispersion relation for q ; for example, in the weak-potential limit, Eq. (224) (which is valid near the gap) yields

$$q = q_m + \tilde{q}, \quad \text{with} \quad \tilde{q} = \pm \frac{1}{\gamma} \left[\tilde{E}^2 - |U_n|^2 \right]^{1/2}, \quad \text{for} |U_n|^2 \leq \tilde{E}^2, \quad (2.253)$$

where $\tilde{E} \equiv E_{\pm} - E^{(n)}$ and $\gamma = 2aE^{(n)}/\pi n$ – see the second of Eqs. (225).

Now, if the energy E is inside one of the energy gaps Δ_n , the wave packet’s propagation in an infinite periodic lattice is impossible, so that it is completely reflected from it. However, our analysis of the potential step problem in Sec. 3 implies that the packet’s wavefunction should still have an exponential tail protruding into the structure and decaying on some length δ – see Eq. (58) and Fig. 2.4.

⁸⁰ D. Haviland *et al.*, *Z. Phys. B* **85**, 339 (1991).

⁸¹ See, e.g., D. Averin *et al.*, *Sov. Phys. – JETP* **61**, 407 (1985). This effect is qualitatively similar to the transfer of single electrons, with a similar frequency $f = \bar{I}/e$, in tunnel junctions between normal (non-superconducting) metals – see, e.g., EM Sec. 2.9 and references therein.

⁸² It was predicted independently by L. Landau, C. Zener, E. Stueckelberg, and E. Majorana in 1932.

Indeed, a straightforward review of the calculations leading to Eq. (253) shows that it remains valid for energies within the gap as well, if the quasimomentum is understood as a purely imaginary number:

$$\tilde{q} \rightarrow \pm i\kappa, \quad \text{where } \kappa \equiv \frac{1}{\gamma} \left[|U_n|^2 - \tilde{E}^2 \right]^{1/2}, \quad \text{for } \tilde{E}^2 \leq |U_n|^2. \quad (2.254)$$

With this replacement, the Bloch solution (193b) indeed describes an exponential decay of the wavefunction at length $\delta \sim 1/\kappa$.

Returning to the effects of weak force F , in the real-space approach described by Eq. (248) and illustrated in Fig. 33b, we may recast Eq. (254) as

$$\kappa \rightarrow \kappa(x) = \frac{1}{\gamma} \left[|U_n|^2 - (F\tilde{x})^2 \right]^{1/2}, \quad (2.255)$$

where \tilde{x} is the particle's (i.e. its wave packet center's) deviation from the mid-gap point. Thus the gap creates a potential barrier of a finite width $\Delta x_0 = 2|U_n|/F$, through which the wave packet may tunnel with a non-zero probability. As we already know, in the WKB approximation (in our case requiring $\kappa\Delta x_0 \gg 1$) this probability is just the potential barrier's transparency \mathcal{T} , which may be calculated from Eq. (117):

$$-\ln \mathcal{T} = 2 \int_{\kappa(x)^2 > 0} \kappa(x) dx = \frac{2}{\gamma} \int_{-x_c}^{x_c} \left[|U_n|^2 - (F\tilde{x})^2 \right]^{1/2} d\tilde{x} = \frac{2|U_n|}{\gamma} 2x_c \int_0^1 (1 - \xi^2)^{1/2} d\xi. \quad (2.256)$$

where $\pm x_c \equiv \pm \Delta x_0/2 = \pm |U_n|/F$ are the classical turning points. Working out this simple integral (or just noticing that it is a quarter of the unit circle's area, and hence is equal to $\pi/4$), we get

$$\mathcal{T} = \exp \left\{ -\frac{\pi |U_n|^2}{\gamma F} \right\}. \quad (2.257)$$

This famous result may be also obtained in a more complex way, whose advantage is a constructive proof that Eq. (257) is valid for an arbitrary relation between γF and $|U_n|^2$, i.e. arbitrary \mathcal{T} , while our simple derivation was limited to the WKB approximation, valid only at $\mathcal{T} \ll 1$.⁸³ Using Eq. (225), we may rewrite the product γF participating in Eq. (257), as

$$\gamma F = \frac{1}{2} \left| \frac{d(E_l - E_{l'})}{dq_0} \right|_{E_l = E_{l'} = E^{(n)}} \hbar \frac{dq_0}{dt} = \frac{\hbar}{2} \left| \frac{d(E_l - E_{l'})}{dt} \right|_{E_l = E_{l'} = E^{(n)}} \equiv \frac{\hbar u}{2}, \quad (2.258)$$

where u has the meaning of the “speed” of the energy level crossing in the absence of the gap. Hence, Eq. (257) may be rewritten in the form

$$\mathcal{T} = \exp \left\{ -\frac{2\pi |U_n|^2}{\hbar u} \right\}, \quad (2.259)$$

which is more transparent physically. Indeed, the fraction $2|U_n|/u = \Delta_n u$ gives the time scale Δt of the energy's crossing the gap region, and according to the Fourier transform, its reciprocal, $\omega_{\max} \sim 1/\Delta t$

⁸³ In Chapter 6 below, Eq. (257) will be derived using a different method, based on the so-called *Golden Rule* of quantum mechanics, but also in the weak-potential limit, i.e. for hyperbolic dispersion law (253).

gives the upper cutoff of the frequencies essentially involved in the Bloch oscillation process. Hence Eq. (259) means that

$$-\ln \mathcal{T} \approx \frac{\Delta_n}{\hbar\omega_{\max}}. \quad (2.260)$$

This formula allows us to interpret the Landau-Zener tunneling as the system's excitation across the energy gap Δ_n by the highest-energy quantum $\hbar\omega_{\max}$ available from the Bloch oscillation process. This interpretation remains valid even in the opposite, tight-binding limit, in which, according to Eqs. (206) and (237), the Bloch oscillations are purely sinusoidal, so that the Landau-Zener tunneling is completely suppressed at $\hbar\omega_B < \Delta_1$.

Interband tunneling is an important ingredient of several physical phenomena and even some practical electron devices, for example, the *tunneling* (or “Esaki”) *diodes*. This simple device is just a junction of two semiconductor electrodes, one of them so strongly *n*-doped by electron donors that some electrons form a degenerate Fermi gas at the bottom of the conduction band.⁸⁴ Similarly, the counterpart semiconductor electrode is *p*-doped so strongly that the Fermi level in the valence band is shifted below the band edge – see Fig. 34.

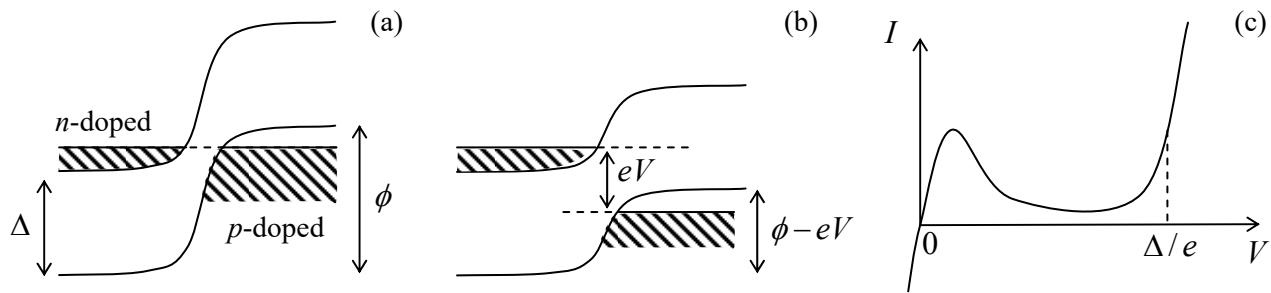

Fig. 2.34. The tunneling (“Esaki”) diode: (a) the band-edge diagram of the device at zero bias; (b) the same diagram at a modest positive bias $eV \sim \Delta/2$, and (c) the I - V curve of the device (schematically). Dashed lines on panels (a) and (b) show the Fermi level positions.

In thermal equilibrium, and in the absence of external voltage bias, the Fermi levels of the two electrodes self-align, leading to the build-up of the *contact potential difference* ϕ/e , with ϕ a bit larger than the energy bandgap Δ – see Fig. 34a. This potential difference creates an internal electric field that tilts the energy bands (just as the external field did in Fig. 33b), and leads to the formation of the so-called *depletion layer*, in which the Fermi level is located within the energy gap and hence there are no charge carriers ready to move. In the usual *p-n* junctions, this layer is broad and prevents any current at applied voltages V lower than $\sim \Delta/e$. In contrast, in a tunneling diode the depletion layer is so thin (below ~ 10 nm) that the interband tunneling is possible and provides a substantial Ohmic current at small applied voltages – see Fig. 34c. However, at larger positive biases, with $eV \sim \Delta/2$, the conduction band is aligned with the middle of the energy gap in the *p*-doped electrode, and electrons cannot tunnel there. Similarly, there are no electrons in the *n*-doped semiconductor to tunnel into the available states just above the Fermi level in the *p*-doped electrode – see Fig. 34b. As a result, at such voltages the current

⁸⁴ Here I have to rely on the reader’s background knowledge of basic semiconductor physics; it will be discussed in more detail in SM Sec. 6.4.

drops significantly, to grow again only when eV exceeds $\sim\Delta$, enabling electron motion within each energy band. Thus the tunnel junction's I - V curve has a part with a *negative differential resistance* ($dV/dI < 0$) – see Fig. 34c. This phenomenon, equivalent in its effect to negative kinematic friction in mechanics, may be used for amplification of weak analog signals, for self-excitation of electronic oscillators⁸⁵ (i.e. an ac signal generation), and for signal swing restoration in digital electronics.

2.9. Harmonic oscillator: Brute force approach

To complete our review of the basic 1D wave mechanics, we have to consider the famous harmonic oscillator, i.e. a 1D particle moving in the quadratic-parabolic potential (111), so that the stationary Schrödinger equation (53) is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + \frac{m\omega_0^2 x^2}{2} \psi = E\psi. \quad (2.261)$$

Conceptually, on the background of the fascinating quantum effects discussed in the previous sections, this is not a very interesting system: Eq. (261) is a standard 1D eigenproblem, resulting in a discrete energy spectrum E_n , with smooth eigenfunctions $\psi_n(x)$ vanishing at $x \rightarrow \pm\infty$ (because the potential energy tends to infinity there).⁸⁶ However, as we will repeatedly see later in the course, this problem's solutions have an enormous range of applications, so we have to know their basic properties.

The direct analytical solution of the problem is not very simple (see below), so let us start by trying some indirect approaches to it. First, as was discussed in Sec. 4, the WKB-approximation-based Wilson-Sommerfeld quantization rule (110), applied to this potential, yields the eigenenergy spectrum (114). With the common quantum number convention, this result is

$$E_n = \hbar\omega_0 \left(n + \frac{1}{2} \right), \quad \text{with } n = 0, 1, 2, \dots, \quad (2.262)$$

so that (in contrast to the 1D rectangular potential well) the ground-state energy corresponds to $n = 0$. However, as was discussed in the end of Sec. 4, for the quadratic potential (111) the WKB approximation's conditions are strictly satisfied only at $E_n \gg \hbar\omega_0$, so that so far we can only trust Eq. (262) for high levels, with $n \gg 1$, rather than for the (most important) ground state.

This is why let me use Eq. (261) to demonstrate another approximate approach, called the *variational method*, whose simplest form is aimed at finding ground states. The method is based on the following observation. (Here I am presenting its 1D wave mechanics form, though the method is much more general.) Let ψ_n be the exact, full, and orthonormal set of stationary wavefunctions of the system under study, and E_n the set of the corresponding energy levels, satisfying Eq. (1.60):

$$\hat{H}\psi_n = E_n\psi_n. \quad (2.263)$$

Then we may use this set for the unique expansion of an arbitrary *trial wavefunction* ψ_{trial} :

⁸⁵ See, e.g., CM Sec. 5.4.

⁸⁶ The stationary state of the harmonic oscillator (which, as will be discussed in Secs. 5.4 and 7.1, may be considered as the state with a definite number of identical bosonic excitations) are sometimes called *Fock states* – after Vladimir Aleksandrovich Fock. (This term is also used in a more general sense, for definite-particle-number states of systems with indistinguishable bosons of any kind – see Sec. 8.3.)

$$\psi_{\text{trial}} = \sum_n \alpha_n \psi_n, \quad \text{so that } \psi_{\text{trial}}^* = \sum_n \alpha_n^* \psi_n^*, \quad (2.264)$$

where α_n are some (generally, complex) coefficients. Let us require the trial function to be normalized, using the condition (1.66) of orthonormality of the eigenfunctions ψ_n :

$$\int \psi_{\text{trial}}^* \psi_{\text{trial}} d^3x \equiv \sum_{n,n'} \int \alpha_n^* \psi_n^* \alpha_{n'} \psi_{n'} d^3x \equiv \sum_{n,n'} \alpha_{n'} \alpha_n^* \int \psi_n^* \psi_{n'} d^3x \equiv \sum_{n,n'} \alpha_{n'} \alpha_n^* \delta_{n,n'} \equiv \sum_n W_n = 1, \quad (2.265)$$

where each of the coefficients W_n , defined as

$$W_n \equiv \alpha_n^* \alpha_n \equiv |\alpha_n|^2 \geq 0, \quad (2.266)$$

may be interpreted as the probability for the particle, in the n^{th} trial state, to be found in the n^{th} genuine stationary state. Now let us use Eq. (1.23) for a similar calculation of the expectation value of the system's Hamiltonian in the trial state:⁸⁷

$$\begin{aligned} \langle H \rangle_{\text{trial}} &= \int \psi_{\text{trial}}^* \hat{H} \psi_{\text{trial}} d^3x \equiv \sum_{n,n'} \int \alpha_n^* \psi_n^* \hat{H} \alpha_{n'} \psi_{n'} d^3x \equiv \sum_{n,n'} \alpha_{n'} \alpha_n^* E_{n'} \int \psi_n^* \psi_{n'} d^3x \\ &\equiv \sum_{n,n'} \alpha_{n'} \alpha_n^* E_{n'} \delta_{n,n'} \equiv \sum_n W_n E_n. \end{aligned} \quad (2.267)$$

Since the exact ground state energy E_g is, by definition, the lowest one of the set E_n , i.e. $E_n \geq E_g$, Eqs. (265) and (267) yield the following inequality:

$$\boxed{\langle H \rangle_{\text{trial}} \geq \sum_n W_n E_g \equiv E_g \sum_n W_n = E_g.} \quad (2.268)$$

Variational method's justification

Thus, the genuine ground state energy of the system is always lower than (or equal to) its energy in any trial state. Hence, if we make several attempts with reasonably selected trial wavefunctions, we may expect the lowest of the results to approximate the genuine ground state energy reasonably well. Even more conveniently, if we select some reasonable class of trial wavefunctions dependent on a free parameter λ , then we may use the necessary condition of the minimum of $\langle H \rangle_{\text{trial}}$,

$$\frac{\partial \langle H \rangle_{\text{trial}}}{\partial \lambda} = 0, \quad (2.269)$$

to find the closest of them to the genuine ground state. Even better results may be obtained using trial wavefunctions dependent on several parameters. Note, however, that the variational method does not tell us how exactly the trial function should be selected, or how close its final result is to the genuine ground-state function. In this sense, this method has “uncontrollable accuracy”, and differs from both the WKB approximation and the perturbation methods (to be discussed in Chapter 6), for which we have certain accuracy criteria. Because of this drawback, the variational method is typically used as the last resort – though sometimes (as in the example that follows) it works remarkably well.⁸⁸

⁸⁷ It is easy (and hence left for the reader) to show that the uncertainty δH in *any* state of a Hamiltonian system, including the trial state (264), vanishes, so that the $\langle H \rangle_{\text{trial}}$ may be interpreted as the definite energy of the state. For our current goals, however, this fact is not important.

⁸⁸ The variational method may be used also to estimate the first excited state (or even a few lowest excited states) of the system, by requiring the new trial function to be orthogonal to the previously calculated eigenfunctions of the lower-energy states. However, the method's error typically grows with the state number.

Let us apply this method to the harmonic oscillator. Since the potential (111) is symmetric with respect to point $x = 0$, and continuous at all points (so that, according to Eq. (261), $d^2\psi/dx^2$ has to be continuous as well), the most natural selection of the ground-state trial function is the Gaussian function

$$\psi_{\text{trial}}(x) = C \exp\{-\lambda x^2\}, \quad (2.270)$$

with some real $\lambda > 0$. The normalization coefficient C may be immediately found either from the standard Gaussian integration of $|\psi_{\text{trial}}|^2$, or just from the comparison of this expression with Eq. (16), in which $\lambda = 1/(2\delta x)^2$, i.e. $\delta x = 1/2\lambda^{1/2}$, giving $|C|^2 = (2\lambda/\pi)^{1/2}$. Now the expectation value of the particle's Hamiltonian,

$$\hat{H} = \frac{\hat{p}^2}{2m} + U(x) = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + \frac{m\omega_0^2 x^2}{2}, \quad (2.271)$$

in the trial state, may be calculated as

$$\begin{aligned} \langle H \rangle_{\text{trial}} &\equiv \int_{-\infty}^{+\infty} \psi_{\text{trial}}^* \left(-\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + \frac{m\omega_0^2 x^2}{2} \right) \psi_{\text{trial}} dx \\ &= \left(\frac{2\lambda}{\pi} \right)^{1/2} \left[\frac{\hbar^2 \lambda}{m} \int_0^{\infty} \exp\{-2\lambda x^2\} dx + \left(\frac{m\omega_0^2}{2} - \frac{2\hbar^2 \lambda^2}{m} \right) \int_0^{\infty} x^2 \exp\{-2\lambda x^2\} dx \right]. \end{aligned} \quad (2.272)$$

Both involved integrals are of the same well-known Gaussian type,⁸⁹ giving

$$\langle H \rangle_{\text{trial}} = \frac{\hbar^2}{2m} \lambda + \frac{m\omega_0^2}{8\lambda}. \quad (2.273)$$

As a function of λ , this expression has a single minimum at the value λ_{opt} that may be found from the requirement (269), giving $\lambda_{\text{opt}} = m\omega_0/2\hbar$. The resulting minimum of $\langle H \rangle_{\text{trial}}$ is *exactly* equal to ground-state energy following from Eq. (262),

$$E_0 = \frac{\hbar\omega_0}{2}. \quad (2.274)$$

Such a coincidence of results of the WKB approximation and the variational method is rather unusual, and implies (though does not strictly prove) that Eq. (274) is exact. As a minimum, this coincidence gives a strong motivation to plug the trial wavefunction (270), with $\lambda = \lambda_{\text{opt}}$, i.e.

$$\psi_0 = \left(\frac{m\omega_0}{\pi\hbar} \right)^{1/4} \exp\left\{ -\frac{m\omega_0 x^2}{2\hbar} \right\}, \quad (2.275)$$

and the energy (274), into the Schrödinger equation (261). Such substitution⁹⁰ shows that the equation is indeed exactly satisfied.

According to Eq. (275), the characteristic scale of the wavefunction's spatial spread⁹¹ is

⁸⁹ See, e.g., MA Eqs. (6.9b) and (6.9c).

⁹⁰ Actually, this is a twist of one of the tasks of Problem 1.12.

⁹¹ Quantitatively, as was already mentioned in Sec. 2.1, $x_0 = \sqrt{2}\delta x = \langle 2x^2 \rangle^{1/2}$.

$$x_0 \equiv \left(\frac{\hbar}{m\omega_0} \right)^{1/2}. \quad (2.276)$$

Due to the importance of this scale, let us give its crude estimates for several representative systems:⁹²

(i) For atom-bound electrons in solids and fluids, $m \sim 10^{-30}$ kg, and $\omega_0 \sim 10^{15}$ s⁻¹, giving $x_0 \sim 0.3$ nm, of the order of the typical inter-atomic distances in condensed matter. As a result, classical mechanics is not valid at all for the analysis of their motion.

(ii) For atoms in solids, $m \approx 10^{-24}$ - 10^{-26} kg, and $\omega_0 \sim 10^{13}$ s⁻¹, giving $x_0 \sim 0.01$ – 0.1 nm, i.e. somewhat smaller than inter-atomic distances. Because of that, the methods based on classical mechanics (e.g., molecular dynamics) are approximately valid for the analysis of atomic motion, though they may miss some fine effects exhibited by lighter atoms – e.g., the so-called *quantum diffusion* of hydrogen atoms, due to their tunneling through the energy barriers of the potential profile created by other atoms.

(iii) Recently, the progress of patterning technologies has enabled the fabrication of high-quality *micromechanical* oscillators consisting of zillions of atoms. For example, the oscillator used in one of the pioneering experiments in this field⁹³ was a ~ 1 -μm thick membrane with a 60-μm diameter, and had $m \sim 2 \times 10^{-14}$ kg and $\omega_0 \sim 3 \times 10^{10}$ s⁻¹, so that $x_0 \sim 4 \times 10^{-16}$ m. It is remarkable that despite such extreme smallness of x_0 (much smaller than not only any atom but even any atomic nucleus!), quantum states of such oscillators may be manipulated and measured, using their coupling to electromagnetic (in particular, optical) resonant cavities.⁹⁴

Returning to the Schrödinger equation (261), in order to analyze its higher eigenstates, we will need more help from mathematics. Let us recast this equation into a dimensionless form by introducing the dimensionless variable $\xi \equiv x/x_0$. This gives

$$-\frac{d^2\psi}{d\xi^2} + \xi^2\psi = \varepsilon\psi, \quad (2.277)$$

where $\varepsilon \equiv 2E/\hbar\omega_0 = E/E_0$. In this notation, the ground-state wavefunction (275) is proportional to $\exp\{-\xi^2/2\}$. Using this clue, let us look for solutions to Eq. (277) in the form

$$\psi = C \exp\left\{-\frac{\xi^2}{2}\right\} H(\xi), \quad (2.278)$$

where $H(\xi)$ is a new function, and C is the normalization constant. With this substitution, Eq. (277) yields

$$\frac{d^2H}{d\xi^2} - 2\xi \frac{dH}{d\xi} + (\varepsilon - 1)H = 0. \quad (2.279)$$

⁹² By order of magnitude, such estimates are valid even for the systems whose dynamics is substantially different from that of harmonic oscillators, if a typical frequency of quantum transitions is taken for ω_0 .

⁹³ A. O'Connell *et al.*, *Nature* **464**, 697 (2010).

⁹⁴ See a review of such experiments by M. Aspelmeyer *et al.*, *Rev. Mod. Phys.* **86**, 1391 (2014), and also recent experiments with nanoparticles placed in much “softer” potential wells – e.g., by U. Delić *et al.*, *Science* **367**, 892 (2020).

It is evident that $H = \text{const}$ and $\varepsilon = 1$ is one of its solutions, describing the ground-state eigenfunction (275) and energy (274), but what are the other eigenstates and eigenvalues? Fortunately, the linear differential equation (274) was studied in detail in the mid-1800s by C. Hermite who has shown that all its eigenvalues are given by the set

$$\varepsilon_n - 1 = 2n, \quad \text{with } n = 0, 1, 2, \dots, \quad (2.280)$$

so that Eq. (262) is indeed exact for any n .⁹⁵ The eigenfunction of Eq. (279), corresponding to the eigenvalue ε_n , is a polynomial (called the *Hermite polynomial*) of degree n , which may be most conveniently calculated using the following explicit formula:

Hermite polynomials

$$H_n = (-1)^n \exp\{\xi^2\} \frac{d^n}{d\xi^n} \exp\{-\xi^2\}. \quad (2.281)$$

It is easy to use this formula to spell out several lowest-degree polynomials – see Fig. 35a:

$$H_0 = 1, \quad H_1 = 2\xi, \quad H_2 = 4\xi^2 - 2, \quad H_3 = 8\xi^3 - 12\xi, \quad H_4 = 16\xi^4 - 48\xi^2 + 12, \dots \quad (2.282)$$

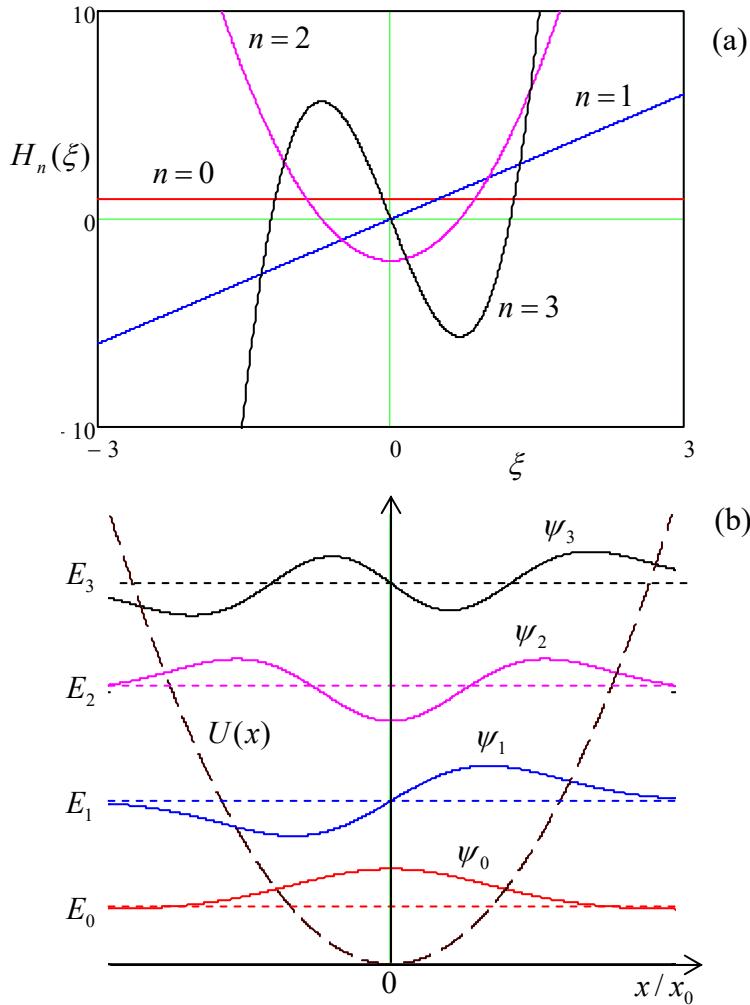

Fig. 2.35. (a) A few lowest Hermite polynomials and (b) the corresponding eigenenergies (horizontal dashed lines) and eigenfunctions (solid lines) of the harmonic oscillator. The black dashed curve shows the potential profile $U(x)$ drawn on the same scale as the energies E_n , so that its crossings with the energy levels correspond to classical turning points.

⁹⁵ Perhaps the most important property of this energy spectrum is that it is equidistant: $E_{n+1} - E_n = \hbar\omega_0 = \text{const}$.

The properties of these polynomials, which most important for applications, are as follows:

- (i) the function $H_n(\xi)$ has exactly n zeros (its plot crosses the ξ -axis exactly n times); as a result, the “parity” (symmetry-antisymmetry) of these functions alternates with n , and
- (ii) the polynomials are mutually orthonormal in the following sense:

$$\int_{-\infty}^{+\infty} H_n(\xi) H_{n'}(\xi) \exp\{-\xi^2\} d\xi = \pi^{1/2} 2^n n! \delta_{n,n'}. \quad (2.283)$$

Using the last property, we may readily calculate, from Eq. (278), the normalized eigenfunctions $\psi_n(x)$ of the harmonic oscillator – see Fig. 35b:

$$\psi_n(x) = \frac{1}{(2^n n!)^{1/2} \pi^{1/4} x_0^{1/2}} \exp\left\{-\frac{x^2}{2x_0^2}\right\} H_n\left(\frac{x}{x_0}\right). \quad (2.284)$$

Harmonic oscillator:
eigen-functions

At this point, it is instructive to compare these eigenfunctions with those of a 1D rectangular potential well, with its ultimately hard walls – see Fig. 1.8. Let us list their *common* features:

- (i) The wavefunctions oscillate in the classically allowed regions with $E_n > U(x)$, while dropping exponentially beyond the boundaries of that region. (For the rectangular well with infinite walls, the latter regions are infinitesimally narrow.)
- (ii) Each step up the energy level ladder increases the number of the oscillation half-waves (and hence the number of its zeros), by one.⁹⁶

And here are the major features *specific* for soft (e.g., the quadratic-parabolic) confinement:

- (i) The spatial spread of the wavefunction grows with n , following the gradual widening of the classically allowed region.
- (ii) Correspondingly, E_n exhibits a slower growth than the $E_n \propto n^2$ law given by Eq. (1.85), because the gradual reduction of spatial confinement moderates the kinetic energy’s growth.

Unfortunately, the “brute-force” approach to the harmonic oscillator problem, discussed above, is not too appealing. First, the proof of Eq. (281) is rather longish – so I do not have time/space for it. More importantly, it is hard to use Eq. (284) for the calculation of the expectation values of observables including the so-called *matrix elements* of the system – as we will see in Chapter 4, virtually the only numbers important for most applications. Finally, it is also almost evident that there has to be some straightforward math leading to any formula as simple as Eq. (262) for E_n . Indeed, there is a much more efficient, operator-based approach to this problem; it will be described in Sec. 5.4.

2.10. Exercise problems

2.1. The initial wave packet of a free 1D particle is described by Eq. (20):

$$\Psi(x,0) = \int a_k e^{ikx} dk.$$

⁹⁶ In mathematics, a slightly more general statement, valid for a broader class of ordinary linear differential equations, is frequently called the *Sturm oscillation theorem*, and is a part of the *Sturm-Liouville theory* of such equations – see, e.g., Chapter 10 in the handbook by G. Arfken *et al.*, cited in MA Sec. 16.

(i) Obtain a compact expression for the expectation value $\langle p \rangle$ of the particle's momentum at an arbitrary moment $t > 0$.

(ii) Calculate $\langle p \rangle$ for the case when the function $|a_k|^2$ is symmetric with respect to some value k_0 .

2.2. Calculate the function a_k defined by Eq. (20), for the wave packet with a rectangular spatial envelope:

$$\Psi(x,0) = \begin{cases} C \exp\{ik_0 x\}, & \text{for } -a/2 \leq x \leq +a/2, \\ 0, & \text{otherwise.} \end{cases}$$

Analyze the result in the limit $k_0 a \rightarrow \infty$.

2.3. Prove Eq. (49) for the 1D propagator of a free quantum particle, starting from Eq. (48).

2.4. Express the 1D propagator defined by Eq. (44), via the eigenfunctions and eigenenergies of a particle moving in an arbitrary stationary potential $U(x)$.

2.5. Calculate the change of the wavefunction of a 1D particle, resulting from a short pulse of an external classical force that may be approximated by the delta function:⁹⁷

$$F(t) = P\delta(t).$$

2.6. Calculate the transparency \mathcal{T} of the rectangular potential barrier (68),

$$U(x) = \begin{cases} 0, & \text{for } x < -d/2, \\ U_0, & \text{for } -d/2 < x < +d/2, \\ 0, & \text{for } d/2 < x, \end{cases}$$

for a particle of energy $E > U_0$. Analyze and interpret the result, taking into account that U_0 may be either positive or negative. (In the latter case, we are speaking about the particle's passage over a rectangular potential well of a finite depth $|U_0|$.)

2.7. Prove Eq. (117) for the case $\mathcal{T}_{\text{WKB}} \ll 1$, using the connection formulas (105).

2.8. Spell out the stationary wavefunctions of a harmonic oscillator in the WKB approximation, and use them to calculate the expectation values $\langle x^2 \rangle$ and $\langle x^4 \rangle$ for the eigenstate number $n \gg 1$.

2.9. Use the WKB approximation to express the expectation value of the kinetic energy of a 1D particle confined in a soft potential well, in its n^{th} stationary state, via the derivative dE_n/dn , for $n \gg 1$.

2.10. Use the WKB approximation to calculate the transparency \mathcal{T} of the following triangular potential barrier:

$$U(x) = \begin{cases} 0, & \text{for } x < 0, \\ U_0 - Fx, & \text{for } x > 0, \end{cases}$$

⁹⁷ The constant P is called the force's *impulse*. (In higher dimensionalities, it is a vector – just as the force is.)

with $F, U_0 > 0$, as a function of the incident particle's energy E .

Hint: Be careful with the sharp potential step at $x = 0$.

2.11.* Prove that the symmetry of the 1D scattering matrix S describing an arbitrary time-independent scatterer, allows its representation in the form (127).

2.12. Prove the universal relations between elements of the 1D transfer matrix T of a stationary (but otherwise arbitrary) scatterer, mentioned in Sec. 5.

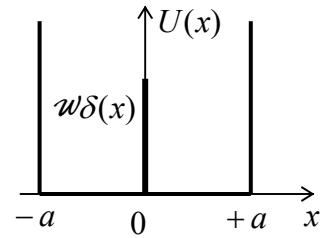

2.13. A 1D particle had been localized in a very narrow and deep potential well, with the “energy area” $\int U(x)dx$ equal to $-w$, where $w > 0$. Then (say, at $t = 0$) the well’s bottom is suddenly lifted up, so that the particle becomes completely free. Calculate the probability density, $w(k)$, to find the particle in a state with a certain wave number k at $t > 0$, and the total final energy of the system.

2.14. Calculate the lifetime of the metastable localized state of a 1D particle in the potential

$$U(x) = -w\delta(x) - Fx, \quad \text{with } w > 0,$$

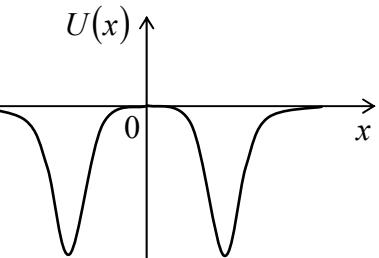

using the WKB approximation. Formulate the condition of validity of the result.

2.15. Calculate the energy levels and the corresponding eigenfunctions of a 1D particle placed into a flat-bottom potential well of width $2a$, with infinitely-high hard walls, and a transparent, short potential barrier in the middle – see the figure on the right. Discuss particle dynamics in the limit when w is very large but still finite.

2.16.* Consider a symmetric system of two potential wells of the type shown in Fig. 21, but with $U(0) = U(\pm\infty) = 0$ – see the figure on the right. What is the sign of the well interaction force due to their sharing a quantum particle of mass m , for the cases when the particle is in:

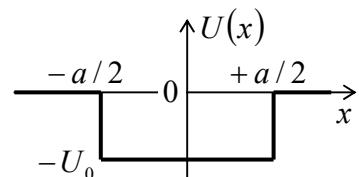

- (i) a symmetric localized eigenstate: $\psi_S(-x) = \psi_S(x)$?
- (ii) an antisymmetric localized eigenstate: $\psi_A(-x) = -\psi_A(x)$?

Use an alternative approach to verify your result for the particular case of delta-functional wells.

2.17. Derive and analyze the characteristic equation for localized eigenstates of a 1D particle in a rectangular potential well of a finite depth (see the figure on the right):

$$U(x) = \begin{cases} -U_0, & \text{for } |x| \leq a/2, \\ 0, & \text{otherwise.} \end{cases}$$

In particular, calculate the number of localized states as a function of well’s width a , and explore the limit $U_0 \ll \hbar^2/2ma^2$.

2.18. Calculate the energy of a 1D particle localized in a potential well of an arbitrary shape $U(x)$, provided that its width a is finite, and the average depth is very small:

$$|\bar{U}| \ll \frac{\hbar^2}{2ma^2}, \quad \text{where } \bar{U} \equiv \frac{1}{a} \int_{\text{well}} U(x) dx$$

2.19. A particle of mass m is moving in a field with the following potential:

$$U(x) = U_0(x) + w\delta(x),$$

where $U_0(x)$ is a smooth, symmetric function with $U_0(0) = 0$, growing monotonically at $x \rightarrow \pm\infty$.

- (i) Use the WKB approximation to derive the characteristic equation for the particle's energy spectrum, and
- (ii) semi-quantitatively describe the spectrum's evolution at the increase of $|w|$, for both signs of this parameter.

Make both results more specific for the quadratic-parabolic potential (111): $U_0(x) = m\omega_0^2 x^2/2$.

2.20. Prove Eq. (189), starting from Eq. (188).

2.21. For the problem discussed at the beginning of Sec. 7, i.e. the 1D particle's motion in an infinite Dirac comb potential shown in Fig. 24,

$$U(x) = w \sum_{j=-\infty}^{+\infty} \delta(x - ja), \quad \text{with } w > 0,$$

(where j takes integer values), write explicit expressions for the eigenfunctions at the very bottom and at the very top of the lowest energy band. Sketch both functions.

2.22. A 1D particle of mass m moves in an infinite periodic system of very narrow and deep potential wells that may be described by delta functions:

$$U(x) = w \sum_{j=-\infty}^{+\infty} \delta(x - ja), \quad \text{with } w < 0.$$

- (i) Sketch the energy band structure of the system for very small and very large values of the potential well's "weight" $|w|$, and
- (ii) calculate explicitly the ground state energy of the system in these two limits.

2.23. For the system discussed in the previous problem, write explicit expressions for the eigenfunctions of the system, corresponding to:

- (i) the bottom of the lowest energy band,
- (ii) the top of that band, and
- (iii) the bottom of each higher energy band.

Sketch these functions.

2.24.* The 1D "crystal" analyzed in the last two problems, now extends only to $x > 0$, with a sharp step to a flat potential plateau at $x < 0$:

$$U(x) = \begin{cases} w \sum_{j=1}^{+\infty} \delta(x - ja), & \text{with } w < 0, \\ U_0 > 0, & \text{for } x < 0. \end{cases} \quad \text{for } x > 0,$$

Prove that the system can have a set of the so-called *Tamm states*, localized near the “surface” $x = 0$, and calculate their energies in the limit when U_0 is very large but finite. (Quantify this condition.)⁹⁸

2.25. Calculate the whole transfer matrix of the rectangular potential barrier, specified by Eq. (68), for particle energies both below and above U_0 .

2.26. Use the results of the previous problem to calculate the transfer matrix of one period of the periodic Kronig-Penney potential shown in Fig. 31b.

2.27. Using the results of the previous problem, derive the characteristic equations for particle's motion in the periodic Kronig-Penney potential, for both $E < U_0$ and $E > U_0$. Try to bring the equations to a form similar to that obtained in Sec. 7 for the delta-functional barriers – see Eq. (198). Use the equations to formulate the conditions of applicability of the tight-binding and weak-potential approximations, in terms of the system's parameters, and the particle's energy E .

2.28. For the Kronig-Penney potential, use the tight-binding approximation to calculate the widths of the allowed energy bands. Compare the results with those of the previous problem (in the corresponding limit).

2.29. For the same Kronig-Penney potential, use the weak-potential limit formulas to calculate the energy gap widths. Again, compare the results with those of Problem 27, in the corresponding limit.

2.30. 1D periodic chains of atoms may exhibit what is called the *Peierls instability*, leading to the *Peierls transition* to a phase in which atoms are slightly displaced, from the exact periodicity, by alternating displacements $\Delta x_j = (-1)^j \Delta x$, with $\Delta x \ll a$, where j is the atom's number in the chain, and a is its initial period. These displacements lead to the alternation of the coupling amplitudes δ_n (see Eq. (204)) between close values δ_n^+ and δ_n^- . Use the tight-binding approximation to calculate the resulting change of the n^{th} energy band, and discuss the result.

2.31.* Use Eqs. (1.73)-(1.74) of the lecture notes to derive Eq. (252), and discuss the relation between these Bloch oscillations and the Josephson oscillations of frequency (1.75).

2.32. A 1D particle of mass m is placed to the following triangular potential well:

$$U(x) = \begin{cases} +\infty, & \text{for } x < 0, \\ Fx, & \text{for } x > 0, \end{cases} \quad \text{with } F > 0.$$

(i) Calculate its energy spectrum using the WKB approximation.

⁹⁸ In applications to electrons in solid-state crystals, the delta-functional potential wells model the attractive potentials of atomic nuclei, while U_0 represents the workfunction, i.e. the energy necessary for the extraction of an electron from the crystal to the free space – see, e.g., Sec. 1.1(ii), and also EM Sec. 2.6 and SM Sec. 6.3.

(ii) Estimate the ground state energy using the variational method, with two different trial functions.

(iii) Calculate the three lowest energy levels, and also the 10th level, with an accuracy better than 0.1%, from the exact solution of the problem.

(iv) Compare and discuss the results.

Hint: The values of the first zeros of the Airy function, necessary for Task (iii), may be found in many math handbooks, for example, in Table 9.9.1 of the online version of the collection edited by Abramowitz and Stegun – see MA Sec. 16(i).

2.33. Use the variational method to estimate the ground state energy E_g of a particle in the following potential well:

$$U(x) = -U_0 \exp\{-\alpha x^2\}, \quad \text{with } \alpha > 0, \text{ and } U_0 > 0.$$

Spell out the results in the limits of small and large U_0 , and give their interpretation.

2.34. For a 1D particle of mass m , placed to a potential well with the following profile,

$$U(x) = ax^{2s}, \quad \text{with } a > 0, \text{ and } s > 0,$$

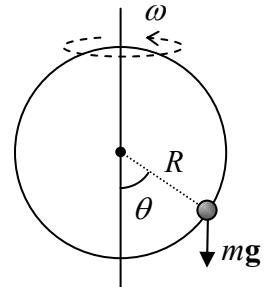

- (i) calculate its energy spectrum using the WKB approximation, and
- (ii) estimate the ground state energy using the variational method.

Compare the ground-state energy results for the parameter s equal to 1, 2, 3, and 100.

2.35. Use the variational method to estimate the 1st excited state of the 1D harmonic oscillator.

2.36. Assuming the quantum effects to be small, calculate the lower part of the energy spectrum of the following system: a small bead of mass m , free to move without friction along a ring of radius R , which is rotated about its vertical diameter with a constant angular velocity ω – see the figure on the right. Formulate a quantitative condition of validity of your results.

Hint: This system was used as the analytical mechanics' “testbed problem” in the CM part of this series, and the reader is welcome to use any relations derived there.

2.37. A 1D harmonic oscillator, with mass m and frequency ω_0 , had been in its ground state; then an additional force F was suddenly applied, and after that kept constant. Calculate the probability of the oscillator staying in its ground state.

2.38. A 1D particle of mass m has been placed to a quadratic potential well (111),

$$U(x) = \frac{m\omega_0^2 x^2}{2},$$

and allowed to relax into the ground state. At $t = 0$, the well was fast accelerated to move with velocity v , without changing its profile, so that at $t \geq 0$ the above formula for U is valid with the replacement $x \rightarrow x' \equiv x - vt$. Calculate the probability for the system to still be in the ground state at $t > 0$.

2.39. Initially, a 1D harmonic oscillator was in its ground state. At a certain moment of time, its spring constant κ is abruptly increased so that its frequency $\omega_0 = (\kappa/m)^{1/2}$ is increased by a factor of α , and then is kept constant at the new value. Calculate the probability that after the change, the oscillator is still in its ground state.

2.40. A 1D particle is placed into the following potential well:

$$U(x) = \begin{cases} +\infty, & \text{for } x < 0, \\ m\omega_0^2 x^2 / 2, & \text{for } x \geq 0. \end{cases}$$

(i) Find its eigenfunctions and eigenenergies.

(ii) This system had been let to relax into its ground state, and then the potential wall at $x < 0$ was rapidly removed so that the system was instantly turned into the usual harmonic oscillator (with the same m and ω_0). Find the probability for the oscillator to remain in its ground state.

2.41. Prove the following formula for the propagator of the 1D harmonic oscillator:

$$G(x, t; x_0, t_0) = \left(\frac{m\omega_0}{2\pi i\hbar \sin[\omega_0(t - t_0)]} \right)^{1/2} \exp \left\{ \frac{i m \omega_0}{2\hbar \sin[\omega_0(t - t_0)]} \left[(x^2 + x_0^2) \cos[\omega_0(t - t_0)] - 2x x_0 \right] \right\}.$$

Discuss the relation between this formula and the propagator of a free 1D particle.

2.42. In the context of the Sturm oscillation theorem mentioned in Sec. 9, prove that the number of eigenfunction's zeros of a particle confined in an arbitrary but finite potential well always increases with the corresponding eigenenergy.

Hint: You may like to use the suitably modified Eq. (186).

2.43.* Use the WKB approximation to calculate the lifetime of the metastable ground state of a 1D particle of mass m in the “pocket” of the potential profile

$$U(x) = \frac{m\omega_0^2}{2} x^2 - \alpha x^3.$$

Contemplate the significance of this problem.

Chapter 3. Higher Dimensionality Effects

The description of the basic quantum-mechanical effects, given in the previous chapter, may be extended to higher dimensions in an obvious way. This is why this chapter is focused on the phenomena (such as the AB effect and the Landau levels) that cannot take place in one dimension due to topological reasons, and also on a few key 3D problems (such as the Born approximation in the scattering theory, and the axially- and spherically-symmetric systems) that are important for numerous applications.

3.1. Quantum interference and the AB effect

In the past two chapters, we have already discussed some effects of the de Broglie wave interference. For example, standing waves inside a potential well, or even on the top of a potential barrier, may be considered as a result of interference of incident and reflected waves. However, there are some remarkable new effects made possible by spatial separation of such waves, and such separation requires a higher (either 2D or 3D) dimensionality. A good example of wave separation is provided by the Young-type experiment (Fig. 1) in which particles, emitted by the same source, are passed through two narrow holes (or slits) in an otherwise opaque partition.

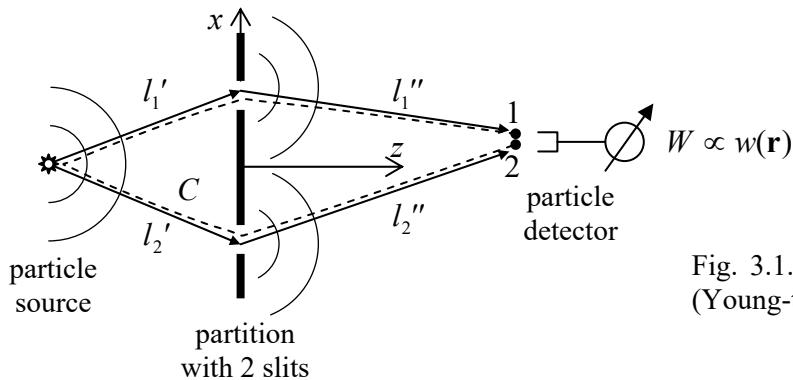

Fig. 3.1. The scheme of the “two-slit” (Young-type) interference experiment.

According to Eq. (1.22), if particle interactions are negligible (which is always true if the emission rate is sufficiently low), the average rate of particle counting by the detector is proportional to the probability density $w(\mathbf{r}, t) = \Psi(\mathbf{r}, t) \Psi^*(\mathbf{r}, t)$ to find a single particle at the detector’s location \mathbf{r} , where $\Psi(\mathbf{r}, t)$ is the solution of the single-particle Schrödinger equation (1.25) for the system. Let us calculate the rate for the case when the incident particles may be represented by virtually-monochromatic waves of energy E (e.g., very long wave packets), so that their wavefunction may be taken in the form given by Eqs. (1.57) and (1.62): $\Psi(\mathbf{r}, t) = \psi(\mathbf{r}) \exp\{-iEt/\hbar\}$. In this case, in the free-space parts of the system, where $U(\mathbf{r}) = 0$, $\psi(\mathbf{r})$ satisfies the stationary Schrödinger equation (1.78a):

$$-\frac{\hbar^2}{2m} \nabla^2 \psi = E \psi . \quad (3.1a)$$

With the standard definition $k \equiv (2mE)^{1/2}/\hbar$, it may be rewritten as the 3D Helmholtz equation:

$$\nabla^2 \psi + k^2 \psi = 0 . \quad (3.1b)$$

The opaque parts of the partition may be well described as classically forbidden regions, so if their size scale a is much larger than the wavefunction penetration depth δ described by Eq. (2.59), we may use on their surface S the same boundary conditions as for the well's walls of infinite height:

$$\psi|_S = 0. \quad (3.2)$$

Eqs. (1) and (2) describe the standard boundary problem of the theory of propagation of scalar waves of any nature. For an arbitrary geometry, this problem does not have a simple analytical solution. However, for a conceptual discussion of wave interference, we may use certain natural assumptions that will allow us to find its particular, approximate solution.

First, let us discuss the wave emission, into free space, by a small-size, isotropic source located at the origin of our reference frame. Naturally, the emitted wave should be spherically symmetric: $\psi(\mathbf{r}) = \psi(r)$. Using the well-known expression for the Laplace operator in spherical coordinates,¹ we may reduce Eq. (1) to the following ordinary differential equation:

$$\frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d\psi}{dr} \right) + k^2 \psi = 0. \quad (3.3)$$

Let us introduce a new function, $f(r) \equiv r\psi(r)$. Plugging the reciprocal relation $\psi = f/r$ into Eq. (3), we see that it is reduced to the 1D wave equation,

$$\frac{d^2 f}{dr^2} + k^2 f = 0. \quad (3.4)$$

As was discussed in Sec. 2.2, for a fixed k , the general solution of Eq. (4) may be represented in the form of two traveling waves:

$$f = f_+ e^{ikr} + f_- e^{-ikr} \quad (3.5)$$

so that the full wavefunction is

$$\psi(\mathbf{r}) = \frac{f_+}{r} e^{ikr} + \frac{f_-}{r} e^{-ikr}, \quad \text{i.e. } \Psi(\mathbf{r}, t) = \frac{f_+}{r} e^{i(kr - \omega t)} + \frac{f_-}{r} e^{-i(kr + \omega t)}, \quad \text{with } \omega \equiv \frac{E}{\hbar} = \frac{\hbar k^2}{2m}. \quad (3.6)$$

If the source is located at point $\mathbf{r}' \neq 0$, the obvious generalization of Eq. (6) is

$$\Psi(\mathbf{r}, t) = \frac{f_+}{R} e^{i(kR - \omega t)} + \frac{f_-}{R} e^{-i(kR + \omega t)}, \quad \text{with } R \equiv |\mathbf{R}|, \quad \mathbf{R} \equiv \mathbf{r} - \mathbf{r}'. \quad (3.7)$$

The first term of this solution describes a spherically-symmetric wave propagating from the source outward, while the second one, a wave converging onto the source point \mathbf{r}' from large distances. Though the latter solution is possible at some very special circumstances (say, when the outgoing wave is reflected back from a spherical shell), for our current problem, only the outgoing waves are relevant, so that we may keep only the first term (proportional to f_+) in Eq. (7). Note that the factor R is the denominator (that was absent in the 1D geometry) has a simple physical sense: it provides the independence of the full probability current $I = 4\pi R^2 j(R)$, with $j(R) \propto k\Psi\Psi^* \propto 1/R^2$, of the distance R between the observation point and the source.

¹ See, e.g., MA Eq. (10.9) with $\partial/\partial\theta = \partial/\partial\varphi = 0$.

Now let us assume that the partition's geometry is not too complicated – for example, it is either planar as shown in Fig. 1, or nearly-planar, and consider the region of the particle detector location far behind the partition (at $z \gg 1/k$), and at a relatively small angle to it: $|x| \ll z$. Then it should be physically clear that the spherical waves (7) emitted by each point inside the slit cannot be perturbed too much by the opaque parts of the partition, and their only role is the restriction of the set of such emitting points to the area of the slits. Hence, an approximate solution of the boundary problem is given by the following *Huygens principle*: the wave behind the partition looks as if it was the sum of contributions (7) of point sources located in the slits, with each source's strength f_+ proportional to the amplitude of the wave arriving at this pseudo-source from the real source – see Fig. 1. This principle finds its confirmation in the strict wave theory, which shows that with our assumptions, the solution of the boundary problem (1)-(2) may be represented as the following *Kirchhoff integral*:²

Kirchhoff integral

$$\psi(\mathbf{r}) = c \int_{\text{slits}} \frac{\psi(\mathbf{r}')}{R} e^{ikR} d^2 r', \quad \text{with } c = \frac{k}{2\pi i}. \quad (3.8)$$

If the source is also far from the partition, its wave's front is almost parallel to the slit plane, and if the slits are not too broad, we can take $\psi(\mathbf{r}')$ constant ($\psi_{1,2}$) at each slit, so that Eq. (8) is reduced to

$$\psi(\mathbf{r}) = a''_1 \exp\{ikl''_1\} + a''_2 \exp\{ikl''_2\}, \quad \text{with } a''_{1,2} = \frac{cA_{1,2}}{l''_{1,2}} \psi_{1,2}, \quad (3.9)$$

where $A_{1,2}$ are the slit areas, and $l''_{1,2}$ are the distances from the slits to the detector. The wavefunctions on the slits may be calculated approximately³ by applying the same Eq. (7) to the region *before* the slits: $\psi_{1,2} \approx (f_+/l'_{1,2}) \exp\{ikl'_{1,2}\}$, where $l'_{1,2}$ are the distances from the source to the slits – see Fig. 1. As a result, Eq. (9) may be rewritten as

Wave-function superposition

$$\psi(\mathbf{r}) = a_1 \exp\{ikl_1\} + a_2 \exp\{ikl_2\}, \quad \text{with } l_{1,2} \equiv l'_{1,2} + l''_{1,2}; \quad a_{1,2} \equiv \frac{c f_+ A_{1,2}}{l'_{1,2} l''_{1,2}}. \quad (3.10)$$

(As Fig. 1 shows, each of $l_{1,2}$ is the full length of the classical path of the particle from the source, through the corresponding slit, and further to the observation point \mathbf{r} .)

According to Eq. (10), the resulting rate of particle counting at point \mathbf{r} is proportional to

$$w(\mathbf{r}) = \psi(\mathbf{r}) \psi^*(\mathbf{r}) = |a_1|^2 + |a_2|^2 + 2|a_1 a_2| \cos \varphi_{12}, \quad (3.11)$$

where

$$\varphi_{12} \equiv k(l_2 - l_1) \quad (3.12)$$

is the difference of the total wave phase accumulations along each of two alternative paths. The last expression may be evidently generalized as

² For the proof and a detailed discussion of Eq. (8), see, e.g., EM Sec. 8.5.

³ A possible (and reasonable) concern about the application of Eq. (7) to the field in the slits is that it ignores the effect of opaque parts of the partition. However, as we know from Chapter 2, the main role of the classically forbidden region is reflecting the incident wave toward its source (i.e. to the left in Fig. 1). As a result, the contribution of this reflection to the field inside the slits is insignificant if $A_{1,2} \gg \lambda^2$, and even in the opposite case provides just some rescaling of the amplitudes $a_{1,2}$, which is not important for our conceptual discussion.

$$\varphi_{12} = \oint_C \mathbf{k} \cdot d\mathbf{r}, \quad (3.13)$$

with integration along the virtually closed contour C (see the dashed line in Fig. 1), i.e. from point 1, in the positive (i.e. counterclockwise) direction all the way to point 2. (From our discussion of the 1D WKB approximation in Sec. 2.4, we may expect such generalization to be valid even if k changes, sufficiently slowly, along the paths.)

Our result (11)-(12) shows that the particle counting rate oscillates as a function of the difference $(l_2 - l_1)$, which in turn changes with the detector's position, giving the famous interference pattern, with the amplitude proportional to the product $|a_1 a_2|$, and hence vanishing if any of the slits is closed. For the wave theory, this is a well-known result,⁴ but for particle physics, it was (and still is :-:) rather shocking. Indeed, our analysis is valid for a very low particle emission rate, so that there is no other way to interpret the pattern other than resulting from a particle's interference *with itself* – or rather the interference of its de Broglie waves passing through each of two slits.⁵ Nowadays, such interference is reliably observed not only for electrons but also for much heavier particles: atoms and molecules, including very complex organic ones;⁶ moreover, atomic interferometers are used as ultra-sensitive instruments for measurements of gravity, rotation, and tilt.⁷

Let us now discuss a very interesting effect of magnetic field on quantum interference. To simplify our discussion, let us consider a slightly different version of the two-slit experiment, in which each of the two alternative paths is constricted to a narrow channel using partial confinement – see Fig. 2. (In this arrangement, moving the particle detector without changing channels' geometry, and hence local values of k may be more problematic experimentally, so let us think about its position \mathbf{r} as fixed.) In this case, because of the effect of the walls providing the path confinement, we cannot use Eqs. (10) for the amplitudes $a_{1,2}$. However, from the discussions in Sec. 1.6 and Sec. 2.2, it should be clear that the first of the expressions (10) remains valid, though maybe with a value of k specific for each channel.

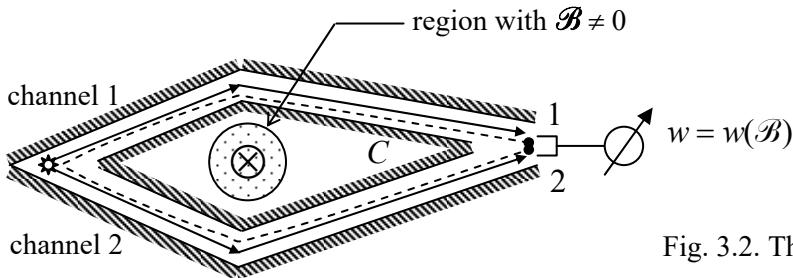

Fig. 3.2. The AB effect.

In this geometry, we can apply some local magnetic field \mathcal{B} , say normal to the plane of particle motion, whose lines would pierce, but not touch the contour C drawn along the particle propagation

⁴ See, e.g., a detailed discussion in EM Sec. 8.4.

⁵ Here I have to mention the fascinating experiments (first performed in 1987 by C. Hong *et al.* with photons, and recently, in 2015, by R. Lopes *et al.*, with non-relativistic particles – helium atoms) on the interference of de Broglie waves of *independent* but *identical* particles, in the same internal quantum state and virtually the same values of E and k . These experiments raise the important issue of particle *indistinguishability*, which will be discussed in Sec. 8.1.

⁶ See, e.g., the recent demonstration of the quantum interference of oligo-porphyrin molecules, consisting of ~2,000 atoms, with a total mass above $25,000 m_p$ – Y. Fein *et al.*, *Nature Physics* **15**, 1242 (2019).

⁷ See, e.g., the review paper by A. Cronin, J. Schmiedmayer, and D. Pritchard, *Rev. Mod. Phys.* **81**, 1051 (2009).

channels – see the dashed line in Fig. 2. In classical electrodynamics,⁸ the external magnetic field's effect on a particle with electric charge q is described by the *Lorentz force*

$$\mathbf{F}_{\mathcal{B}} = q\mathbf{v} \times \mathcal{B}, \quad (3.14)$$

where \mathcal{B} is the field value at the point of its particle's location, so that for the experiment shown in Fig. 2, $\mathbf{F}_{\mathcal{B}} = 0$, and the field would not affect the particle motion at all. In quantum mechanics, this is not so, and the field does affect the probability density w , even if $\mathcal{B} = 0$ at all points where the wavefunction $\psi(\mathbf{r})$ is not equal to zero.

In order to describe this surprising effect, let us first develop a general framework for an account of electromagnetic field effects on a quantum particle, which will also give us some by-product results important for forthcoming discussions. To do that, we need to calculate the Hamiltonian of a charged particle in electric and magnetic fields. For an electrostatic field, this is easy. Indeed, from classical electrodynamics we know that such field may be represented as a gradient of its electrostatic potential ϕ ,

$$\mathcal{E} = -\nabla\phi(\mathbf{r}), \quad (3.15)$$

so that the force exerted by the field on a particle with electric charge q ,

$$\mathbf{F}_{\mathcal{E}} = q\mathcal{E}, \quad (3.16)$$

may be described by adding the field-induced potential energy,

$$U(\mathbf{r}) = q\phi(\mathbf{r}), \quad (3.17)$$

to other (possible) components of the full potential energy of the particle. As was already discussed in Sec. 1.4, such potential energy may be included in the particle's Hamiltonian operator just by adding it to the kinetic energy operator – see Eq. (1.41).

However, the magnetic field's effect is peculiar: since its Lorentz force (14) cannot do any work on a classical particle:

$$d\mathcal{W}_{\mathcal{B}} \equiv \mathbf{F}_{\mathcal{B}} \cdot d\mathbf{r} = \mathbf{F}_{\mathcal{B}} \cdot \mathbf{v} dt = q(\mathbf{v} \times \mathcal{B}) \cdot \mathbf{v} dt = 0, \quad (3.18)$$

the field cannot be represented by any potential energy, so it may not be immediately clear how to account for it in the Hamiltonian. The crucial help comes from the analytical-mechanics approach to classical electrodynamics:⁹ in the non-relativistic limit, the Hamiltonian function of a particle in an electromagnetic field looks like that in the electric field only:

$$H = \frac{mv^2}{2} + U = \frac{p^2}{2m} + q\phi; \quad (3.19)$$

however, the momentum $\mathbf{p} \equiv mv$ that participates in this expression is now the difference

$$\mathbf{p} = \mathbf{P} - q\mathbf{A}. \quad (3.20)$$

Here \mathbf{A} is the vector potential, defined by the well-known relations for the electric and magnetic fields:¹⁰

⁸ See, e.g., EM Sec. 5.1. Note that Eq. (14), as well as all other formulas of this course, are in the SI units.

⁹ See, e.g., EM Sec. 9.7, in particular Eq. (9.196).

¹⁰ See, e.g., EM Sec. 6.1, in particular Eqs. (6.7).

$$\mathcal{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t}, \quad \mathcal{B} = \nabla \times \mathbf{A}, \quad (3.21)$$

while \mathbf{P} is the *canonical momentum*, whose Cartesian components may be calculated (in classics) from the Lagrangian function L using the standard formula of analytical mechanics,

$$P_j \equiv \frac{\partial L}{\partial v_j}. \quad (3.22)$$

To emphasize the difference between the two momenta, $\mathbf{p} = m\mathbf{v}$ is frequently called the *kinematic momentum* (or “ $m\mathbf{v}$ -momentum”). The distinction between \mathbf{p} and $\mathbf{P} = \mathbf{p} + q\mathbf{A}$ becomes more clear if we notice that the vector potential is not *gauge-invariant*: according to the second of Eqs. (21), at the so-called *gauge transformation*

$$\mathbf{A} \rightarrow \mathbf{A} + \nabla\chi, \quad (3.23)$$

with an arbitrary single-valued scalar *gauge function* $\chi = \chi(\mathbf{r}, t)$, the magnetic field does not change. Moreover, according to the first of Eqs. (21), if we make the simultaneous replacement

$$\phi \rightarrow \phi - \frac{\partial\chi}{\partial t}, \quad (3.24)$$

the gauge transformation does not affect the electric field either. With that, the gauge function’s choice does not affect the classical particle’s equation of motion, and hence the velocity \mathbf{v} and momentum \mathbf{p} . Hence, the kinematic momentum is gauge-invariant, while \mathbf{P} is not, because according to Eqs. (20) and (23), the introduction of χ changes it by $q\nabla\chi$.

Now the standard way of transfer to quantum mechanics is to treat the canonical rather than kinematic momentum as prescribed by the correspondence postulate discussed in Sec. 1.2. This means that in the wave mechanics, the operator of this variable is still given by Eq. (1.26):¹¹

$$\hat{\mathbf{P}} = -i\hbar\nabla. \quad (3.25)$$

Canonical momentum operator

Hence the Hamiltonian operator corresponding to the classical function (19) is

$$\hat{H} = \frac{1}{2m}(-i\hbar\nabla - q\mathbf{A})^2 + q\phi \equiv -\frac{\hbar^2}{2m}\left(\nabla - \frac{iq}{\hbar}\mathbf{A}\right)^2 + q\phi, \quad (3.26)$$

Charged particle in EM field

so that the stationary Schrödinger equation (1.60) of a particle moving in an electromagnetic field (but otherwise free) is

$$-\frac{\hbar^2}{2m}\left(\nabla - \frac{iq}{\hbar}\mathbf{A}\right)^2\psi + q\phi\psi = E\psi, \quad (3.27)$$

We may now repeat all the calculations of Sec. 1.4 for the case $\mathbf{A} \neq 0$, and get the following generalized expression for the probability current density:

¹¹ The validity of this choice is clear from the fact that if the *kinetic* momentum was described by this differential operator, the Hamiltonian operator corresponding to the classical Hamiltonian function (19), and the corresponding Schrödinger equation would not describe the magnetic field effects at all.

$$\mathbf{j} = \frac{\hbar}{2im} \left[\psi^* \left(\nabla - \frac{iq}{\hbar} \mathbf{A} \right) \psi - \text{c.c.} \right] \equiv \frac{1}{2m} [\psi^* \hat{\mathbf{p}} \psi - \text{c.c.}] \equiv \frac{\hbar}{m} |\psi|^2 \left(\nabla \varphi - \frac{q}{\hbar} \mathbf{A} \right). \quad (3.28)$$

We see that the current density is gauge-invariant (as required for any observable) only if the wavefunction's phase φ changes as

$$\varphi \rightarrow \varphi + \frac{q}{\hbar} \chi. \quad (3.29)$$

This may be a point of conceptual concern: since quantum interference is described by the spatial dependence of the phase φ , can the observed interference pattern depend on the gauge function's choice? (That would not make any sense, because we may change the gauge in our mind.) Fortunately, this is not true, because the spatial phase *difference* between two interfering paths, participating in Eq. (12), is gauge-transformed as

$$\varphi_{12} \rightarrow \varphi_{12} + \frac{q}{\hbar} (\chi_2 - \chi_1). \quad (3.30)$$

But χ has to be a single-valued function of coordinates, hence in the limit when the points 1 and 2 coincide, $\chi_1 = \chi_2$, so that $\Delta\varphi$ gauge-invariant, and so is the interference pattern.

However, the difference φ *may be* affected by the magnetic field, even if it is localized outside the channels in which the particle propagates. Indeed, in this case, the field cannot affect the particle's velocity \mathbf{v} and the probability current density \mathbf{j} :

$$\mathbf{j}(\mathbf{r})|_{\mathcal{B} \neq 0} = \mathbf{j}(\mathbf{r})|_{\mathcal{B}=0}, \quad (3.31)$$

so that the last form of Eq. (28) yields

$$\nabla \varphi(\mathbf{r})|_{\mathcal{B} \neq 0} = \nabla \varphi(\mathbf{r})|_{\mathcal{B}=0} + \frac{q}{\hbar} \mathbf{A}. \quad (3.32)$$

Integrating this equation along the contour C (Fig. 2), for the phase difference between points 1 and 2 we get

$$\varphi_{12}|_{\mathcal{B} \neq 0} = \varphi_{12}|_{\mathcal{B}=0} + \frac{q}{\hbar} \oint_C \mathbf{A} \cdot d\mathbf{r}, \quad (3.33)$$

where the integral should be taken along the same contour C as before (in Fig. 2, from point 1, counterclockwise along the dashed line to point 2). But from classical electrodynamics we know¹² that as points 1 and 2 tend to each other, i.e. the contour C becomes closed, the last integral is just the magnetic flux $\Phi \equiv \int \mathcal{B}_n d^2 r$ through any smooth surface limited by the contour, so that Eq. (33) may be rewritten as

$$\boxed{\varphi_{12}|_{\mathcal{B} \neq 0} = \varphi_{12}|_{\mathcal{B}=0} + \frac{q}{\hbar} \Phi.} \quad (3.34a)$$

In terms of the interference pattern, this means a shift of interference fringes, proportional to the magnetic flux (Fig. 3).

AB
effect

¹² See, e.g., EM Sec. 5.3.

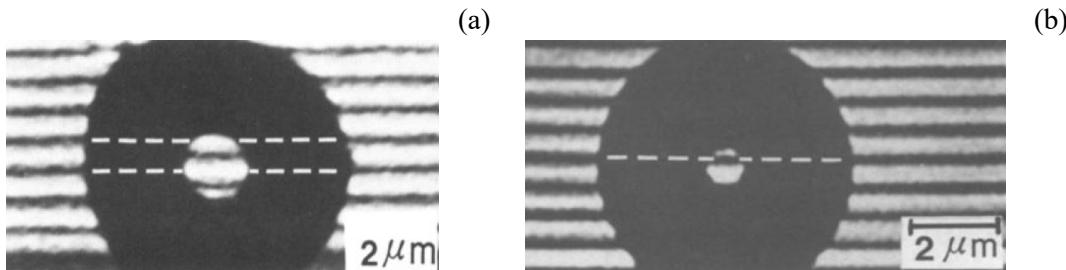

Fig. 3.3. Typical results of a two-paths interference experiment by A. Tonomura *et al.*, *Phys. Rev. Lett.* **56**, 792 (1986), showing the AB effect for electrons well shielded from the applied magnetic field. In this particular experimental geometry, the AB effect produces a relative shift of the interference patterns inside and outside the dark ring. (a) $\Phi = \Phi_0'/2$, (b) $\Phi = \Phi_0'$. © 1986 APS.

This phenomenon is usually called the “Aharonov-Bohm” (or just the *AB*) effect.¹³ For particles with a single elementary charge, $q = \pm e$, this result is frequently represented as

$$\varphi_{12} \Big|_{\mathcal{B} \neq 0} = \varphi_{12} \Big|_{\mathcal{B} = 0} \pm 2\pi \frac{\Phi}{\Phi_0'}, \quad (3.34b)$$

where the fundamental constant $\Phi_0' \equiv 2\pi\hbar/e \approx 4.14 \times 10^{-15}$ Wb has the meaning of the magnetic flux necessary to change φ_{12} by 2π , i.e. to shift the interference pattern (11) by one period, and is called the *normal magnetic flux quantum* – “normal” because of the reasons we will soon discuss.

The AB effect may be “almost explained” classically, in terms of Faraday’s electromagnetic induction. Indeed, a change $\Delta\Phi$ of magnetic flux in time induces a vortex-like electric field $\Delta\mathcal{E}$ around it. That field is *not* restricted to the magnetic field’s location, i.e. may reach the particle’s trajectories. The field’s magnitude (or rather of its integral along the contour C) may be readily calculated by integration of the first of Eqs. (21):

$$\Delta V \equiv \oint_C \Delta\mathcal{E} \cdot d\mathbf{r} = -\frac{d\Phi}{dt}. \quad (3.35)$$

I hope that in this expression the reader readily recognizes the integral (“undergraduate”) form of Faraday’s induction law.¹⁴ To calculate the effect of this electric field of the particles, let us assume that the variable separation described by Eq. (1.57) may be applied to the end points 1 and 2 of particle’s alternative trajectories as two independent systems,¹⁵ and that the magnetic flux’ change by a certain amount $\Delta\Phi$ does not change the spatial factors $\psi_{1,2}$, with the phases $\varphi_{1,2}$ included into the time-dependent factors $a_{1,2}$. Then we may repeat the arguments that were used in Sec. 1.6 at the discussion of

¹³ I prefer the latter, less personable name, because the effect had been actually predicted by Werner Ehrenberg and Raymond Siday in 1949, before it was rediscovered (also theoretically) by Y Aharonov and D. Bohm in 1959. To be fair to Aharonov and Bohm, it was their work that triggered a wave of interest in the phenomenon, resulting in its first experimental observation by Robert G. Chambers in 1960 and several other groups soon after that. Later, the experiments were improved using ferromagnetic cores and/or superconducting shielding to provide a better separation between the electrons and the applied field – as in the work whose result is shown in Fig. 3.

¹⁴ See, e.g., EM Sec. 6.1.

¹⁵ This assumption may seem a little bit of a stretch, but the resulting relation (37) may be indeed proven for a rather realistic model, though that would take more time/space than I can afford.

the Josephson effect, and since the change (35) leads to the change of the potential energy difference $\Delta U = q\Delta V$ between the two points, we may rewrite Eq. (1.72) as

$$\frac{d\varphi_{12}}{dt} = -\frac{\Delta U}{\hbar} = -\frac{q}{\hbar} \Delta V = \frac{q}{\hbar} \frac{d\Phi}{dt}. \quad (3.36)$$

Integrating this relation over the time of the magnetic field's change, we get

$$\Delta\varphi_{12} = \frac{q}{\hbar} \Delta\Phi, \quad (3.37)$$

- superficially, the same result as given by Eq. (34).

However, this interpretation of the AB effect is limited. Indeed, it requires the particle to be in the system (on the way from the source to the detector) during the flux change, i.e. when the induced electric field \mathcal{E} may affect its dynamics. On the contrary, Eq. (34) predicts that the interference pattern would shift even if the field change has been made when there was no particle in the system, and hence the field \mathcal{E} could not be felt by it. Experiment confirms the latter conclusion. Hence, there is *something* in the space where a particle propagates (i.e., outside of the magnetic field region), that transfers the information about even the static magnetic field to the particle. The standard interpretation of this surprising fact is as follows: the vector potential \mathbf{A} is not just a convenient mathematical tool, but a physical reality (just as its scalar counterpart ϕ), despite the large freedom of choice we have in prescribing specific spatial and temporal dependences of these potentials without affecting any observable – see Eqs. (23)-(24).

To conclude this section, let me briefly discuss the very interesting form taken by the AB effect in superconductivity. To be applied to this case, our results require two changes. The first one is simple: since superconductivity may be interpreted as the Bose-Einstein condensate of Cooper pairs with electric charge $q = -2e$, Φ_0 has to be replaced by the so-called *superconducting flux quantum*¹⁶

$$\Phi_0 \equiv \frac{\pi\hbar}{e} \approx 2.07 \times 10^{-15} \text{ Wb} = 2.07 \times 10^{-7} \text{ Gs} \cdot \text{cm}^2.$$

(3.38)

Superconducting flux quantum

Second, since the pairs are Bose particles and are all condensed in the same (ground) quantum state, described by the same wavefunction, the total electric current density, proportional to the probability current density j , may be extremely large – in practical superconducting materials, up to $\sim 10^{12} \text{ A/m}^2$. In these conditions, one cannot neglect the contribution of that current into the magnetic field and hence into its flux Φ , which (according to the Lenz rule of the Faraday induction law) tries to compensate for changes in external flux. To see possible results of this contribution, let us consider a closed superconducting loop (Fig. 4). Due to the Meissner effect (which is just another version of the flux self-compensation), the current and magnetic field penetrate into a superconductor by only a small distance (called the *London penetration depth*) $\delta_L \sim 10^{-7} \text{ m}$.¹⁷ If the loop is made of a superconducting “wire” that is considerably thicker than δ_L , we may draw a contour deep inside the wire, at that the current density is negligible. According to the last form of Eq. (28), everywhere at the contour,

$$\nabla\varphi - \frac{q}{\hbar} \mathbf{A} = 0. \quad (3.39)$$

¹⁶ One more bad, though common term: a metallic wire may (super)conduct, but a quantum hardly can!

¹⁷ For more detail, see EM Sec. 6.4.

Integrating this equation along the contour as before (in Fig. 4, from some point 1, all the way around the ring to the virtually coinciding point 2), we need to have the phase difference φ_{12} equal to $2\pi n$, because the wavefunction $\psi \propto \exp\{i\varphi\}$ in the initial and final points 1 and 2 should be “essentially” the same, i.e. produce the same observables. As a result, we get

$$\Phi \equiv \oint_C \mathbf{A} \cdot d\mathbf{r} = \frac{\hbar}{q} 2\pi n \equiv n\Phi_0. \quad (3.40)$$

Flux quantization

This is the famous *flux quantization effect*,¹⁸ which justifies the term “magnetic flux quantum” for the constant Φ_0 given by Eq. (38).

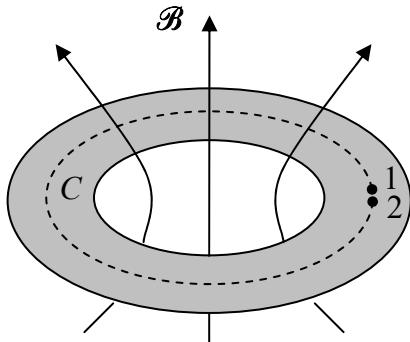

Fig. 3.4. The magnetic flux quantization in a superconducting loop (schematically).

Unfortunately, in this course I have no space/time to discuss the very interesting effects of “partial flux quantization” that arise when a superconductor loop is closed with a Josephson junction, forming the so-called *Superconductor QUantum Interference Device* – “SQUID”. Such devices are used, in particular, for supersensitive magnetometry and ultrafast, low-power computing.¹⁹

3.2. Landau levels and quantum Hall effect

In the last section, we have used the Schrödinger equation (27) for an analysis of static magnetic field effects in “almost-1D”, circular geometries shown in Figs. 1, 2, and 4. However, this equation describes very interesting effects in fully-higher-dimensions as well, especially in the 2D case. Let us consider a quantum particle free to move in the $[x, y]$ plane only (say, due to its strong confinement in the perpendicular direction z – see the discussion in Sec. 1.8). Taking the confinement energy for the reference, we may reduce Eq. (27) to a similar equation, but with the Laplace operator acting only in the directions x and y :

$$-\frac{\hbar^2}{2m} \left(\mathbf{n}_x \frac{\partial}{\partial x} + \mathbf{n}_y \frac{\partial}{\partial y} - i \frac{q}{\hbar} \mathbf{A} \right)^2 \psi = E \psi. \quad (3.41)$$

Let us find its solutions for the simplest case when the applied static magnetic field is uniform and perpendicular to the motion plane:

$$\mathcal{B} = \mathcal{B} \mathbf{n}_z. \quad (3.42)$$

¹⁸ It was predicted in 1949 by Fritz London and experimentally discovered (independently and virtually simultaneously) in 1961 by two experimental groups: B. Deaver and W. Fairbank, and R. Doll and M. Nähauer.

¹⁹ A brief review of these effects, and recommendations for further reading may be found in EM Sec. 6.5.

According to the second of Eqs. (21), this relation imposes the following restriction on the choice of the vector potential:

$$\frac{\partial A_y}{\partial x} - \frac{\partial A_x}{\partial y} = \mathcal{B}, \quad (3.43)$$

but the gauge transformations still give us a lot of freedom in its choice. The “natural” axially-symmetric form, $\mathbf{A} = \mathbf{n}_\phi \rho \mathcal{B}/2$, where $\rho = (x^2 + y^2)^{1/2}$ is the distance from some z -axis, leads to cumbersome math. In 1930, L. Landau realized that the energy spectrum of Eq. (41) may be obtained by making a much simpler, though very counter-intuitive choice:

$$A_x = 0, \quad A_y = \mathcal{B}(x - x_0), \quad (3.44)$$

(with arbitrary x_0), which evidently satisfies Eq. (43), though ignores the physical symmetry of the x and y directions for the field (42).

Now, expanding the eigenfunction into the Fourier integral in the y -direction:

$$\psi(x, y) = \int X_k(x) \exp\{ik(y - y_0)\} dk, \quad (3.45)$$

we see that for each component of this integral, Eq. (41) yields a specific equation

$$-\frac{\hbar^2}{2m} \left\{ \mathbf{n}_x \frac{d}{dx} + i \mathbf{n}_y \left[k - \frac{q}{\hbar} \mathcal{B}(x - x_0) \right] \right\}^2 X_k = E X_k. \quad (3.46)$$

Since the two vectors inside the curly brackets are mutually perpendicular, its square has no cross-terms, so that Eq. (46) reduces to

$$-\frac{\hbar^2}{2m} \frac{d^2}{dx^2} X_k + \frac{q^2}{2m} \mathcal{B}^2 (x - x_0')^2 X_k = E X_k, \quad \text{where } x_0' \equiv x_0 + \frac{\hbar k}{q \mathcal{B}}. \quad (3.47)$$

But this 1D Schrödinger equation is identical to Eq. (2.261) for a 1D harmonic oscillator,²⁰ with the center at point x_0' , and frequency ω_0 equal to

$$\omega_c = \frac{|q\mathcal{B}|}{m}. \quad (3.48)$$

In the last expression, it is easy to recognize the *cyclotron frequency* of the classical particle’s rotation in the magnetic field. (It may be readily obtained using the 2nd Newton law for a circular orbit of radius r ,

$$m \frac{v^2}{r} = F_\mathcal{B} \equiv qv\mathcal{B}, \quad (3.49)$$

and noting that the resulting ratio $v/r = |q\mathcal{B}|/m$ is just the radius-independent angular velocity ω_c of the particle’s rotation.) Hence, the energy spectrum for each Fourier component of the expansion (45) is the same:

²⁰ This result may become a bit less puzzling if we recall that at the classical circular cyclotron motion of a particle, each of its Cartesian coordinates, including x , performs sinusoidal oscillations with frequency (48), just as a 1D harmonic oscillator with this frequency.

$$E_n = \hbar\omega_c \left(n + \frac{1}{2} \right), \quad (3.50)$$

Landau levels

independent of either x_0 , or y_0 , or k .

This is a good example of a highly *degenerate* system: for each eigenvalue E_n , there are many similar eigenfunctions that differ only by the positions $\{x_0, y_0\}$ of their centers, and the rate k of their phase change along the y -axis. They may be used to assemble a large variety of linear combinations, including 2D wave packets whose centers move along classical circular orbits. Note, however, that the radius of such rotation cannot be smaller than the so-called *Landau radius*,

$$r_L \equiv \left(\frac{\hbar}{m\omega_c} \right)^{1/2} \equiv \left(\frac{\hbar}{|q\mathcal{B}|} \right)^{1/2}, \quad (3.51)$$

Landau radius

which characterizes the minimum size of the wave packet, and follows from Eq. (2.276) after the replacement $\omega_0 \rightarrow \omega_c$. This radius is remarkably independent of the particle mass, and may be interpreted in the following way: the scale $\mathcal{B}A_{\min}$ of the applied magnetic field's flux through the effective area $A_{\min} = 2\pi r_L^2$ of the smallest wave packet is just one normal flux quantum $\Phi_0' \equiv 2\pi\hbar/|q\mathcal{B}|$.

A detailed analysis of such wave packets (for which we would not have time in this course), in particular proves the virtually evident fact: the applied magnetic field does not change the *average* density dN_2/dE of different 2D states on the energy scale, following from Eq. (1.99), but just “assembles” them on the Landau levels (see Fig. 5a), so that the number of different orbital states on each Landau level (per unit area) is

$$n_L \equiv \frac{N_2}{A} = \frac{1}{A} \frac{dN_2}{dE} \Big|_{\mathcal{B}=0} \Delta E \equiv \frac{1}{A} \frac{dN_2}{d^2k} \Big|_{\mathcal{B}=0} \frac{d^2k}{dk} \frac{1}{dE/dk} \Delta E = \frac{1}{A} \frac{A}{(2\pi)^2} 2\pi k \frac{1}{\hbar^2 k/m} \hbar\omega_c \equiv \frac{|q\mathcal{B}|}{2\pi\hbar}. \quad (3.52)$$

This expression may again be interpreted in terms of magnetic flux quanta: $n_L\Phi_0' = \mathcal{B}$, i.e. there is one particular state on each Landau level per each normal flux quantum.

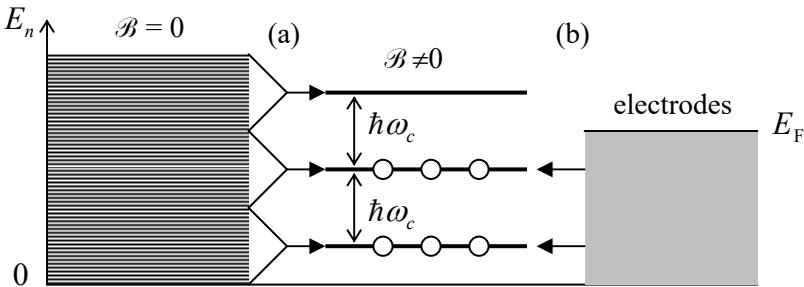

Fig. 3.5. (a) The “assembly” of 2D states on Landau levels, and (b) filling the levels with electrons at the quantum Hall effect.

The most famous application of the Landau levels picture is the explanation of the *quantum Hall effect*²¹. It is usually observed in the “Hall bar” geometry sketched in Fig. 6, where electric current I is passed through a rectangular conducting sample placed into magnetic field \mathcal{B} perpendicular to the

²¹ It was first observed in 1980 by a group led by Klaus von Klitzing, while the classical version (54) of the effect was first observed by Edwin Hall a century earlier – in 1879.

sample's plane. The classical analysis of the effect is based on the notion of the Lorentz force (14). As the magnetic field is turned on, this force starts to deviate the effective charge carriers (electrons or holes) from their straight motion between the electrodes, bending them toward the insulated sides of the bar (in Fig. 6, parallel to the x -axis). Here the carriers accumulate, generating a gradually increasing electric field \mathcal{E} until its force (16) exactly balances the Lorentz force (14):

$$q\mathcal{E}_y = qv_x\mathcal{B}, \quad (3.53)$$

where v_x is the drift velocity of the carriers along the bar (Fig. 6), providing the sustained balance condition $\mathcal{E}_y/v_x = \mathcal{B}$ at each point of the sample.

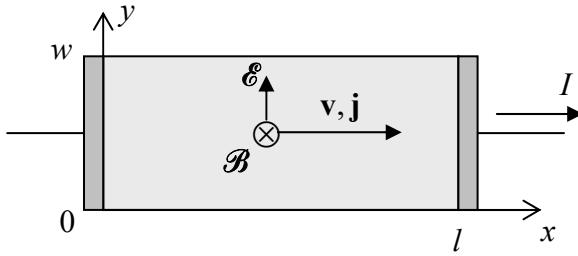

Fig. 3.6. The Hall bar geometry. Darker rectangles show external (3D) electrodes.

With n_2 carriers per unit area, in a sample of width w , this condition yields the following classical expression for the so-called *Hall resistance* R_H , remarkably independent of w and l :

$$R_H \equiv \frac{V_y}{I_x} = \frac{\mathcal{E}_y w}{qn_2 v_x w} = \frac{\mathcal{B}}{qn_2}. \quad (3.54)$$

This formula is broadly used in practice for the measurement of the 2D density n_2 of the charge carriers, and of the carrier type – electrons with $q = -e < 0$, or holes with the effective charge $q = +e > 0$.

However, in experiments with high-quality (low-defect) 2D well structures, at sub-kelvin temperatures²² and high magnetic fields, the linear growth of R_H with \mathcal{B} , described by Eq. (54), is interrupted by virtually horizontal plateaus (Fig. 7). Most remarkably, the experimental values of R_H on these plateaus are reproduced with extremely high accuracy (up to $\sim 10^{-9}$) from experiment to experiment and, even more remarkably, from sample to sample.²³ They are described by the following formula:

$$R_H = \frac{1}{i} R_K, \quad \text{where } R_K \equiv \frac{2\pi\hbar}{e^2}, \quad (3.55)$$

so that

$$R_K \approx 25.812\,807\,459\,304\dots \text{k}\Omega, \quad (3.56)$$

and i is (only until the end of this section, following tradition!) the plateau number, i.e. a real integer.

²² In some systems, such as the *graphene* (virtually perfect 2D sheets of carbon atoms – see Sec. 4 below), the effect may be more stable to thermal fluctuations, due to their topological properties, so that it may be observed even at room temperature – see, e.g., K. Novoselov *et al.*, *Science* **315**, 1379 (2007). Also note that in some thin ferromagnetic layers, the quantum Hall effects may be observed in the absence of an external magnetic field – see, e.g., M. Götz *et al.*, *Appl. Phys. Lett.* **112**, 072102 (2018) and references therein.

²³ Due to this high accuracy (which is a rare exception in solid-state physics!), since 2018 the *von Klitzing constant* R_K is used in metrology for the “legal” ohm’s definition, with its value (56) considered fixed – see Appendix CA: Selected Physical Constants.

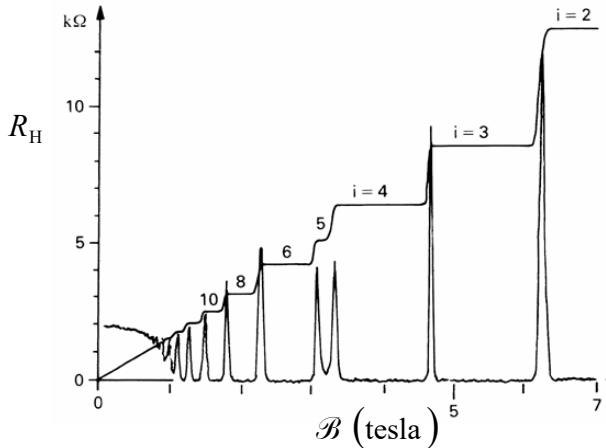

Fig. 3.7. A typical record of the integer quantum Hall effect. The lower trace (with sharp peaks) shows the diagonal element, V_x/I_x , of the resistance tensor. (Adapted from https://www.nobelprize.org/nobel_prizes/physics/laureates/1998/press.html).

This effect may be explained using the Landau level picture. The 2D sample is typically in a weak contact with 3D electrodes whose conductivity electrons, at low temperatures, fill all states with energies below a certain Fermi energy E_F – see Fig. 5b. According to Eqs. (48) and (50), as \mathcal{B} is increased, the spacing $\hbar\omega_c$ between the Landau levels increases proportionately, so that fewer and fewer of these levels are below E_F (and hence all their states are filled in equilibrium), and within certain ranges of field variations, the number i of the filled levels is constant. (In Fig. 5b, $i = 2$.) So, plugging $n_2 = in_L$ and $q = -e$ into Eq. (54), and using Eq. (52) for n_L , we get

$$R_H = \frac{1}{i} \frac{\mathcal{B}}{qn_L} = \frac{1}{i} \frac{2\pi\hbar}{e^2}, \quad (3.57)$$

i.e. exactly the experimental result (55).

This admittedly oversimplified explanation of the quantum Hall effect does not take into account at least two important factors:

- (i) the nonuniformity of the background potential $U(x, y)$ in realistic Hall bar samples, and the role of the quasi-1D *edge channels* this nonuniformity produces,²⁴ and
- (ii) the Coulomb interaction of the electrons, in high-quality samples leading to the formation of R_H plateaus with not only integer but also fractional values of i ($1/3, 2/5, 3/7$, etc.).²⁵

Unfortunately, a thorough discussion of these very interesting features is well beyond the framework of this course.²⁶²⁷

²⁴ Such quasi-1D regions, with the width of the order of r_L , form along the lines where the Landau levels cross the Fermi surface, and are actually responsible for all the electron transfer at the quantum Hall effect (giving the pioneering example of what is nowadays called the *topological insulators*). The particle motion along these channels is effectively one-dimensional; because of this, it cannot be affected by modest unintentional nonuniformities of the potential $U(x, y)$. This fact is responsible for the extraordinary accuracy of Eq. (55).

²⁵ This *fractional quantum Hall effect* was discovered in 1982 by D. Tsui, H. Stormer, and A. Gossard. In contrast, the effect described by Eq. (55) with an integer i (Fig. 7) is now called the *integer quantum Hall effect*.

²⁶ For a comprehensive discussion of these effects, I can recommend, e.g., either the monograph by D. Yoshioka, *The Quantum Hall Effect*, Springer, 1998, or the review by D. Yennie, *Rev. Mod. Phys.* **59**, 781 (1987). (See also the later publications cited above.)

²⁷ Note also that the quantum Hall effect is sometimes discussed in terms of the so-called *Berry phase*, one of the *geometric phases* – the notion apparently pioneered by S. Pancharatnam in 1956. However, in the “usual”

3.3. Scattering and diffraction

The second class of quantum effects, which becomes richer in multi-dimensional spaces, is typically referred to as either *diffraction* or *scattering* – depending on the context. In classical physics, these two terms are used to describe very different effects. The term “diffraction” is used for the interference of the waves re-emitted by elementary components of extended objects, under the effect of a single incident wave.²⁸ On the other hand, the term “scattering” is used in classical mechanics to describe the result of the interaction of a beam of incident *particles*²⁹ with such an extended object, called the *scatterer* – see Fig. 8.

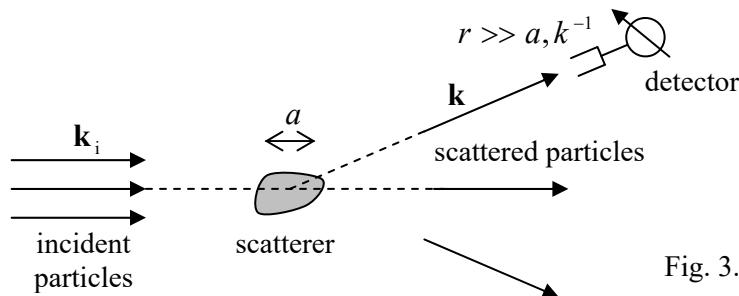

Fig. 3.8. Scattering (schematically).

Most commonly, the detector of the scattered particles is located at a large distance $r \gg a$ from the scatterer. In this case, the main observable independent of r is the *flux* (the number per unit time) of particles scattered in a certain direction, i.e. their flux per unit solid angle Ω . Since it is proportional to the incident flux of particles per unit area, the efficiency of scattering in a particular direction may be characterized by the ratio of these two fluxes. This ratio has is called the *differential cross-section* of the scatterer:

Differential cross-section

$$\frac{d\sigma}{d\Omega} \equiv \frac{\text{flux of scattered particles per unit solid angle}}{\text{flux of incident particles per unit area}}. \quad (3.58)$$

Such terminology and notation stem from the fact that the integral of $d\sigma/d\Omega$ over all scattering angles,

Total cross-section

$$\sigma \equiv \oint \frac{d\sigma}{d\Omega} d\Omega = \frac{\text{total flux of scattered particles}}{\text{incident flux per per unit area}}, \quad (3.59)$$

evidently having the dimensionality of area, has a simple interpretation as the *total cross-section* of scattering. For the simplest case when a solid object scatters all classical particles hitting its surface, but does not affect the particles flying by it, σ is just the geometric area of the scatterer, as observed from the direction of the incident particles. In classical mechanics, we first calculate the particle’s scattering

quantum Hall effect the Berry phase equals zero, and I believe that this concept should be saved for the discussion of more topologically involved systems. Unfortunately, I will have no time/space for a discussion of such systems in this course, and have to refer the interested reader to special literature – see, e.g., either the key papers collected by A. Shapere and F. Wilczek, *Geometric Phases in Physics*, World Scientific, 1992, or the monograph by A. Bohm *et al.*, *The Geometric Phase in Quantum Systems*, Springer, 2003.

²⁸ The notion of interference is very close to diffraction, but the former term is typically reserved for the wave re-emission by just a few components, such as two slits in the Young experiment – see Figs. 1 and 2. A detailed discussion of diffraction and interference of electromagnetic waves may be found in EM Secs. 8.3-8.8.

²⁹ In the context of classical waves, the term “scattering” is typically reserved for wave interaction with disordered sets of small objects – see, e.g., EM Sec. 8.3.

angle as a function of its *impact parameter* b and then average the result over all values of b , considered random.³⁰

In quantum mechanics, due to the particle/wave duality, a relatively broad, parallel beam of incident particles of the same energy E may be fairly represented with a plane de Broglie wave (1.88):

$$\psi_i = |\psi_i| \exp\{i\mathbf{k}_i \cdot \mathbf{r}\}, \quad (3.60)$$

with the free-space wave number $k_i = k = (2mE)^{1/2}/\hbar$. As a result, the particle scattering becomes a synonym of the de Broglie wave diffraction, and (somewhat counter-intuitively) the description of the effect becomes simpler, excluding the notion of the impact parameter. Indeed, the wave (60) corresponds to a constant probability current density (1.49):

$$\mathbf{j}_i = |\psi_i|^2 \frac{\hbar}{m} \mathbf{k}_i, \quad (3.61)$$

which is exactly the flux of incident particles per unit area that is used in the denominator of Eq. (58), while the numerator of that fraction may be simply expressed via the probability current density \mathbf{j}_s of the scattered de Broglie waves:

$$\frac{d\sigma}{d\Omega} = \frac{j_s r^2}{j_i}, \quad \text{at } r \gg a. \quad (3.62)$$

Hence our task is reduced to the calculation of j_s at sufficiently large distances r from the scatterer. For that, let us rewrite the stationary Schrödinger equation for the *elastic* scattering problem (when the energy E of the scattered particles is the same as that of the incident particles) in the form

$$(E - \hat{H}_0) \psi = U(\mathbf{r}) \psi, \quad \text{with } \hat{H}_0 \equiv -\frac{\hbar^2}{2m} \nabla^2, \quad \text{and } E = \frac{\hbar^2 k^2}{2m}, \quad (3.63)$$

where the potential energy $U(\mathbf{r})$ describes the effect of the scatterer. Looking for the solution of Eq. (62) in the natural form

$$\psi = \psi_i + \psi_s, \quad (3.64)$$

where ψ_i is the incident wave (60) and ψ_s has the sense of the scattered wave, and taking into account that the former wave satisfies the free-space Schrödinger equation

$$\hat{H}_0 \psi_i = E \psi_i, \quad (3.65)$$

we may reduce Eq. (63) to either of the following equivalent forms:

$$(E - \hat{H}_0) \psi_s = U(\mathbf{r})(\psi_i + \psi_s), \quad (\nabla^2 + k^2) \psi_s = \frac{2m}{\hbar^2} U(\mathbf{r}) \psi. \quad (3.66)$$

For applications, an integral form of this equation is more convenient. To derive it, we may look at the second of Eqs. (66) as a linear, inhomogeneous differential equation for the function ψ_s , thinking of its right-hand side as a known “source”. The solution of such an equation obeys the linear superposition principle, i.e. we may represent it as the sum of the waves outgoing from all elementary volumes d^3r' of the scatterer. Mathematically, this sum may be expressed as either

³⁰ See, e.g., CM Sec. 3.5.

$$\psi_s(\mathbf{r}) = \frac{2m}{\hbar^2} \int U(\mathbf{r}') \psi(\mathbf{r}') G(\mathbf{r}, \mathbf{r}') d^3 r', \quad (3.67a)$$

or, equivalently, as³¹

$$\psi(\mathbf{r}) = \psi_i(\mathbf{r}) + \frac{2m}{\hbar^2} \int U(\mathbf{r}') \psi(\mathbf{r}') G(\mathbf{r}, \mathbf{r}') d^3 r', \quad (3.67b)$$

where $G(\mathbf{r}, \mathbf{r}')$ is the *spatial Green's function*, defined as such an elementary, spherically-symmetric response of the 3D Helmholtz equation to a point source, i.e. the outward-propagating solution of the following equation³²

$$(\nabla^2 + k^2)G = \delta(\mathbf{r} - \mathbf{r}'). \quad (3.68)$$

But we already know such solution of this equation – see Eq. (7) and its discussion:

$$G(\mathbf{r}, \mathbf{r}') = \frac{f_+}{R} e^{ikR}, \quad \text{where } \mathbf{R} \equiv \mathbf{r} - \mathbf{r}', \quad (3.69)$$

so that we need just to calculate the coefficient f_+ for Eq. (68). This can be done in several ways, for example by noticing that at $R \ll k^{-1}$, the second term on the left-hand side of Eq. (68) is negligible, so that it is reduced to the well-known Poisson equation with a delta-functional right-hand side, which describes, for example, the electrostatic potential induced by a point electric charge. Either recalling the Coulomb law or applying the Gauss theorem,³³ we readily get the asymptote

$$G \rightarrow -\frac{1}{4\pi R}, \quad \text{at } kR \ll 1, \quad (3.70)$$

which is compatible with Eq. (69) only if $f_+ = -1/4\pi$, i.e. if

$$G(\mathbf{r}, \mathbf{r}') = -\frac{1}{4\pi R} e^{ikR}. \quad (3.71)$$

Plugging this result into Eq. (67a), we get the following formal solution of Eq. (66):

$$\psi_s(\mathbf{r}) = -\frac{m}{2\pi\hbar^2} \int U(\mathbf{r}') \frac{\psi(\mathbf{r}')}{R} e^{ikR} d^3 r'. \quad (3.72)$$

Note that if the function $U(\mathbf{r})$ is smooth, the singularity in the denominator is integrable (i.e. not dangerous); indeed, the contribution of a sphere with some radius $\mathcal{R} \rightarrow 0$, with the center at point \mathbf{r}' , into this integral scales as

³¹ This formula is sometimes called the *Lipmann-Schwinger equation*, though more frequently this term is reserved for either its operator form or the resulting equation for the spatial Fourier components of ψ and ψ_i .

³² Please notice both the similarity and difference between this Green's function and the propagator discussed in Sec. 2.1. In both cases, we use the linear superposition principle to solve wave equations, but while Eq. (67) gives the solution of the *inhomogeneous* equation (66), Eq. (2.44) does that for a *homogeneous* Schrödinger equation. In the latter case, the elementary wave sources are the elementary parts of the initial wavefunction, rather than of the equation's right-hand side as in our current problem.

³³ See, e.g., EM Sec. 1.2.

$$\int_{R < \mathcal{R}} \frac{d^3 R}{R} \equiv 4\pi \int_0^{\mathcal{R}} \frac{R^2 dR}{R} \equiv 4\pi \int_0^{\mathcal{R}} R dR = 2\pi \mathcal{R}^2 \rightarrow 0. \quad (3.73)$$

So far, our result (72) is exact, but its apparent simplicity is deceiving, because the wavefunction ψ on its right-hand side generally includes not only the incident wave ψ_i but also the scattered wave ψ_s – see Eq. (64). The most straightforward, and most common simplification of this problem, called the *Born approximation*,³⁴ is possible if the scattering potential $U(\mathbf{r})$ is in some sense small. (We will derive the quantitative condition of this smallness in a minute.) Since at $U(\mathbf{r}) = 0$ the scattering wave ψ_s has to disappear, at small but non-zero $U(\mathbf{r})$, $|\psi_s|$ has to be much smaller than $|\psi_i|$. In this case, on the right-hand side of Eq. (73) we may ignore ψ_s in comparison with ψ_i , getting

$$\psi_s(\mathbf{r}) = -\frac{m}{2\pi\hbar^2} |\psi_i| \int U(\mathbf{r}') \frac{\exp\{i\mathbf{k}_i \cdot \mathbf{r}'\}}{R} e^{ikR} d^3 r'. \quad (3.74)$$

Born approximation

Actually, Eq. (74) gives us even *more* than we wanted: it evaluates the scattered wave at *any* point, including those within of the scattering object, while to spell out Eq. (62), we only need to find the wave *far* from the scatterer, at $r \rightarrow \infty$. However, before going to that limit, we can use this general formula to find a quantitative criterion of the Born approximation's validity. For that, let us estimate the magnitude of the right-hand side of this equation for a scatterer of a linear size $\sim a$, and the potential magnitude's scale U_0 . The results are different in the following two limits:

(i) If $ka \ll 1$, then inside the scatterer (i.e., at distances $\Delta r' \sim a$), both $\exp\{i\mathbf{k} \cdot \mathbf{r}'\}$ and the second exponent under the integral in Eq. (74) change little, so that a crude but fair estimate of the solution's magnitude is

$$|\psi_s| \sim \frac{m}{2\pi\hbar^2} |\psi_i| U_0 a^2. \quad (3.75)$$

(ii) In the opposite limit $ka \gg 1$, the function under the integral is nearly periodic in one of the spatial directions (that of the scattered wave propagation), so that the net integral accumulates only on distances of the order of the de Broglie wavelength, $\sim k^{-1}$, and the integral is correspondingly smaller:

$$|\psi_s| \sim \frac{m}{2\pi\hbar^2} |\psi_i| U_0 \frac{a^2}{ka}. \quad (3.76)$$

These relations allow us to spell out the Born approximation's condition, $|\psi_s| \ll |\psi_i|$, as

$$U_0 \ll \frac{\hbar^2}{ma^2} \max[ka, 1]. \quad (3.77)$$

In the fraction on the right-hand side, we may readily recognize the scale of the kinetic (quantum-confinement) energy E_a of the particle inside a potential well of a size of the order of a , so that the Born approximation is valid essentially if the potential energy of particle's interaction with the scatterer is

³⁴ Named after M. Born, who was the first to apply this approximation in quantum mechanics. However, the basic idea of this approach had been developed much earlier (in 1881) by Lord Rayleigh in the context of electromagnetic wave scattering – see, e.g., EM Sec. 8.3. Note also that the contents of that section repeat some aspects of our current discussion – perhaps regrettably but unavoidably so, because the Born approximation is a centerpiece of the theory of scattering/diffraction for both the electromagnetic waves and the de Broglie waves. Hence I felt I had to cover it in this course for the benefit of the readers who skipped the EM part of my series.

smaller than E_a . Note, however, that the estimates (75) and (76) are not valid in some special situations when the effects of scattering *accumulate* in some direction. This is frequently the case for small angles θ of scattering by extended objects, when $ka \gg 1$, but $ka\theta \lesssim 1$.

Now let us proceed to large distances $r \gg r' \sim a$, and simplify Eq. (74) using an approximation similar to the dipole expansion in electrodynamics.³⁵ Namely, in the denominator's R , we may ignore r' in comparison with the much larger r , but the exponents require more care, because even if $r' \sim a \ll r$, the product $kr' \sim ka$ may still be of the order of 1. In the first approximation in r' , we can take (Fig. 9a):

$$R \equiv |\mathbf{r} - \mathbf{r}'| \approx r - \mathbf{n}_r \cdot \mathbf{r}', \quad (3.78)$$

and since directions of the vectors \mathbf{k} and \mathbf{r} coincide, i.e. $\mathbf{k} = k\mathbf{n}_r$, we get

$$kR \approx kr - \mathbf{k} \cdot \mathbf{r}', \quad \text{so that } e^{ikR} \approx e^{ikr} e^{-i\mathbf{k} \cdot \mathbf{r}'}. \quad (3.79)$$

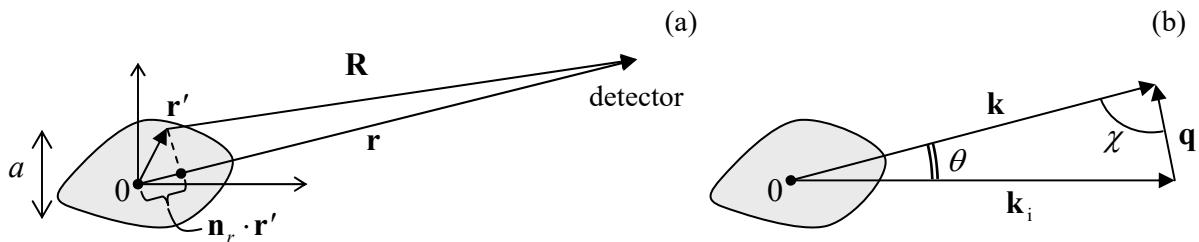

Fig. 3.9. (a) The long-range expansion of R , and (b) the definitions of \mathbf{q} , χ , and θ .

With this replacement, Eq. (74) yields

$$\psi_s(\mathbf{r}) = -\frac{m}{2\pi\hbar^2} \frac{|\psi_i|}{r} e^{ikr} \int U(\mathbf{r}') \exp\{-i(\mathbf{k} - \mathbf{k}_i) \cdot \mathbf{r}'\} d^3 r'. \quad (3.80)$$

This relation is a particular case of a more general formula³⁶

$$\psi_s = |\psi_i| \frac{f(\mathbf{k}, \mathbf{k}_i)}{r} e^{ikr}, \quad (3.81)$$

where $f(\mathbf{k}, \mathbf{k}_i)$ is called the *scattering function*.³⁷ The physical sense of this function becomes clear from the calculation of the corresponding probability current density \mathbf{j}_s . For that, generally, we need to use Eq. (1.47) with the gradient operator having all spherical-coordinate components.³⁸ However, at $kr \gg 1$, the main contribution to $\nabla \psi_s$, proportional to $k \gg 1/r$, is provided by differentiating the factor e^{ikr} , which changes in the common direction of vectors \mathbf{r} and \mathbf{k} , so that

³⁵ See, e.g., EM Sec. 8.2.

³⁶ It is easy to prove that this form is an asymptotic form of *any* solution ψ_s of the scattering problem (even that beyond the Born approximation) at sufficiently large distances $r \gg a, k^{-1}$.

³⁷ Note that the function f has the dimension of length, and does not account for the incident wave. This is why sometimes a dimensionless function, $S = 1 + 2ikf$, is used instead. This function S is called the *scattering matrix*, because it may be considered a natural generalization of the 1D matrix S defined by Eq. (2.124), to higher dimensionality.

³⁸ See, e.g., MA Eq. (10.8).

$$\nabla \psi_s \approx \mathbf{n}_r \frac{\partial}{\partial r} \psi_s \approx \mathbf{k} \psi_s, \quad \text{at } kr \gg 1, \quad (3.82)$$

and Eq. (1.47) yields

$$\mathbf{j}_s(\theta) \approx \frac{\hbar}{m} |\psi_i|^2 \frac{|f(\mathbf{k}, \mathbf{k}_i)|^2}{r^2} \mathbf{k}. \quad (3.83)$$

Plugging this expression, and also Eq. (61) into Eq. (62), for the differential cross-section we get simply

$$\frac{d\sigma}{d\Omega} = |f(\mathbf{k}, \mathbf{k}_i)|^2, \quad (3.84)$$

while the total cross-section is

$$\sigma = \oint |f(\mathbf{k}, \mathbf{k}_i)|^2 d\Omega, \quad (3.85)$$

so that the scattering function $f(\mathbf{k}, \mathbf{k}_i)$ gives us everything we need – and in fact more, because the function also contains information about the phase of the scattered wave.

According to Eq. (80), in the Born approximation the scattering function is reduced to the so-called *Born integral*

$$f(\mathbf{k}, \mathbf{k}_i) = -\frac{m}{2\pi\hbar^2} \int U(\mathbf{r}) e^{-i\mathbf{q} \cdot \mathbf{r}} d^3 r, \quad (3.86)$$

Born integral

where for the notation simplicity \mathbf{r}' is replaced with \mathbf{r} , and the following *scattering vector* is introduced:

$$\mathbf{q} \equiv \mathbf{k} - \mathbf{k}_i, \quad (3.87)$$

with the length $q = 2k \sin(\theta/2)$, where θ is the *scattering angle* between the vectors \mathbf{k} and \mathbf{k}_i – see Fig. 9b. For the differential cross-section, Eqs. (84) and (86) yield³⁹

$$\frac{d\sigma}{d\Omega} = \left(\frac{m}{2\pi\hbar^2} \right)^2 \left| \int U(\mathbf{r}) e^{-i\mathbf{q} \cdot \mathbf{r}} d^3 r \right|^2. \quad (3.88)$$

Differential cross-section: Born approximation

This is the main result of this section; it may be further simplified for spherically-symmetric scatterers, with

$$U(\mathbf{r}) = U(r). \quad (3.89)$$

In this case, it is convenient to represent the exponent in the Born integral as $\exp\{-iqr' \cos \chi\}$, where χ is the angle between the vectors \mathbf{k} (i.e. the direction \mathbf{n}_r toward the detector) and \mathbf{q} (rather than the incident wave vector \mathbf{k}_i !) – see Fig. 9b. Now, for a fixed \mathbf{q} , we can take this vector's direction for the polar axis of a spherical coordinate system, and reduce Eq. (86) to a 1D integral:

$$f(\mathbf{k}, \mathbf{k}_i) = -\frac{m}{2\pi\hbar^2} \int_0^\infty r^2 dr U(r) \int_0^{2\pi} d\phi \int_0^\pi \sin \chi d\chi \exp\{-iqr' \cos \chi\}$$

³⁹ Note that according to Eq. (88), in the Born approximation the scattering intensity does not depend on the sign of the potential U , and also that scattering in a certain direction is completely determined by a specific Fourier component of the function $U(\mathbf{r})$, namely by its harmonic with the wave vector equal to the scattering vector \mathbf{q} .

$$\equiv -\frac{m}{2\pi\hbar^2} \int_0^\infty r^2 dr U(r) 2\pi \frac{2\sin qr}{qr} \equiv -\frac{2m}{\hbar^2 q} \int_0^\infty U(r) \sin(qr) r dr. \quad (3.90)$$

As a simple example, let us use the Born approximation to analyze scattering on the following spherically-symmetric potential:

$$U(\mathbf{r}) = U_0 \exp\left\{-\frac{r^2}{2a^2}\right\}. \quad (3.91)$$

In this particular case, it is better to avoid the temptation to exploit the spherical symmetry by using Eq. (90), and instead, use the general Eq. (88), because it may be represented as a product of three similar Cartesian factors:

$$f(\mathbf{k}, \mathbf{k}_i) = -\frac{mU_0}{2\pi\hbar^2} I_x I_y I_z, \quad \text{with } I_x \equiv \int_{-\infty}^{+\infty} \exp\left\{-\left(\frac{x^2}{2a^2} + iq_x x\right)\right\} dx, \quad (3.92)$$

and similar integrals for I_y and I_z . From Chapter 2, we already know that the Gaussian integrals like I_x may be readily worked out by complementing the exponent to the full square, in our current case giving

$$\begin{aligned} I_x &= (2\pi)^{1/2} a \exp\left\{-\frac{q_x^2 a^2}{2}\right\}, \quad \text{etc.,} \\ \frac{d\sigma}{d\Omega} &= \left(\frac{mU_0}{2\pi\hbar^2} I_x I_y I_z \right)^2 = 2\pi a^2 \left(\frac{mU_0 a^2}{\hbar^2} \right)^2 e^{-q^2 a^2}. \end{aligned} \quad (3.93)$$

Now, the total cross-section σ is an integral of $d\sigma/d\Omega$ over all directions of the vector \mathbf{k} . Since in our case the scattering intensity does not depend on the azimuthal angle φ , the only nontrivial integration is over the scattering angle θ – see Fig. 9b:

$$\begin{aligned} \sigma &\equiv \oint \frac{d\sigma}{d\Omega} d\Omega = 2\pi \int_0^\pi \frac{d\sigma}{d\Omega} \sin\theta d\theta = 4\pi^2 a^2 \left(\frac{mU_0 a^2}{\hbar^2} \right)^2 \int_0^\pi \exp\left\{-\left(2k \sin\frac{\theta}{2}\right)^2 a^2\right\} \sin\theta d\theta \\ &\equiv 4\pi^2 a^2 \left(\frac{mU_0 a^2}{\hbar^2} \right)^2 \int_{\theta=0}^{\theta=\pi} \exp\{-2k^2 a^2 (1 - \cos\theta)\} d(1 - \cos\theta) = \frac{2\pi^2}{k^2} \left(\frac{mU_0 a^2}{\hbar^2} \right)^2 \left(1 - e^{-4k^2 a^2} \right). \end{aligned} \quad (3.94)$$

Let us analyze these results. In the low-energy limit, $ka \ll 1$ (and hence $qa \ll 1$ for any scattering angle), the scattered wave is virtually isotropic: $d\sigma/d\Omega \approx \text{const}$ – a very typical feature of a scalar-wave scattering⁴⁰ by small objects, in any approximation. Note that according to Eq. (77), the Born expression for σ , following from Eq. (94) in this limit,

$$\sigma = 8\pi^2 a^2 \left(\frac{mU_0 a^2}{\hbar^2} \right)^2, \quad (3.95)$$

⁴⁰ Note that this is only true for scalar (e.g., the de Broglie) waves, and different for vector ones, in particular the electromagnetic waves, where the intensity of the dipole radiation, and hence the scattering by small objects vanishes in the direction of the incident field's polarization – see, e.g., EM Eqs. (8.26) and (8.139).

is only valid if σ is much smaller than the scale a^2 of the physical cross-section of the scatterer. In the opposite, high-energy limit $ka \gg 1$, the scattering is dominated by small angles $\theta \approx q/k \sim 1/ka \sim \lambda/a$:

$$\frac{d\sigma}{d\Omega} \approx 2\pi a^2 \left(\frac{mU_0 a^2}{\hbar^2} \right)^2 \exp\{-k^2 a^2 \theta^2\}. \quad (3.96)$$

This is, again, very typical for diffraction. Note, however, that due to the smooth character of the Gaussian potential (91), the diffraction pattern (98) exhibits no oscillations of $d\sigma/d\Omega$ as a function of the diffraction angle θ .

Such oscillations naturally appear for scatterers with sharp borders. Indeed, let us consider a uniform spherical scatterer, described by the potential

$$U(\mathbf{r}) = \begin{cases} U_0, & \text{for } r < R, \\ 0, & \text{otherwise.} \end{cases} \quad (3.97)$$

In this case, integration by parts of Eq. (90) readily yields

$$f(\mathbf{k}, \mathbf{k}_i) = \frac{2mU_0}{\hbar^2 q^3} (qR \cos qR - \sin qR), \quad \text{so that } \frac{d\sigma}{d\Omega} = \left(\frac{2mU_0}{\hbar^2 q^3} \right)^2 (qR \cos qR - \sin qR)^2. \quad (3.98)$$

According to this result, the scattered wave's intensity drops very fast with q , so that one needs a semi-log plot (such as shown in Fig. 10) to reveal small diffraction fringes,⁴¹ with the n^{th} destructive interference (zero-intensity) point tending to $qR = \pi(n + \frac{1}{2})$ at $n \rightarrow \infty$. Since, as Fig. 9b shows, q may only change from 0 to $2k$, these intensity minima are only observable at sufficiently large values of the parameter kR , when they correspond to real values of the scattering angle θ . (At $kR \gg 1$, approximately kR/π of these minima, i.e. “dark rings” of low scattering probability, are observable.) On the contrary, at $kR \ll 1$ all allowed values of qR are much smaller than 1, and in this limit, the differential cross-section does not depend on qR , i.e. the scattering by the sphere (as by *any* object in this limit) is isotropic.

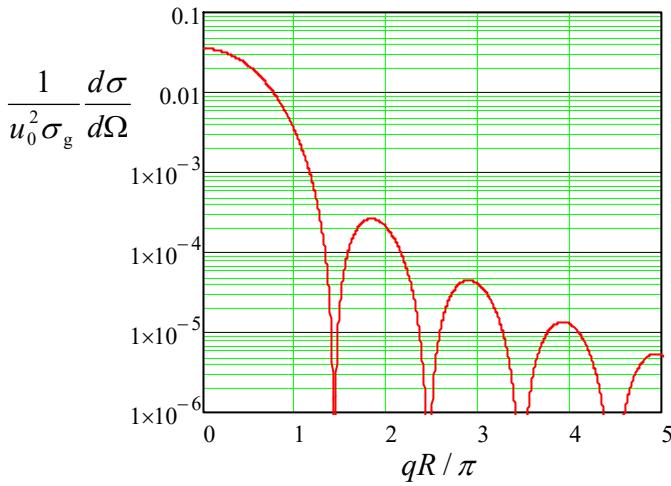

Fig. 3.10. The differential cross-section of the Born scattering of a particle by a “hard” (sharp-border) sphere (97), normalized to its geometric cross-section $\sigma_g \equiv \pi R^2$ and the square of the potential’s magnitude parameter $u_0 \equiv U_0/(\hbar^2/2mR^2)$, as a function of the normalized magnitude of the scattering vector \mathbf{q} .

This example shows that in quantum mechanics the notions of particle scattering and diffraction are essentially inseparable.

⁴¹ Their physics is very similar to that of the Fraunhofer diffraction on a 1D scatterer – see, e.g., EM Sec. 8.4.

The Born approximation, while being very simple and used more than any other scattering theory, is not without substantial shortcomings, as becomes clear from the following example. It is not too difficult to prove the so-called *optical theorem*, strictly valid for an arbitrary scatterer:

Optical theorem

$$\text{Im } f(\mathbf{k}_i, \mathbf{k}_i) = \frac{k}{4\pi} \sigma. \quad (3.99)$$

However, Eq. (86) shows that in the Born approximation, the function f is purely real at $q = 0$ (i.e. for $\mathbf{k} = \mathbf{k}_i$), and hence cannot satisfy the optical theorem. Even more evidently, it cannot describe such a simple effect as a dark shadow ($\psi \approx 0$) cast by a virtually opaque object (say, with $U \gg E$). There are several ways to improve the Born approximation, while still keeping its general idea of an approximate treatment of U .

(i) Instead of the main assumption $\psi_s \propto U_0$, we may use a complete perturbation series:

$$\psi_s = \psi_1 + \psi_2 + \dots \quad (3.100)$$

with $\psi_n \propto U_0^n$, and find successive approximations ψ_n one by one. In the 1st approximation we return to the Born formula, but already the 2nd approximation yields

$$\text{Im } f_2(\mathbf{k}_i, \mathbf{k}_i) = \frac{k}{4\pi} \sigma_1, \quad (3.101)$$

where σ_1 is the total cross-section calculated in the 1st approximation, so that the optical theorem (99) is “almost satisfied”.

(ii) As was mentioned above, the Born approximation does not work very well for the objects stretching along the direction (say, x) of the initial wave vector \mathbf{k}_i . This deficiency may be corrected by the so-called *eikonal*⁴² approximation, which replaces the plane-wave representation (60) of the incident wave with a WKB-like exponent, though still in the 1st approximation in $U \rightarrow 0$:

$$\begin{aligned} \exp\{ik_0x\} &\rightarrow \exp\left\{i\int_0^x k(\mathbf{r}')dx'\right\} \equiv \exp\left\{i\int_0^x \frac{\{2m[E-U(\mathbf{r}')]\}^{1/2}}{\hbar} dx'\right\} \\ &\approx \exp\left\{i\left[k_0x - \frac{m}{\hbar^2 k_0} \int_0^x U(\mathbf{r}')dx'\right]\right\}. \end{aligned} \quad (3.102)$$

Results of this approach satisfy the optical theorem (99) already in the 1st approximation.

Another way toward quantitative results in the theory of scattering, beyond the Born approximation, may be pursued for spherically-symmetric potentials (89); I will discuss it in Sec. 8, after a general discussion of particle motion in such potentials in Sec. 7.

3.4. Energy bands in higher dimensions

In Sec. 2.7, we have discussed the 1D band theory for potential profiles $U(x)$ that obey the periodicity condition (2.192). For what follows, let us notice that the condition may be rewritten as

$$U(x + X) = U(x), \quad (3.103)$$

⁴² From the Greek word εἰκόνα, meaning “image”. In our current context, this term is purely historic.

where $X = \tau a$, with τ being an arbitrary integer. One may say that the set of points X forms a periodic *1D lattice* in the direct (\mathbf{r} -) space. We have also seen that each Bloch state (i.e., each eigenstate of the Schrödinger equation for such periodic potential) is characterized by the quasimomentum $\hbar q$, and its energy does not change if q is changed by a multiple of $2\pi/a$. Hence if we form, in the reciprocal (\mathbf{q} -) space, a 1D lattice of points $Q = lb$, with $b \equiv 2\pi/a$ and integer l , any pair of points from these two mutually reciprocal lattices satisfies the following rule:

$$\exp\{iQX\} = \exp\left\{il\frac{2\pi}{a}\tau a\right\} \equiv e^{2\pi i \tau l} = 1. \quad (3.104)$$

In this form, the results of Sec. 2.7 may be readily extended to d -dimensional periodic potentials whose translational symmetry obeys the following natural generalization of Eq. (103):

$$U(\mathbf{r} + \mathbf{R}) = U(\mathbf{r}), \quad (3.105)$$

where the points \mathbf{R} , which may be numbered by d integers τ_j , form the so-called *Bravais lattice*:⁴³

$$\mathbf{R} = \sum_{j=1}^d \tau_j \mathbf{a}_j,$$

Bravais
lattice
(3.106)

with d primitive vectors \mathbf{a}_j . The simplest example of a 3D Bravais lattice is given by the *simple cubic* lattice (Fig. 11a), which may be described by a system of mutually perpendicular primitive vectors \mathbf{a}_j of equal length. However, not in any lattice these vectors are perpendicular; for example, Figs. 11b and 11c show possible sets of the primitive vectors describing, respectively, the *face-centered cubic* (fcc) lattice and the *body-centered cubic* (bcc) lattice. In 3D, the science of crystallography, based on group theory, distinguishes, by their symmetry properties, 14 Bravais lattices grouped into 7 different *lattice systems*.⁴⁴

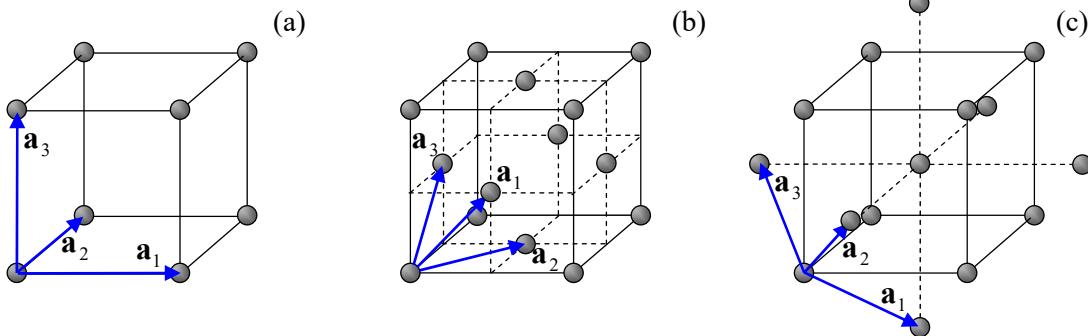

Fig. 3.11. The simplest (and most common) 3D Bravais lattices: (a) simple cubic, (b) face-centered cubic (fcc), and (c) body-centered cubic (bcc), and possible choices of their primitive vector sets (blue arrows).

Note, however, not all highly symmetric sets of points form Bravais lattices. As probably the most striking example, the nodes of a very simple 2D *honeycomb lattice* (Fig. 12a)⁴⁵ cannot be

⁴³ Named after Auguste Bravais, the crystallographer who introduced this notion in 1850.

⁴⁴ A very clear, well-illustrated introduction to the Bravais lattices is given in Chapters 4 and 7 of the famous textbook by N. Ashcroft and N. Mermin, *Solid State Physics*, Saunders College, 1976.

⁴⁵ This structure describes, for example, the now-famous *graphene*: isolated monolayer sheets of carbon atoms arranged in a honeycomb lattice with an interatomic distance of 0.142 nm.

described by a Bravais lattice – while those of the 2D hexagonal lattice shown in Fig. 12b, can. The most prominent 3D case of such a lattice is the diamond structure (Fig. 12c), which describes, in particular, silicon crystals.⁴⁶ In cases like these, the band theory is much facilitated by the fact that the Bravais lattices using some point groups (called *primitive unit cells*) may describe these systems.⁴⁷ For example, Fig. 12a shows a possible choice of the primitive vectors for the honeycomb lattice, with the primitive unit cell formed by any two adjacent points of the original lattice (say, within the dashed ovals on that panel). Similarly, the diamond lattice may be described as an fcc Bravais lattice with a two-point primitive unit cell – see Fig. 12c.

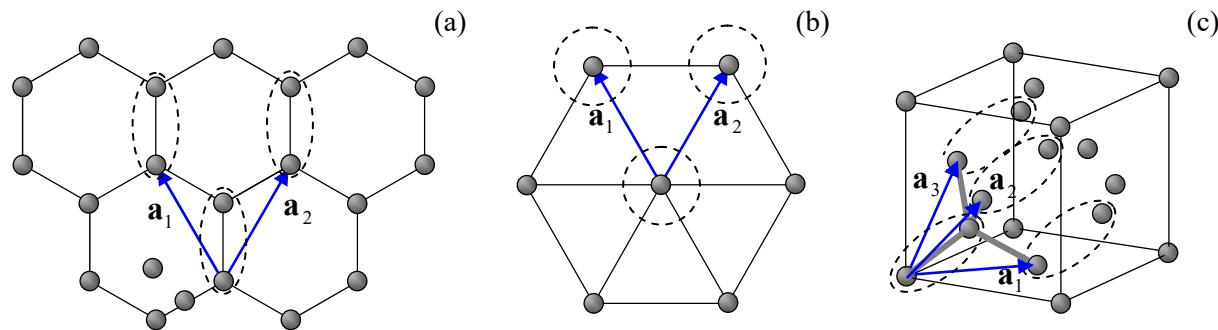

Fig. 3.12. Two important periodic structures that require two-point primitive cells for their Bravais lattice representation: (a) 2D honeycomb lattice and (c) 3D diamond lattice, and their primitive vectors. For contrast, panel (b) shows the 2D hexagonal structure which forms a Bravais lattice with a single-point primitive cell.

Now we are ready for the following generalization of the 1D Bloch theorem, given by Eqs. (2.193) and (2.210), to higher dimensions: any eigenfunction of the Schrödinger equation describing particle's motion in the spatially-unlimited periodic potential (105) may be represented either as

$$\psi(\mathbf{r} + \mathbf{R}) = \psi(\mathbf{r})e^{i\mathbf{q} \cdot \mathbf{R}}, \quad (3.107)$$

3D Bloch theorem

or as

$$\psi(\mathbf{r}) = u(\mathbf{r})e^{i\mathbf{q} \cdot \mathbf{r}}, \quad \text{with } u(\mathbf{r} + \mathbf{R}) = u(\mathbf{r}), \quad (3.108)$$

where the quasimomentum $\hbar\mathbf{q}$ is again a constant of motion, but now it is a vector. The key notion of the band theory in d dimensions is the *reciprocal lattice* in the wave-vector (\mathbf{q}) space, formed as

$$\mathbf{Q} = \sum_{j=1}^d l_j \mathbf{b}_j, \quad (3.109)$$

with integer l_j , and vectors \mathbf{b}_j selected in such a way that the following natural generalization of Eq. (104) is valid for any pair of points of the direct and reciprocal lattices:

⁴⁶ This diamond structure may be best understood as an overlap of two fcc lattices of side a , mutually shifted by the vector $\{1, 1, 1\} \times a/4$, so that the distances between each point of the combined lattice and its 4 nearest neighbors (see the solid gray lines in Fig. 12c) are all equal.

⁴⁷ A harder case is presented by so-called *quasicrystals* (whose idea may be traced down to medieval Islamic tilings, but was discovered in natural crystals, by D. Shechtman *et al.*, only in 1984), which obey a high (say, the 5-fold) rotational symmetry, but cannot be described by a Bravais lattice with *any* finite primitive unit cell. For a popular review of quasicrystals see, for example, P. Stephens and A. Goldman, *Sci. Amer.* **264**, #4, 24 (1991).

$$e^{i\mathbf{Q}\cdot\mathbf{R}} = 1. \quad (3.110)$$

One way to describe the physical sense of the lattice \mathbf{Q} is to say that according to Eqs. (80) and/or (86), it gives the set of the vectors $\mathbf{q} \equiv \mathbf{k} - \mathbf{k}_i$ for that the interference of the waves scattered by all Bravais lattice points is constructive, and hence strongly enhanced.⁴⁸ Another way to look at the reciprocal lattice follows from the first formulation of the Bloch theorem, given by Eq. (107): if we add to the quasimomentum \mathbf{q} of a particle any vector \mathbf{Q} of the reciprocal lattice, the wavefunction does not change. This means, in particular, that all information about the system's eigenfunctions is contained in just one elementary cell of the reciprocal space \mathbf{q} . Its most frequent choice, called the *1st Brillouin zone*, is the set of all points \mathbf{q} that are closer to the origin than to any other point of the lattice \mathbf{Q} . (Evidently, the 1st Brillouin zone in one dimension, discussed in Sec. 2.7, falls under this definition – see, e.g., Figs. 2.26 and 2.28.)

It is easy to see that the primitive vectors \mathbf{b}_j of the reciprocal lattice may be constructed as

$$\mathbf{b}_1 = 2\pi \frac{\mathbf{a}_2 \times \mathbf{a}_3}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}, \quad \mathbf{b}_2 = 2\pi \frac{\mathbf{a}_3 \times \mathbf{a}_1}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}, \quad \mathbf{b}_3 = 2\pi \frac{\mathbf{a}_1 \times \mathbf{a}_2}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}. \quad (3.111)$$

Reciprocal
lattice:
primitive
vectors

Indeed, from the “operand rotation rule” of the vector algebra⁴⁹ it is evident that $\mathbf{a}_j \cdot \mathbf{b}_{j'} = 2\pi\delta_{jj'}$. Hence, with the account of Eq. (109), the exponent on the left-hand side of Eq. (110) is reduced to

$$e^{i\mathbf{Q}\cdot\mathbf{R}} = \exp\{2\pi i(l_1\tau_1 + l_2\tau_2 + l_3\tau_3)\}. \quad (3.112)$$

Since all l_j and all τ_j are integers, the expression in the parentheses is also an integer, so that the exponent indeed equals 1, thus satisfying the definition of the reciprocal lattice given by Eq. (110).

As the simplest example, let us return to the simple cubic lattice of a period a (Fig. 11a), oriented in space so that

$$\mathbf{a}_1 = a\mathbf{n}_x, \quad \mathbf{a}_2 = a\mathbf{n}_y, \quad \mathbf{a}_3 = a\mathbf{n}_z, \quad (3.113)$$

According to Eq. (111), its reciprocal lattice is also cubic:

$$\mathbf{Q} = \frac{2\pi}{a}(l_x\mathbf{n}_x + l_y\mathbf{n}_y + l_z\mathbf{n}_z), \quad (3.114)$$

so that the 1st Brillouin zone is a cube with the side $b = 2\pi/a$.

Almost equally simple calculations show that the reciprocal lattice of fcc is bcc, and vice versa. Figure 13 shows the resulting 1st Brillouin zone of the fcc lattice.

The notion of the reciprocal lattice makes the multi-dimensional band theory not much more complex than that in 1D, especially for numerical calculations, at least for the single-point Bravais lattices. Indeed, repeating all the steps that have led us to Eq. (2.218), but now with a d -dimensional Fourier expansion of the functions $U(\mathbf{r})$ and $u(\mathbf{r})$, we readily get its generalization:

⁴⁸ This is why the notion of the \mathbf{Q} -lattice is also the main starting point of X-ray diffraction studies of crystals. Indeed, it allows rewriting the well-known Bragg condition for diffraction peaks in an extremely simple form: $\mathbf{k} = \mathbf{k}_i + \mathbf{Q}$, where \mathbf{k}_i and \mathbf{k} are the wave vectors of the, respectively, incident and diffracted waves – see, e.g., EM Sec. 8.4 (where it was more convenient for me to use the notation \mathbf{k}_0 for \mathbf{k}_i).

⁴⁹ See, e.g., MA Eq. (7.6).

$$\sum_{l' \neq l} U_{l'-l} u_{l'} = (E - E_l) u_l, \quad (3.115)$$

where \mathbf{l} is now a d -dimensional vector of integer indices l_j . The summation in Eq. (115) should be carried over all essential components of this vector (i.e. over all relevant nodes of the reciprocal lattice), so that writing a corresponding computer code requires a bit more care than in 1D. However, this is just a homogeneous system of linear equations, and numerous routines of finding its eigenvalues E are readily available from both public sources and commercial software packages.

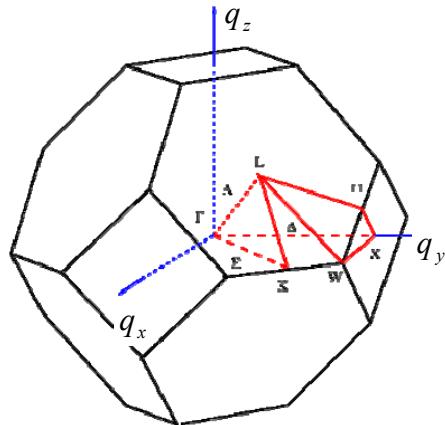

Fig. 3.13. The 1st Brillouin zone of the fcc lattice, and the traditional notation of its main directions. Adapted from http://en.wikipedia.org/wiki/Band_structure, as a public domain material.

What is indeed more complex than in 1D is representation (and hence comprehension :-), of the calculated results and experimental data. Typically, the representation is limited to plotting the Bloch state eigenenergy as a function of components of the vector q along certain special directions the reciprocal space of quasimomentum (see, e.g., the red lines in Fig. 13), typically on a single panel. Fig. 14 shows perhaps the most famous (and certainly the most practically important) of such plots, the band structure of electrons in crystalline silicon. The dashed horizontal lines mark the so-called *indirect gap* of the width ~ 1.12 eV between the “valence” (nominally occupied) and the next “conduction” (nominally unoccupied) energy bands.

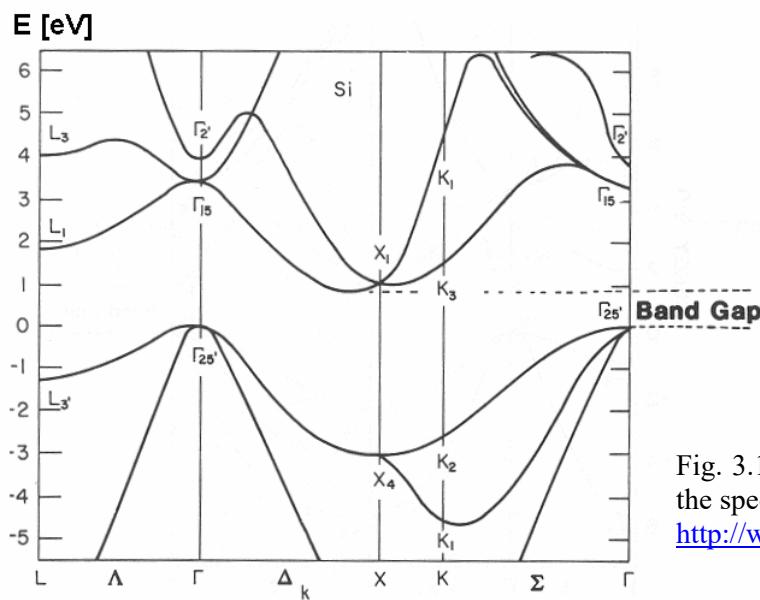

Fig. 3.14. The band structure of silicon, plotted along the special directions shown in Fig. 13. (Adapted from http://www.tf.uni-kiel.de/matwis/amat/semi_en/.)

In order to understand the reason for such complexity, let us see how we would start to calculate such a picture in the weak-potential approximation, for the simplest case of a 2D square lattice – which is a subset of the cubic lattice (106), with $\tau_3 = 0$. Its 1st Brillouin zone is of course also a square, of the area $(2\pi/a)^2$ – see the dashed lines in Fig. 15. Let us draw the lines of the constant energy of a free particle ($U = 0$) in this zone. Repeating the arguments of Sec. 2.7 (see especially Fig. 2.28 and its discussion), we may conclude that Eq. (2.216) should be now generalized as follows,

$$E = \frac{\hbar^2 k^2}{2m} = \frac{\hbar^2}{2m} \left[\left(q_x - \frac{2\pi l_x}{a} \right)^2 + \left(q_y - \frac{2\pi l_y}{a} \right)^2 \right], \quad (3.116)$$

with all possible integers l_x and l_y . Considering this result only within the 1st Brillouin zone, we see that as the particle's energy E grows, the lines of equal energy, for the lowest energy band, evolve as shown in Fig. 15. Just like in 1D, the weak-potential effects are only important at the Brillouin zone boundaries, and may be crudely considered as the appearance of narrow energy gaps, but one can see that the band structure in \mathbf{q} -space is complex enough even without these effects – and becomes even more involved at higher E .

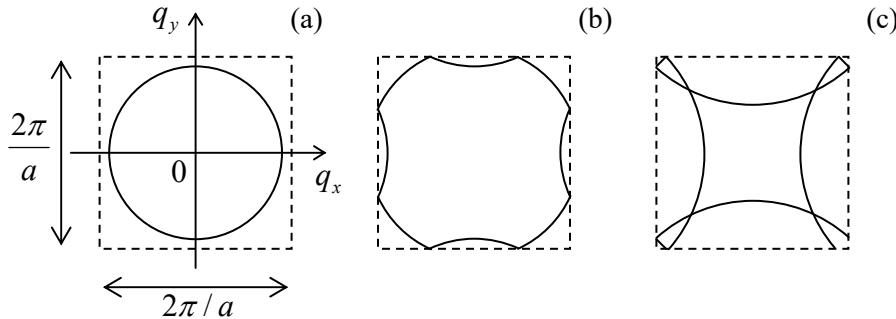

Fig. 3.15. The lines of constant energy E of a free particle, within the 1st Brillouin zone of a square Bravais lattice, for: (a) $E/E_1 \approx 0.95$, (b) $E/E_1 \approx 1.05$; and (c) $E/E_1 \approx 2.05$, where $E_1 \equiv \pi^2 \hbar^2 / 2ma^2$.

The tight-binding approximation is usually easier to follow. For example, for the same square 2D lattice, we may repeat the arguments that have led us to Eq. (2.203), to write⁵⁰

$$i\hbar \dot{a}_{0,0} = -\delta_n (a_{-1,0} + a_{+1,0} + a_{0,+1} + a_{0,-1}), \quad (3.117)$$

where the indices correspond to the deviations of the integers τ_x and τ_y from an arbitrarily selected minimum of the potential energy – and hence of the wavefunction's “hump”, quasi-localized at this minimum. Now, looking for the stationary solution of these equations, that would obey the Bloch theorem (107), instead of Eq. (2.206) we get

$$E = E_n + \varepsilon_n = E_n - \delta_n \left(e^{iq_x a} + e^{-iq_x a} + e^{iq_y a} + e^{-iq_y a} \right) \equiv E_n - 2\delta_n (\cos q_x a + \cos q_y a). \quad (3.118)$$

Figure 16 shows this result, within the 1st Brillouin zone, in two forms: as color-coded lines of equal energy, and as a 3D plot (also enhanced by color). It is evident that the plots of this function along different lines on the \mathbf{q} -plane, for example along one of the axes (say, q_x) and along a diagonal of the 1st Brillouin zone (say, with $q_x = q_y$) give different curves $E(q)$, qualitatively similar to those of silicon (Fig.

⁵⁰ Actually, using the same values of δ_n in both directions (x and y) implies some sort of symmetry of the quasi-localized states. For example, the s -states of axially-symmetric potentials (see the next section) always have such symmetry.

14). However, the latter structure is further complicated by the fact that the primitive cell of its Bravais lattice contains 2 atoms – see Fig. 12c and its discussion. In this case, even the tight-binding picture becomes more complex. Indeed, even if the atoms at different positions of the primitive unit cell are similar (as they are, for example, in both graphene and silicon), and hence the potential wells near those points and the corresponding local wavefunctions $u(\mathbf{r})$ are similar as well, the Bloch theorem (which only pertains to Bravais lattices!) does not forbid them to have different complex probability amplitudes $a(t)$ whose time evolution should be described by a specific differential equation.

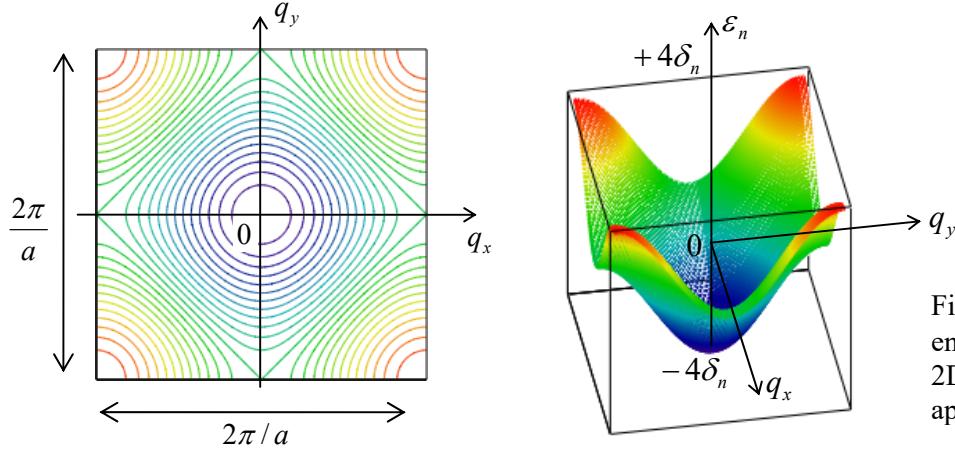

Fig. 3.16. The allowed band energy $\varepsilon_n \equiv E - E_n$ for a square 2D lattice, in the tight-binding approximation.

As the simplest example, to describe the honeycomb lattice shown in Fig. 12a, we have to prescribe different probability amplitudes to the “top” and “bottom” points of its primitive cell – say, α and β , correspondingly. Since each of these points is surrounded (and hence weakly interacts) with three neighbors of the opposite type, instead of Eq. (117) we have to write two equations:

$$i\hbar\dot{\alpha} = -\delta_n \sum_{j=1}^3 \beta_j, \quad i\hbar\dot{\beta} = -\delta_n \sum_{j'=1}^3 \alpha_{j'}, \quad (3.119)$$

where each summation is over three next-neighbor points. (In these two sums, I am using different summation indices just to emphasize that these directions are different for the “top” and “bottom” points of the primitive cell – see Fig. 12a.) Now using the Bloch theorem (107) in the form similar to Eq. (2.205), we get two coupled systems of linear algebraic equations:

$$(E - E_n)\alpha = -\delta_n \beta \sum_{j=1}^3 e^{i\mathbf{q}\cdot\mathbf{r}_j}, \quad (E - E_n)\beta = -\delta_n \alpha \sum_{j'=1}^3 e^{i\mathbf{q}\cdot\mathbf{r}'_{j'}}, \quad (3.120)$$

where \mathbf{r}_j and $\mathbf{r}'_{j'}$ are the next-neighbor positions, as seen from the top and bottom points, respectively. Writing the condition of consistency of this system of homogeneous linear equations, we get two equal and opposite values for energy correction for each value of \mathbf{q} :

$$E_{\pm} = E_n \pm \delta_n \Sigma^{1/2}, \quad \text{where } \Sigma \equiv \sum_{j,j'=1}^3 e^{i\mathbf{q}\cdot(\mathbf{r}_j + \mathbf{r}'_{j'})}. \quad (3.121)$$

According to Eq. (120), these two energy bands correspond to the phase shifts (on the top of the regular Bloch shift $\mathbf{q}\cdot\Delta\mathbf{r}$) of either 0 or π between the adjacent quasi-localized wavefunctions $u(\mathbf{r})$.

The most interesting corollary of such energy symmetry, augmented by the honeycomb lattice's symmetry, is that for certain values \mathbf{q}_D of the vector \mathbf{q} (that turn out to be in each of six corners of the honeycomb-shaped 1st Brillouin zone), the double sum Σ vanishes, i.e. the two band surfaces $E_{\pm}(\mathbf{q})$ touch each other. As a result, in the vicinities of these so-called *Dirac points*,⁵¹ the dispersion relation is linear:

$$E_{\pm}|_{\mathbf{q} \approx \mathbf{q}_D} \approx E_n \pm \hbar v_n |\tilde{\mathbf{q}}|, \quad \text{where } \tilde{\mathbf{q}} \equiv \mathbf{q} - \mathbf{q}_D, \quad (3.122)$$

with $v_n \propto \delta_n$ being a constant with the dimension of velocity – for graphene, close to 10^6 m/s. Such a linear dispersion relation ensures several interesting transport properties of graphene, in particular of the quantum Hall effect in it – as was already mentioned in Sec. 2. For their more detailed discussion, I have to refer the reader to special literature.⁵²

3.5. Axially-symmetric systems

I cannot conclude this chapter (and hence our review of wave mechanics) without addressing the exact solutions of the stationary Schrödinger equation⁵³ possible in the cases of highly symmetric functions $U(\mathbf{r})$. Such solutions are very important, in particular, for atomic and nuclear physics, and will be used in the later chapters of this course.

In some rare cases, such symmetries may be exploited by the separation of variables in Cartesian coordinates. The most famous (and rather important) example is the d -dimensional harmonic oscillator – a particle moving inside the potential

$$U = \frac{m\omega_0^2}{2} \sum_{j=1}^d r_j^2. \quad (3.123)$$

Separating the variables exactly as we did in Sec. 1.7 for the rectangular hard-wall box (1.77), for each degree of freedom we get the Schrödinger equation (2.261) of a 1D oscillator, whose eigenfunctions are

⁵¹ This term is based on a (rather indirect) analogy with the Dirac theory of relativistic quantum mechanics, to be discussed in Chapter 9 below.

⁵² See, e.g., the reviews by A. Castro Neto *et al.*, *Rev. Mod. Phys.* **81**, 109 (2009) and by X. Lu *et al.*, *Appl. Phys. Rev.* **4**, 021306 (2017). Note that the transport properties of graphene are determined by coupling of $2p$ -state electrons of its carbon atoms (see Secs. 6 and 7 below), whose wavefunctions are proportional to $\exp\{\pm i\varphi\}$ rather than are axially-symmetric as implied by Eqs. (120). However, due to the lattice symmetry, this fact does not affect the above dispersion relation $E(\mathbf{q})$.

⁵³ This is my best chance to mention, in passing, that the eigenfunctions $\psi_n(\mathbf{r})$ of any such problem do not feature the instabilities typical for the *deterministic chaos* effects of classical mechanics – see, e.g., CM Chapter 9. (This is why the term *quantum mechanics of classically chaotic systems* is preferable to the occasionally used term “quantum chaos”.) It is curious that at the initial stages of the time evolution of the wavefunctions of such systems, their certain correlation functions still grow exponentially, reminding the *Lyapunov exponents* λ of their classical chaotic dynamics. This growth stops at the so-call *Ehrefect times* $t_E \sim \lambda^{-1} \ln(S/\hbar)$, where S is the action scale of the problem – see, e.g., I. Aleiner and A. Larkin, *Phys. Rev. E* **55**, R1243 (1997). In a stationary quantum state, the most essential trace of the classical chaos in a system is an unusual statistics of its eigenvalues, in particular of the energy spectra. We will have a chance for a brief look at such statistics in Chapter 5, but unfortunately, I will not have time/space to discuss this field in much detail. Perhaps the best available book for further reading is the monograph by M. Gutzwiller, *Chaos in Classical and Quantum Mechanics*, Springer, 1991.

given by Eq. (2.284), and the energy spectrum is described by Eq. (2.162). As a result, the total energy spectrum may be indexed by a vector $\mathbf{n} = \{n_1, n_2, \dots, n_d\}$ of d independent integer quantum numbers n_j :

$$E_{\mathbf{n}} = \hbar\omega_0 \left(\sum_{j=1}^d n_j + \frac{d}{2} \right), \quad (3.124)$$

each ranging from 0 to ∞ . Note that every energy level of this system, with the only exception of its ground state,

$$\psi_g = \prod_{j=1}^d \psi_0(r_j) = \frac{1}{\pi^{d/4} x_0^{d/2}} \exp \left\{ -\frac{1}{2x_0^2} \sum_{j=1}^d r_j^2 \right\}, \quad (3.125)$$

is *degenerate*: several different wavefunctions, each with its own different set of quantum numbers n_j , but the same value of their sum, have the same energy.

However, the harmonic oscillator problem is an exception: for other central- and spherically-symmetric problems the solution is made easier by using more appropriate curvilinear coordinates. Let us start with the simplest axially-symmetric problem: the so-called *planar rigid rotator* (or “rotor”), i.e. a particle of mass m ,⁵⁴ constrained to move along a plane circle of radius R (Fig. 17).⁵⁵

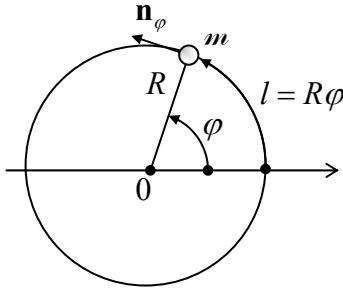

Fig. 3.17. A planar rigid rotator.

The classical planar rotator may be described by just *one* degree of freedom, say the angle displacement φ (or equivalently the arc displacement $l \equiv R\varphi$) from some reference direction, with the energy (and the Hamiltonian function) $H = p^2/2m$, where $\mathbf{p} \equiv m\mathbf{v} = m\mathbf{n}_\varphi (dl/dt)$, \mathbf{n}_φ being the unit vector in the azimuthal direction – see Fig. 17. This function is similar to that of a free 1D particle (with the replacement $x \rightarrow l \equiv R\varphi$), and hence the rotator’s quantum properties may be described by a similar Hamiltonian operator:

$$\hat{H} = \frac{\hat{p}^2}{2m}, \quad \text{with } \hat{\mathbf{p}} = -i\hbar\mathbf{n}_\varphi \frac{\partial}{\partial l} \equiv -i\frac{\hbar}{R}\mathbf{n}_\varphi \frac{\partial}{\partial\varphi}, \quad (3.126)$$

whose eigenfunctions have a similar structure:

$$\psi = Ce^{ikl} \equiv Ce^{ikR\varphi}. \quad (3.127)$$

⁵⁴ From this point on (until the chapter’s end), I will use this exotic font for the particle’s mass, to avoid any chance of its confusion with the impending “magnetic” quantum number m , traditionally used in axially-symmetric problems.

⁵⁵ This is a reasonable model for the confinement of light atoms, notably hydrogen, in some organic compounds, but I am addressing this system mostly as the basis for the following, more complex problems.

The “only” new feature is that in the rotator, all observables should be 2π -periodic functions of the angle φ . Hence, as we have already discussed in the context of the magnetic flux quantization (see Fig. 4 and its discussion), as the particle makes one turn around the central point 0, its wavefunction’s phase $kR\varphi$ may only change by $2\pi m$, with an arbitrary integer m (ranging from $-\infty$ to $+\infty$):

$$\psi_m(\varphi + 2\pi) = \psi_m(\varphi)e^{2\pi im}. \quad (3.128)$$

With the eigenfunctions (127), this periodicity condition immediately gives $2\pi kR = 2\pi m$. Thus, the wave number k can take only quantized values $k_m = m/R$, so that the eigenfunctions should be indexed by this *magnetic quantum number* m :

$$\psi_m = C_m \exp\left\{im \frac{l}{R}\right\} \equiv C_m \exp\{im\varphi\},$$

(3.129) Planar rotator:
eigenfunctions

and the energy spectrum is discrete:

$$E_m = \frac{p_m^2}{2m} = \frac{\hbar^2 k_m^2}{2m} = \frac{\hbar^2 m^2}{2mR^2}.$$

(3.130) Planar rotator:
eigenenergies

This simple model allows exact analysis of the external magnetic field effects on a confined motion of an electrically charged particle. Indeed, in the simplest case when this field is axially symmetric (or just uniform) and directed normally to the rotator’s plane, it does not violate the axial symmetry of the system. According to Eq. (26), in this case, we have to generalize Eq. (126) as

$$\hat{H} = \frac{1}{2m} \left(-i\hbar \mathbf{n}_\varphi \frac{\partial}{\partial l} - q\mathbf{A} \right)^2 \equiv \frac{1}{2m} \left(-i \frac{\hbar}{R} \mathbf{n}_\varphi \frac{\partial}{\partial \varphi} - q\mathbf{A} \right)^2. \quad (3.131)$$

Here, in contrast to the Cartesian gauge choice (44), which was so instrumental for the solution of the Landau level problem, it is beneficial to take the vector potential in the axially-symmetric form $\mathbf{A} = A(\rho)\mathbf{n}_\varphi$, where $\rho = \{x, y\}$ is the 2D radius-vector, with the magnitude $\rho = (x^2 + y^2)^{1/2}$. Using the well-known expression for the curl operator in the cylindrical coordinates,⁵⁶ we can readily check that the requirement $\nabla \times \mathbf{A} = \mathcal{B}\mathbf{n}_z$, with $\mathcal{B} = \text{const}$, is satisfied by the following function:

$$\mathbf{A} = \mathbf{n}_\varphi \frac{\mathcal{B}\rho}{2}. \quad (3.132)$$

For the planar rotator, $\rho = R = \text{const}$, so that the stationary Schrödinger equation becomes

$$\frac{1}{2m} \left(-i \frac{\hbar}{R} \frac{\partial}{\partial \varphi} - q \frac{\mathcal{B}R}{2} \right)^2 \psi_m = E_n \psi_m. \quad (3.133)$$

A little bit surprisingly, this equation is still satisfied with the eigenfunctions (127). Moreover, since the periodicity condition (128) is also unaffected by the applied magnetic field, we return to the periodic eigenfunctions (129), independent of \mathcal{B} . However, the field does affect the system’s eigenenergies:

⁵⁶ See, e.g., MA Eq. (10.5).

Planar rotator:
magnetic field's effect

$$E_m = \frac{1}{\psi_m} \frac{1}{2m} \left(-i \frac{\hbar}{R} \frac{\partial}{\partial \varphi} - q \frac{\mathcal{B}R}{2} \right)^2 \psi_m = \frac{1}{2m} \left(\frac{\hbar m}{R} - q \frac{\mathcal{B}R}{2} \right)^2 \equiv \frac{\hbar^2}{2mR^2} \left(m - \frac{\Phi}{\Phi_0'} \right)^2, \quad (3.134)$$

where $\Phi = \pi R^2 \mathcal{B}$ is the magnetic flux through the particle's trajectory, and $\Phi_0' = 2\pi\hbar/q$ is the “normal” magnetic flux quantum we have already met in the AB effect’s context – see Eq. (34) and its discussion. The field also changes the electric current of the particle in each eigenstate:

$$I_m = q \frac{\hbar}{2imR} \left[\psi_m^* \left(\frac{\partial}{\partial \varphi} - \frac{iqR\mathcal{B}}{2\hbar} \right) \psi_m - \text{c.c.} \right] = q \frac{\hbar}{mR} |C_m|^2 \left(m - \frac{\Phi}{\Phi_0'} \right). \quad (3.135)$$

Normalizing the wavefunction (129) to have $W_m = 1$, we get $|C_m|^2 = 1/2\pi R$, so that Eq. (135) becomes

$$I_m = \left(m - \frac{\Phi}{\Phi_0'} \right) I_0, \quad \text{with } I_0 \equiv \frac{\hbar q}{2\pi m R^2}. \quad (3.136)$$

The functions $E_m(\Phi)$ and $I_m(\Phi)$ are shown in Fig. 18. Note that since $\Phi_0' \propto 1/q$, for any sign of the particle’s charge q , $dI_m/d\Phi < 0$. It is easy to verify that this means that the current is *diamagnetic* for any sign of q :⁵⁷ the field-induced current flows in the direction that its own magnetic field tries to compensate for the external magnetic flux applied to the loop. This result may be interpreted as a different manifestation of the AB effect.⁵⁸ In contrast to the interference experiment that was discussed in Sec. 1, in the situation shown in Fig. 17 the particle is not absorbed by the detector but travels around the ring continuously. As a result, its wavefunction is “rigid”: due to the periodicity condition (128), the quantum number m is discrete, and the applied magnetic field cannot change the wavefunction gradually. In this sense, the system is similar to a superconducting loop – see Fig. 4 and its discussion. The difference between these systems is two-fold:

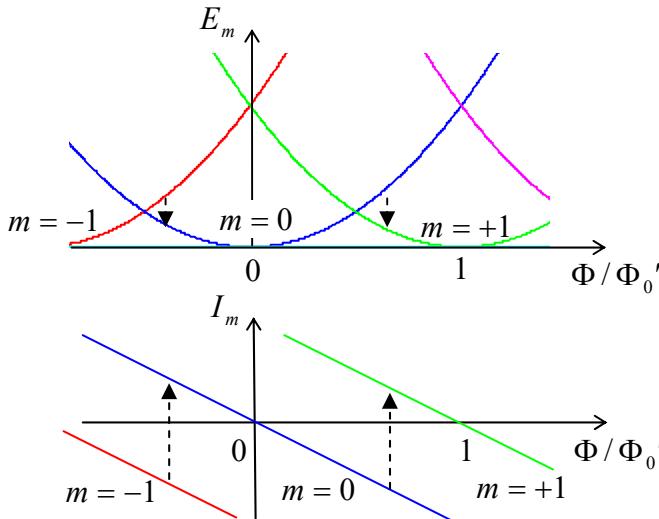

Fig. 3.18. The magnetic field effect on a charged planar rotator. Dashed arrows show possible inelastic transitions between metastable and ground states, due to weak interaction with the environment, as the external magnetic field is slowly increased.

⁵⁷ This effect, whose qualitative features remain the same for all 2D or 3D localized states (see Chapter 6 below), is frequently referred to as *orbital diamagnetism*. In magnetic materials consisting of particles with uncompensated spins, this effect competes with an opposite effect, *spin paramagnetism* – see, e.g., EM Sec. 5.5.

⁵⁸ It is straightforward to check that the final forms of Eqs. (134)-(136) remain valid even if the magnetic field is localized well inside the rotator’s circumference so that its lines do not touch the particle’s trajectory.

(i) For a single charged particle, in macroscopic systems with practicable values of q , R , and m , the scale I_0 of the induced current is very small. For example, for $m = m_e$, $q = -e$, and $R = 1 \mu\text{m}$, Eq. (136) yields $I_0 \approx 3 \text{ pA}$.⁵⁹ With the ring's inductance \mathcal{L} of the order of $\mu_0 R$,⁶⁰ the contribution $\Phi_I = \mathcal{L}I \sim \mu_0 R I_0 \sim 10^{-24} \text{ Wb}$ of such a small current into the net magnetic flux Φ is negligible in comparison with $\Phi_0' \sim 10^{-15} \text{ Wb}$, so that the wavefunction quantization does not lead to the constancy of the total magnetic flux.

(ii) As soon as the magnetic field raises the eigenstate energy E_m above that of another eigenstate $E_{m'}$, the former state becomes metastable, and a weak interaction of the system with its environment (which is neglected in our simple model, but will be discussed in Chapter 7) may induce a quantum transition of the system to the lower-energy state, thus reducing the diamagnetic current's magnitude – see the dashed lines in Fig. 18. The flux quantization in superconductors is much more robust to such perturbations.⁶¹

Now let us return, once again, to the key Eq. (129), and see what does it give for one more important observable, the particle's angular momentum

$$\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}, \quad (3.137)$$

In this particular geometry, the vector \mathbf{L} has just one component, normal to the rotator plane:

$$L_z = Rp. \quad (3.138)$$

In classical mechanics, L_z of the rotator should be conserved (due to the absence of external torque), but it may take arbitrary values. In quantum mechanics, the situation changes: with $p = \hbar k$, our result $k_m = m/R$ for the m^{th} eigenstate may be rewritten as

$(L_z)_m = R\hbar k_m = \hbar m.$

(3.139)
Angular momentum quantization

Thus, the angular momentum is quantized: it may be only a multiple of the Planck constant \hbar – confirming the N. Bohr's guess – see Eq. (1.8). As we will see in Chapter 5, this result is very general (though it may be modified by spin effects), and the wavefunctions (129) may be interpreted as eigenfunctions of the angular momentum operator.

Let us see whether this quantization persists in more general, but still axial-symmetric systems. To implement the planar rotator in our 3D world, we needed to provide rigid confinement of the particle both in the motion plane and along the 2D radius ρ . Let us consider a more general situation when only the former confinement is strict, i.e. to the case when a 2D particle moves in an arbitrary centrally-symmetric potential

$$U(\mathbf{p}) = U(\rho). \quad (3.140)$$

⁵⁹ Such weak persistent, macroscopic diamagnetic currents in non-superconducting systems have been experimentally observed by measuring the weak magnetic field induced by the currents, in systems of a large number ($\sim 10^7$) of similar conducting rings – see, e.g., L. Lévy *et al.*, *Phys. Rev. Lett.* **64**, 2074 (1990). Due to the dephasing effects of electron scattering by phonons and other electrons (unaccounted for in our simple theory), the effect's observation requires submicron rings and millikelvin temperatures.

⁶⁰ See, e.g., EM Sec. 5.3.

⁶¹ Interrupting a superconducting ring with a weak link (Josephson junction), i.e. forming a SQUID, we may get a switching behavior similar to that shown with dashed arrows in Fig. 18 – see, e.g., EM Sec. 6.5.

Using the well-known expression for the 2D Laplace operator in polar coordinates,⁶² we may represent the 2D stationary Schrödinger equation in the form

$$-\frac{\hbar^2}{2m} \left[\frac{1}{\rho} \frac{\partial}{\partial \rho} \left(\rho \frac{\partial}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2}{\partial \varphi^2} \right] \psi + U(\rho) \psi = E \psi. \quad (3.141)$$

Separating the radial and angular variables as⁶³

$$\psi = \mathcal{R}(\rho) \mathcal{A}(\varphi), \quad (3.142)$$

we get, after the division of all terms by ψ and their multiplication by ρ^2 , the following equation:

$$-\frac{\hbar^2}{2m} \left[\frac{\rho}{\mathcal{R}} \frac{d}{d\rho} \left(\rho \frac{d\mathcal{R}}{d\rho} \right) + \frac{1}{\mathcal{A}} \frac{d^2\mathcal{A}}{d\varphi^2} \right] + \rho^2 U(\rho) = \rho^2 E. \quad (3.143)$$

The fraction $(d^2\mathcal{A}/d\varphi^2)/\mathcal{A}$ should be a constant (because all other terms of the equation may be functions only of ρ), so that for the function $\mathcal{A}(\varphi)$ we get an ordinary differential equation,

$$\frac{d^2\mathcal{A}}{d\varphi^2} + \nu^2 \mathcal{A} = 0, \quad (3.144)$$

where ν^2 is the variable separation constant. The fundamental solutions of Eq. (144) are evidently $\mathcal{A} \propto \exp\{\pm i \nu \varphi\}$. Now requiring, as we did for the planar rotator, the 2π periodicity of any observable, i.e.

$$\mathcal{A}(\varphi + 2\pi) = \mathcal{A}(\varphi) e^{2\pi i m}, \quad (3.145)$$

where m is an integer, we see that the constant ν has to be equal to m , and get, for the angular factor, the same result as for the full wavefunction of the planar rotator – cf. Eq. (129):

$$\mathcal{A}_m = C_m e^{im\varphi}, \quad \text{with } m = 0, \pm 1, \pm 2, \dots \quad (3.146)$$

Plugging the resulting relation $(d^2\mathcal{A}/d\varphi^2)/\mathcal{A} = -m^2$ back into Eq. (143), we may rewrite it as

$$-\frac{\hbar^2}{2m} \left[\frac{1}{\rho \mathcal{R}} \frac{d}{d\rho} \left(\rho \frac{d\mathcal{R}}{d\rho} \right) - \frac{m^2}{\rho^2} \right] + U(\rho) = E. \quad (3.147)$$

The physical interpretation of this equation is that the full energy is a sum,

$$E = E_\rho + E_\varphi, \quad (3.148)$$

of the radial-motion part

$$E_\rho = -\frac{\hbar^2}{2m} \frac{1}{\rho} \frac{d}{d\rho} \left(\rho \frac{d\mathcal{R}}{d\rho} \right) + U(\rho). \quad (3.149)$$

and the angular-motion part

⁶² See, e.g., MA Eq. (10.3) with $\partial/\partial z = 0$.

⁶³ At this stage, I do not want to mark the particular solution (eigenfunction) ψ and corresponding eigenenergy E with any single index, because based on our experience in Sec. 1.7, we already may expect that in a 2D problem the role of this index will be played by *two* integers – two quantum numbers.

$$E_\varphi = \frac{\hbar^2 m^2}{2m\rho^2}. \quad (3.150)$$

Now let us recall that a similar separation exists in classical mechanics,⁶⁴ because the total energy of a particle moving in a central field may be represented as

$$E = \frac{m}{2} v^2 + U(\rho) = \frac{m}{2} (\dot{\rho}^2 + \rho^2 \dot{\varphi}^2) + U(\rho) \equiv E_\rho + E_\varphi, \quad (3.151)$$

$$\text{with } E_\rho \equiv \frac{p_\rho^2}{2m} + U(\rho), \quad \text{and } E_\varphi \equiv \frac{m}{2} \rho^2 \dot{\varphi}^2 \equiv \frac{p_\varphi^2}{2m} \equiv \frac{L_z^2}{2m\rho^2}. \quad (3.152)$$

The comparison of the latter relation with Eqs. (139) and (150) gives us grounds to expect that the quantization rule $L_z = m\hbar$ may be valid not only for this 2D problem but in 3D cases as well. In Sec. 5.6, we will see that this is indeed the case.

Returning to Eq. (147), with our 1D wave mechanics experience we may expect that any fixed m this ordinary, linear, second-order differential equation should have (for a motion confined to a certain final region of its argument ρ) a discrete energy spectrum described by another integer quantum number – say, n . This means that the eigenfunctions (142) and corresponding eigenenergies (148) and $\mathcal{R}(\rho)$ should be indexed by two quantum numbers, m and n . So, the variable separation is not so “clean” as it was for the rectangular potential well. Normalizing the angular function \mathcal{F} to the full circle, $\Delta\varphi = 2\pi$, we may rewrite Eq. (142) as

$$\psi_{m,n} = \mathcal{R}_{m,n}(\rho)\mathcal{F}_m(\varphi) = \frac{1}{(2\pi)^{1/2}} \mathcal{R}_{m,n}(\rho)e^{im\varphi}. \quad (3.153)$$

A good (and important) example of an analytically solvable problem of this type is a 2D particle whose motion is rigidly confined to a disk of radius R , but otherwise free:

$$U(\rho) = \begin{cases} 0, & \text{for } 0 \leq \rho < R, \\ +\infty, & \text{for } R < \rho. \end{cases} \quad (3.154)$$

In this case, the solutions $\mathcal{R}_{m,n}(\rho)$ of Eq. (147) are proportional to the first-order Bessel functions $J_m(k_n\rho)$,⁶⁵ with the spectrum of possible values k_n following from the boundary condition $\mathcal{R}_{m,n}(R) = 0$. Let me leave a detailed analysis of this problem for the reader’s exercise.

3.6. Spherically-symmetric systems: Brute force approach

Now let us proceed to the mathematically more involved, but practically even more important case of the 3D motion, in a spherically-symmetric potential

$$U(\mathbf{r}) = U(r). \quad (3.155)$$

⁶⁴ See, e.g., CM Sec. 3.5.

⁶⁵ A short summary of properties of these functions, including the most important plots and a useful table of values, may be found in EM Sec. 2.7.

Let us start, again, with solving the eigenproblem for a rigid rotator – now a *spherical rotator*, i.e. a particle confined to move on the spherical surface of radius R . The rotator has two degrees of freedom because its position on the surface is completely described by two coordinates – say, the polar angle θ and the azimuthal angle φ . In this case, the kinetic energy we need to consider is limited to its angular part, so that in the Laplace operator in spherical coordinates⁶⁶ we may keep only those parts, with fixed $r = R$. Because of this, the stationary Schrödinger equation becomes

$$-\frac{\hbar^2}{2mR^2} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \varphi^2} \right] \psi = E \psi. \quad (3.156)$$

(Again, we will attach indices to ψ and E in a minute.) With the natural variable separation,

$$\psi = \Theta(\theta) \mathcal{F}(\varphi), \quad (3.157)$$

Eq. (156), with all terms multiplied by $\sin^2 \theta / \Theta \mathcal{F}$, yields

$$-\frac{\hbar^2}{2mR^2} \left[\frac{\sin \theta}{\Theta} \frac{d}{d\theta} \left(\sin \theta \frac{d\Theta}{d\theta} \right) + \frac{1}{\mathcal{F}} \frac{d^2 \mathcal{F}}{d\varphi^2} \right] = E \sin^2 \theta. \quad (3.158)$$

Just as in Eq. (143), the fraction $(d^2 \mathcal{F}/d\varphi^2)/\mathcal{F}$ may be a function of φ only, and hence has to be constant, giving Eq. (144) for it. So, with the same periodicity condition (145), the azimuthal functions are expressed by (146) again; in the normalized form,

$$\mathcal{F}_m(\varphi) = \frac{1}{(2\pi)^{1/2}} e^{im\varphi}. \quad (3.159)$$

With that, the fraction $(d^2 \mathcal{F}/d\varphi^2)/\mathcal{F}$ in Eq. (158) equals $(-m^2)$, and after the multiplication of all terms of that equation by $\Theta/\sin^2 \theta$, it is reduced to the following ordinary linear differential equation for the polar eigenfunctions $\Theta(\theta)$:

$$-\frac{1}{\sin \theta} \frac{d}{d\theta} \left(\sin \theta \frac{d\Theta}{d\theta} \right) + \frac{m^2}{\sin^2 \theta} \Theta = \varepsilon \Theta, \quad \text{with } \varepsilon \equiv E / \frac{\hbar^2}{2mR^2}. \quad (3.160)$$

It is common to recast it into an equation for a new function $P(\xi) \equiv \Theta(\theta)$, with $\xi \equiv \cos \theta$:

$$\frac{d}{d\xi} \left[(1 - \xi^2) \frac{dP}{d\xi} \right] + \left[l(l+1) - \frac{m^2}{1 - \xi^2} \right] P = 0, \quad (3.161)$$

where a new notation for the normalized energy is introduced: $l(l+1) \equiv \varepsilon$. The motivation for such notation is that, according to the mathematical analysis of Eq. (161) with integer m ,⁶⁷ it has solutions only if the parameter l is an integer: $l = 0, 1, 2, \dots$, and only if that integer is not smaller than $|m|$, i.e. if

$$-l \leq m \leq +l. \quad (3.162)$$

This fact immediately gives the following spectrum of the spherical rotator's energy E – and, as we will see later, the angular part of the energy of any spherically-symmetric system:

⁶⁶ See, e.g., MA Eq. (10.9).

⁶⁷ This analysis was first carried out by A.-M. Legendre (1752-1833). Just as a historic note: besides many original mathematical achievements, Dr. Legendre had authored a famous textbook, *Éléments de Géométrie*, which dominated teaching geometry through the 19th century.

$$E_l = \frac{\hbar^2 l(l+1)}{2mR^2}, \quad (3.163)$$

Angular energy spectrum

so that the only effect of the magnetic quantum number m here is imposing the restriction (162) on the non-negative integer l – the so-called *orbital quantum number*. This means, in particular, that each energy (163) corresponds to $(2l+1)$ different values of m , i.e. is $(2l+1)$ -degenerate.

To understand the nature of this degeneracy, we need to explore the corresponding eigenfunctions of Eq. (161). They are naturally numbered by two integers, m and l , and are called the associated *Legendre functions* P_l^m . (Note that here m is an upper index, not a power!) For the particular, simplest case $m = 0$, these functions are the so-called *Legendre polynomials* $P_l(\xi) \equiv P_l^0(\xi)$, which may be defined as the solutions of the following *Legendre equation*, resulting from Eq. (161) at $m = 0$:

$$\frac{d}{d\xi} \left[(1 - \xi^2) \frac{d}{d\xi} P \right] + l(l+1)P = 0, \quad (3.164)$$

Legendre equation

but also may be calculated explicitly from the following *Rodrigues formula*:⁶⁸

$$P_l(\xi) = \frac{1}{2^l l!} \frac{d^l}{d\xi^l} (\xi^2 - 1)^l, \quad l = 0, 1, 2, \dots \quad (3.165)$$

Legendre polynomials

Using this formula, it is easy to spell out a few lowest Legendre polynomials:

$$P_0(\xi) = 1, \quad P_1(\xi) = \xi, \quad P_2(\xi) = \frac{1}{2}(3\xi^2 - 1), \quad P_3(\xi) = \frac{1}{2}(5\xi^3 - 3\xi), \dots, \quad (3.166)$$

though such explicit expressions become bulkier and bulkier as l is increased. As these expressions (and Fig. 19) show, as the argument ξ is increased, all these functions end up at the same point, $P_l(+1) = +1$, while starting at either at the same point or at the opposite point: $P_l(-1) = (-1)^l$. On the way between these two end points, the l^{th} polynomial crosses the horizontal axis exactly l times, i.e. Eq. (164) has l roots.⁶⁹

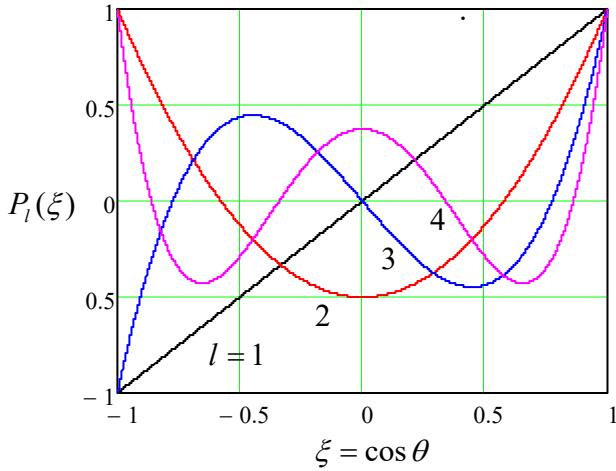

Fig. 3.19. A few lowest Legendre polynomials.

⁶⁸ This wonderful formula may be readily proved by plugging it into Eq. (164), but was not so easy to discover! This was done (independently) by B. O. Rodrigues in 1816, J. Ivory in 1824, and C. Jacobi in 1827.

⁶⁹ In this behavior, we may readily recognize the “standing wave” pattern typical for all 1D eigenproblems – cf. Figs. 1.8 and 2.35, as well as the discussion of the Sturm oscillation theorem at the end of Sec. 2.9.

It is also easy to use the Rodrigues formula (165) and the integration by parts to show that on the segment $-1 \leq \xi \leq +1$, the Lagrange polynomials form a full orthogonal set of functions, with the following normalization rule:

$$\int_{-1}^{+1} P_l(\xi) P_{l'}(\xi) d\xi = \frac{2}{2l+1} \delta_{ll'}, \quad (3.167)$$

For $m > 0$, the associated Legendre functions (now *not* necessarily polynomials!), may be expressed via the Legendre polynomials (165) using the following formula:⁷⁰

$$P_l^m(\xi) = (-1)^m (1 - \xi^2)^{m/2} \frac{d^m}{d\xi^m} P_l(\xi), \quad (3.168)$$

while the functions with a negative magnetic quantum number may be found as

$$P_l^{-m}(\xi) = (-1)^m \frac{(l-m)!}{(l+m)!} P_l^m(\xi), \quad \text{for } m > 0. \quad (3.169)$$

On the segment $-1 \leq \xi \leq +1$, the associated Legendre functions with a fixed index m form a full orthogonal set, with the normalization relation,

$$\int_{-1}^{+1} P_l^m(\xi) P_{l'}^m(\xi) d\xi = \frac{2}{2l+1} \frac{(l+m)!}{(l-m)!} \delta_{ll'}, \quad (3.170)$$

which is evidently a generalization of Eq. (167) for arbitrary m .

Since the difference between the angles θ and φ is to large extent artificial (due to an arbitrary direction of the polar axis), physicists prefer to use not the functions $\Theta(\theta) \propto P_l^m(\cos \theta)$ and $\mathcal{Z}_m(\varphi) \propto e^{im\varphi}$ separately, but normalized products of the type (157), which are called the *spherical harmonics*:

$$Y_l^m(\theta, \varphi) = \left[\frac{(2l+1)}{4\pi} \frac{(l-m)!}{(l+m)!} \right]^{1/2} P_l^m(\cos \theta) e^{im\varphi}. \quad (3.171)$$

The specific front factor in Eq. (171) is chosen in a way to simplify the following two expressions: the relation of the spherical harmonics with opposite signs of the magnetic quantum number,

$$Y_l^{-m}(\theta, \varphi) = (-1)^m [Y_l^m(\theta, \varphi)]^*, \quad (3.172)$$

and the following normalization relation:

$$\oint_{4\pi} Y_l^m(\theta, \varphi) [Y_{l'}^{m'}(\theta, \varphi)]^* d\Omega = \delta_{ll'} \delta_{mm'}, \quad (3.173)$$

with the integration over the whole solid angle. The last formula shows that on a spherical surface, the spherical harmonics form an orthonormal set of functions. This set is also full, so that any function defined on the surface, may be uniquely represented as a linear combination of Y_l^m .

Despite a somewhat intimidating character of the formulas given above, they yield quite simple expressions for the lowest spherical harmonics, which are most important for applications:

⁷⁰ Note that some texts use different choices for the front factor (called the *Condon-Shortley phase*) in the functions P_l^m , which do not affect the final results for the spherical harmonics Y_l^m .

$$l=0 : \quad Y_0^0 = (1/4\pi)^{1/2}, \quad (3.174)$$

$$l=1 : \quad \begin{cases} Y_1^{-1} = (3/8\pi)^{1/2} \sin \theta e^{-i\varphi}, \\ Y_1^0 = (3/4\pi)^{1/2} \cos \theta, \\ Y_1^1 = -(3/8\pi)^{1/2} \sin \theta e^{i\varphi}, \end{cases} \quad (3.175)$$

$$l=2 : \quad \begin{cases} Y_2^{-2} = -(15/32\pi)^{1/2} \sin^2 \theta e^{-2i\varphi}, \\ Y_2^{-1} = (15/8\pi)^{1/2} \sin \theta \cos \theta e^{-i\varphi}, \\ Y_2^0 = (3/16\pi)^{1/2} (3 \cos^2 \theta - 1), \quad \text{etc.} \\ Y_2^1 = -(15/8\pi)^{1/2} \sin \theta \cos \theta e^{i\varphi}, \\ Y_2^2 = (15/32\pi)^{1/2} \sin^2 \theta e^{2i\varphi}, \end{cases} \quad (3.176)$$

It is important to understand the general structure and symmetry of these functions. Since the spherical harmonics with $m \neq 0$ are complex, the most popular way of their graphical representation is to normalize their real and imaginary parts as⁷¹

$$Y_{lm} \equiv \sqrt{2}(-1)^m \times \begin{cases} \text{Im}(Y_l^{|m|}) \propto \sin m\varphi, & \text{for } m < 0, \\ \text{Re}(Y_l^{|m|}) \propto \cos m\varphi, & \text{for } m > 0, \end{cases} \quad (3.177)$$

(for $m = 0$, $Y_{l0} \equiv Y_l^0$), and then plot the magnitude of these real functions in the spherical coordinates as the distance from the origin, while using two colors to show their sign – see Fig. 20.

Let us start from the simplest case $l = 0$. According to Eq. (162), for this lowest orbital quantum number, there may be only one magnetic quantum number, $m = 0$. According to Eq. (174), the spherical harmonic corresponding to that state is just a constant, so that the wavefunction of this so-called *s state*⁷² is uniformly distributed over the sphere. Since this function has no gradient in any angular direction, it is only natural that the angular kinetic energy (163) of the particle equals zero.

According to the same Eq. (162), for $l = 1$, there are 3 different *p states*, with $m = -1$, $m = 0$, and $m = +1$ – see Eq. (175). As the second row of Fig. 20 shows, these states are essentially identical in structure and are just differently oriented in space, thus readily explaining the 3-fold degeneracy of the kinetic energy (163). Such a simple explanation, however, is not valid for the 5 different *d states* ($l = 2$), shown in the third row of Fig. 20, as well as the states with higher l : despite their equal energies, they differ not only by their spatial orientation but their structure as well. All states with $m = 0$ have a nonzero gradient only in the θ direction. On the contrary, the states with the ultimate values of m ($\pm l$), change only monotonically (as $\sin^l \theta$) in the polar direction, while oscillating in the azimuthal direction. The states with intermediate values of m provide a gradual transition between these two extremes, oscillating in both directions, stronger and stronger in the azimuthal direction as $|m|$ is increased. Still, the magnetic quantum number, surprisingly, does not affect the angular energy for any l .

⁷¹ Such real functions Y_{lm} , which also form a full orthonormal set, and are frequently called the *real* (or “tesseral”) *spherical harmonics*, are more convenient than the complex harmonics Y_l^m for several applications, especially when the variables of interest are real by definition.

⁷² The letter names for the states with various values of l stem from the history of optical spectroscopy – for example, the letter “s” used for states with $l = 0$, originally denoted the “sharp” optical line series, etc. The sequence of the letters is as follows: *s, p, d, f, g*, and then continuing in alphabetical order.

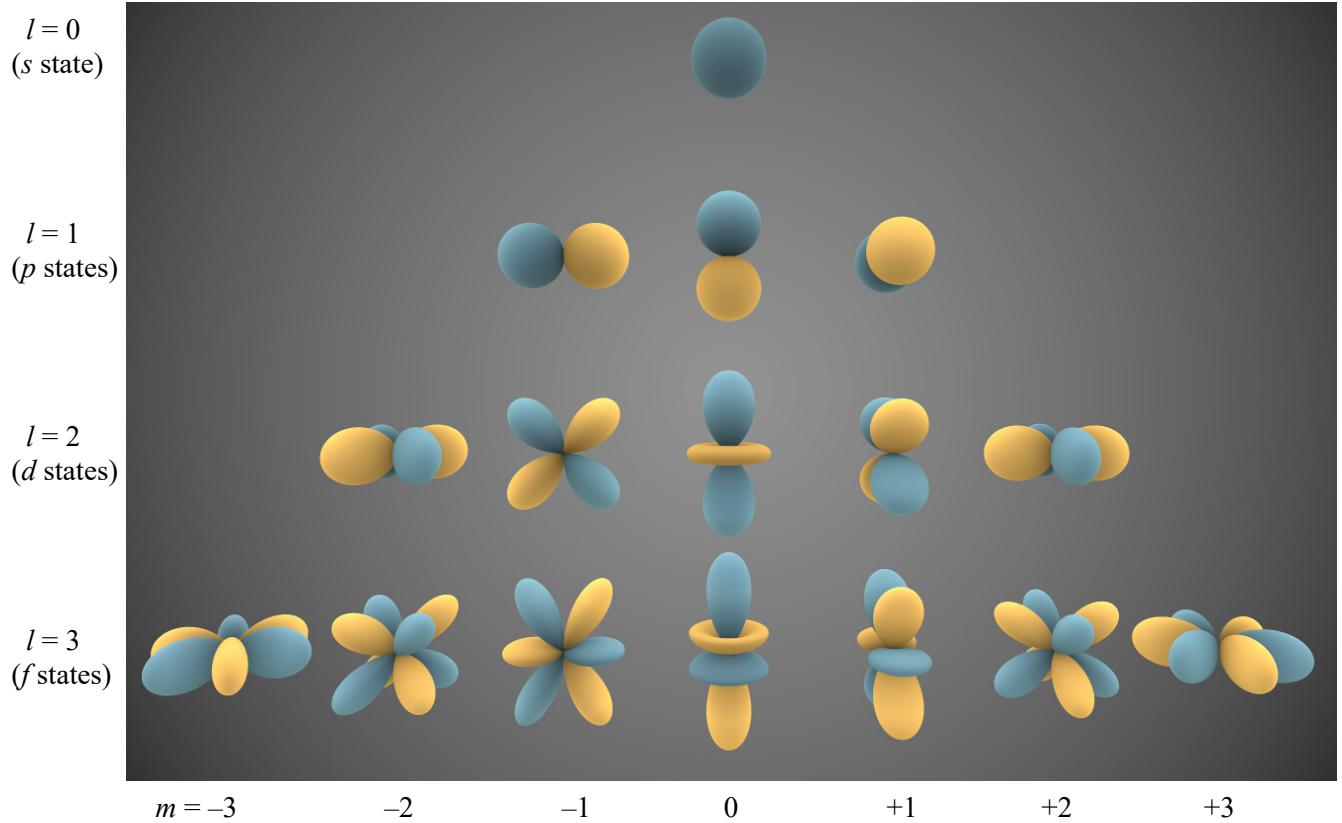

Fig. 3.20. Radial plots of several lowest real spherical harmonics Y_{lm} . (Adapted from https://en.wikipedia.org/wiki/Spherical_harmonics under the CC BY-SA 3.0 license.)

Another counter-intuitive feature of the spherical harmonics follows from the comparison of Eq. (163) with the second of the classical relations (152). These expressions coincide if we interpret the constant

$$L^2 \equiv \hbar^2 l(l+1), \quad (3.178)$$

as the value of the full angular momentum squared, $L^2 = |\mathbf{L}|^2$ (including its both θ and φ components) in the eigenstate with eigenfunction Y_l^m . On the other hand, the structure (159) of the azimuthal component $\mathcal{H}(\varphi)$ of the wavefunction is exactly the same as in 2D axially-symmetric problems, implying that Eq. (139) still gives correct values $L_z = m\hbar$ for the z -component of the angular momentum. This fact invites a question: why for any state with $l > 0$, $(L_z)^2 = m^2\hbar^2 \leq l^2\hbar^2$ is always less than $L^2 = l(l+1)\hbar^2$? In other words, what prevents the angular momentum vector to be fully aligned with the axis z ?

Besides the difficulty of answering this question using the above formulas, this analysis (though mathematically complete), is as intellectually unsatisfactory as the harmonic oscillator analysis in Sec. 2.9. In particular, it does not explain the meaning of the extremely simple relations for the eigenvalues of the energy and the angular momentum, coexisting with rather complicated eigenfunctions.

We will obtain natural answers to all these questions and concerns in Sec. 5.6 below, and now proceed to the extension of our wave-mechanical analysis to the 3D motion in an *arbitrary* spherically-symmetric potential (155). In this case, we have to use the full form of the Laplace operator in spherical

coordinates.⁷³ The variable separation procedure is an evident generalization of what we have done before, with the particular solutions of the type

$$\psi = \mathcal{R}(\rho)\Theta(\theta)\mathcal{F}(\phi), \quad (3.179)$$

whose substitution into the stationary Schrödinger equation yields

$$-\frac{\hbar^2}{2mr^2} \left[\frac{1}{\mathcal{R}} \frac{d}{dr} \left(r^2 \frac{d\mathcal{R}}{dr} \right) + \frac{1}{\Theta \sin \theta} \frac{d}{d\theta} \left(\sin \theta \frac{d\Theta}{d\theta} \right) + \frac{1}{\sin^2 \theta} \frac{1}{\mathcal{F}} \frac{d^2\mathcal{F}}{d\phi^2} \right] + U(r) = E. \quad (3.180)$$

It is evident that the angular part of the left-hand side (the two last terms in the square brackets) separates from the radial part, and that for the former part we get Eq. (156) again, with the only change, $R \rightarrow r$. This change does not affect the fact that the eigenfunctions of that equation are still the spherical harmonics (171), which obey Eq. (164). As a result, Eq. (180) gives the following equation for the radial function $\mathcal{R}(r)$:

$$-\frac{\hbar^2}{2mr^2} \left[\frac{1}{\mathcal{R}} \frac{d}{dr} \left(r^2 \frac{d\mathcal{R}}{dr} \right) - l(l+1) \right] + U(r) = E. \quad (3.181)$$

Note that no information about the magnetic quantum number m has crept into this radial equation (besides setting the limitation (162) for the possible values of l) so that it includes only the orbital quantum number l .

Let us explore the radial equation for the simplest case when $U(r) = 0$ – for example, to solve the eigenproblem for a 3D particle free to move only inside the sphere of radius R – say, confined there by the potential⁷⁴

$$U = \begin{cases} 0, & \text{for } 0 \leq r < R, \\ +\infty, & \text{for } R < r. \end{cases} \quad (3.182)$$

In this case, Eq. (181) is reduced to

$$-\frac{\hbar^2}{2mr^2} \left[\frac{1}{\mathcal{R}} \frac{d}{dr} \left(r^2 \frac{d\mathcal{R}}{dr} \right) - l(l+1) \right] = E. \quad (3.183)$$

Multiplying both parts of this equality by $r^2 \mathcal{R}$, and introducing the dimensionless argument $\xi \equiv kr$, where k^2 is defined by the usual relation $\hbar^2 k^2 / 2m = E$, we obtain the canonical form of this equation,

$$\xi^2 \frac{d^2\mathcal{R}}{d\xi^2} + 2\xi \frac{d\mathcal{R}}{d\xi} + [\xi^2 - l(l+1)]\mathcal{R} = 0, \quad (3.184)$$

Satisfied by so-called *spherical Bessel functions* of the first and second kind, $j_l(\xi)$ and $y_l(\xi)$.⁷⁵ These functions are directly related to the Bessel functions of semi-integer order,⁷⁶

⁷³ Again, see MA Eq. (10.9).

⁷⁴ This problem, besides giving a simple example of the quantization in spherically-symmetric systems, is also an important precursor for the discussion of scattering by spherically-symmetric potentials in Sec. 8.

⁷⁵ Alternatively, $y_l(\xi)$ are called “spherical Weber functions” or “spherical Neumann functions”.

⁷⁶ Note that the Bessel functions $J_v(\xi)$ and $Y_v(\xi)$ of *any* order v obey the universal recurrence relations and asymptotic formulas (discussed, e.g., in EM Sec. 2.7), so that many properties of the functions $j_l(\xi)$ and $y_l(\xi)$ may be readily derived from these relations and Eqs. (185).

$$j_l(\xi) = \left(\frac{\pi}{2\xi} \right)^{1/2} J_{l+\frac{1}{2}}(\xi), \quad y_l(\xi) = \left(\frac{\pi}{2\xi} \right)^{1/2} Y_{l+\frac{1}{2}}(\xi), \quad (3.185)$$

but are actually much simpler than even the “usual” Bessel functions, such as $J_n(\xi)$ and $Y_n(\xi)$ of an integer order n , because the former ones may be directly expressed via elementary functions:

$$\begin{aligned} j_0(\xi) &= \frac{\sin \xi}{\xi}, & j_1(\xi) &= \frac{\sin \xi}{\xi^2} - \frac{\cos \xi}{\xi}, & j_2(\xi) &= \left(\frac{3}{\xi^3} - \frac{1}{\xi} \right) \sin \xi - \frac{3}{\xi^2} \cos \xi, \dots, \\ y_0(\xi) &= -\frac{\cos \xi}{\xi}, & y_1(\xi) &= -\frac{\cos \xi}{\xi^2} - \frac{\sin \xi}{\xi}, & y_2(\xi) &= -\left(\frac{3}{\xi^3} - \frac{1}{\xi} \right) \cos \xi - \frac{3}{\xi^2} \sin \xi, \dots, \end{aligned} \quad (3.186)$$

A few lowest-order spherical Bessel functions are plotted in Fig. 21.

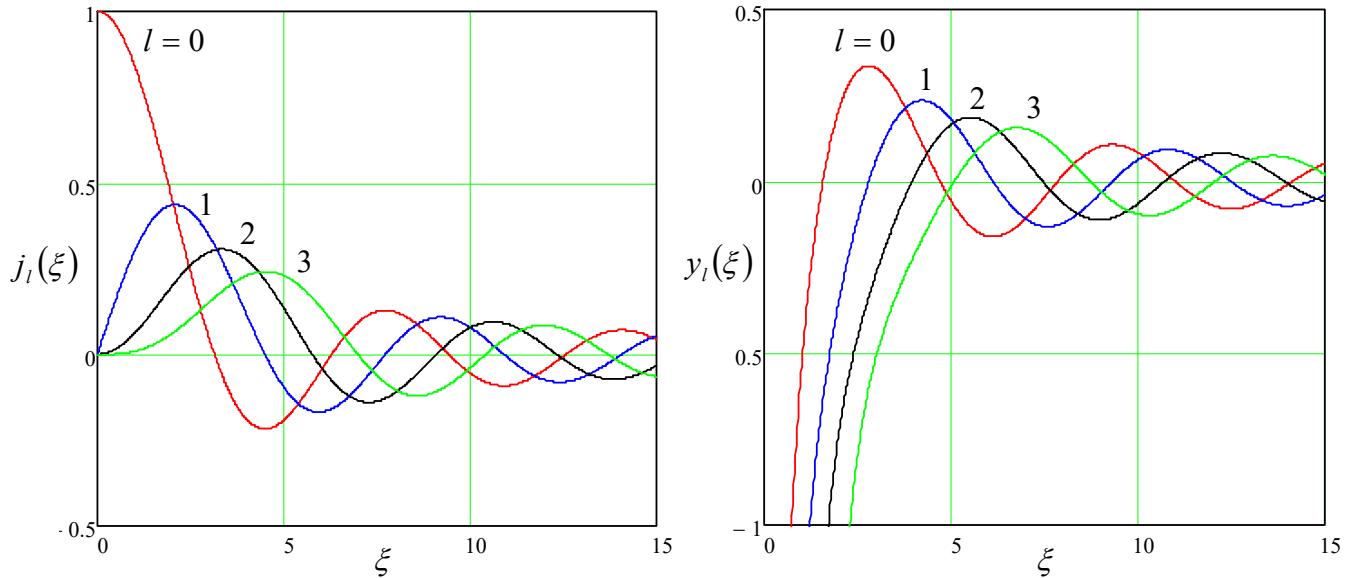

Fig. 3.21. Several lowest-order spherical Bessel functions.

As these formulas and plots show, the functions $y_l(\xi)$ are diverging at $\xi \rightarrow 0$, and thus cannot be used in the solution of our current problem (182), so that we have to take

$$\mathcal{R}_l(r) = \text{const} \times j_l(kr). \quad (3.187)$$

Still, even for these functions, with the sole exception of the simplest function $j_0(\xi)$, the characteristic equation $j_l(kR) = 0$, resulting from the boundary condition $\mathcal{R}(R) = 0$, can be solved only numerically. However, the roots $\xi_{l,n}$ of the equation $j_l(\xi) = 0$, where the integer $n (= 1, 2, 3, \dots)$ is the root’s number, are tabulated in virtually any math handbook, and we may express the eigenvalues we are interested in,

$$k_{l,n} = \frac{\xi_{l,n}}{R}, \quad E_{l,n} = \frac{\hbar^2 k_{l,n}^2}{2m} \equiv \frac{\hbar^2 \xi_{l,n}^2}{2m R^2}, \quad (3.188)$$

via these tabulated numbers. The table below lists several smallest roots, and the corresponding eigenenergies (normalized to their natural unit $E_0 \equiv \hbar^2/2mR^2$), in the order of their growth. It shows a

very interesting effect: going up the energy spectrum, first the eigenenergies grow because of increases of the orbital quantum number l , at the same (lowest) radial quantum number $n = 1$, due to the growth of the first roots of functions $j_l(\xi)$, but then suddenly the second root of $j_0(\xi)$ cuts into this orderly sequence, just to be followed by the first root of $j_3(\xi)$. With the further growth of energy, the sequences of l and n become even more entangled.

l	n	$\xi_{l,n}$	$E_{l,n}/E_0 = (\xi_{l,n})^2$
0	1	$\pi \approx 3.1415$	$\pi^2 \approx 9.87$
1	1	4.493	20.19
2	1	5.763	33.21
0	2	$2\pi \approx 6.283$	$4\pi^2 \approx 39.48$
3	1	6.988	48.83

To complete the discussion of our current problem (182), note again that the energy levels, listed in the table above, are $(2l + 1)$ -degenerate because each of them corresponds to $(2l + 1)$ different eigenfunctions, each with a specific value of the magnetic quantum number m :

$$\psi_{n,l,m} = C_{l,n} j_l \left(\frac{\xi_{l,n} r}{R} \right) Y_l^m(\theta, \varphi), \quad \text{with } -l \leq m \leq +l. \quad (3.189)$$

3.7 Atoms

Now we are ready to discuss atoms, starting from the simplest, exactly solvable *Bohr atom problem*, i.e. that of a single particle's motion in the so-called *attractive Coulomb potential*⁷⁷

$$U(r) = -\frac{C}{r}, \quad \text{with } C > 0. \quad (3.190)$$

Attractive Coulomb potential

The natural scales of E and r in this problem are commonly defined by the requirement of equality of the kinetic and potential energy magnitude scales (dropping all numerical coefficients):

$$E_0 \equiv \frac{\hbar^2}{mr_0^2} \equiv \frac{C}{r_0}, \quad (3.191)$$

similar to its particular case (1.13b). Solving this system of two equations, we get⁷⁸

$$E_0 \equiv \frac{\hbar^2}{mr_0^2} \equiv m \left(\frac{C}{\hbar} \right)^2, \quad \text{and} \quad r_0 \equiv \frac{\hbar^2}{mC}. \quad (3.192)$$

⁷⁷ Historically, the solution of this problem in 1928, that reproduced the main result (1.12)-(1.13) of the “old” quantum theory developed by N. Bohr in 1912, without its phenomenological assumptions, was the decisive step toward the general acceptance of Schrödinger’s wave mechanics.

⁷⁸ For the most important case of the hydrogen atom, with $C = e^2/4\pi\varepsilon_0$, these scales are reduced, respectively, to the Bohr radius r_B (1.10) and the Hartree energy E_H (1.13a). Note also that according to Eq. (192), for the so-called *hydrogen-like atom* (actually, a positive ion) with $C = Z(e^2/4\pi\varepsilon_0)$, these two key parameters are rescaled as $r_0 = r_B/Z$ and $E_0 = Z^2 E_H$.

In the normalized units $\varepsilon \equiv E/E_0$ and $\xi \equiv r/r_0$, equation (181) for our current case (190), looks relatively simple,

$$\frac{d^2\mathcal{R}}{d\xi^2} + \frac{2}{\xi} \frac{d\mathcal{R}}{d\xi} - l(l+1)\mathcal{R} + 2\left(\varepsilon + \frac{1}{\xi}\right)\mathcal{R} = 0, \quad (3.193)$$

but unfortunately, its eigenfunctions may be called elementary only in the most generous meaning of the word. With the adequate normalization,

$$\int_0^\infty \mathcal{R}_{n,l} \mathcal{R}_{n',l'} r^2 dr = \delta_{nn'}, \quad (3.194)$$

these (mutually orthogonal) functions may be represented as

$$\mathcal{R}_{n,l}(r) = -\left\{\left(\frac{2}{nr_0}\right)^3 \frac{(n-l-1)!}{2n[(n+l)!]^3}\right\}^{1/2} \exp\left\{-\frac{r}{nr_0}\right\} \left(\frac{2r}{nr_0}\right)^l L_{n-l-1}^{2l+1}\left(\frac{2r}{nr_0}\right). \quad (3.195)$$

Here $L_p^q(\xi)$ are the so-called *associated Laguerre polynomials*, which may be calculated as

$$L_p^q(\xi) = (-1)^q \frac{d^q}{d\xi^q} L_{p+q}(\xi). \quad (3.196)$$

from the *simple Laguerre polynomials* $L_p(\xi) \equiv L_p^0(\xi)$.⁷⁹ In turn, the easiest way to obtain $L_p(\xi)$ is to use the following *Rodrigues formula*:⁸⁰

$$L_p(\xi) = e^\xi \frac{d^p}{d\xi^p} (\xi^p e^{-\xi}). \quad (3.197)$$

Note that in contrast with the associated Legendre *functions* P_l^m , participating in the spherical harmonics, all L_p^q are just *polynomials*, and those with small indices p and q are indeed quite simple:

$$\begin{aligned} L_0^0(\xi) &= 1, & L_1^0(\xi) &= -\xi + 1, & L_2^0(\xi) &= \xi^2 - 4\xi + 2, \\ L_0^1(\xi) &= 1, & L_1^1(\xi) &= -2\xi + 4, & L_2^1(\xi) &= 3\xi^2 - 18\xi + 18, \\ L_0^2(\xi) &= 2, & L_1^2(\xi) &= -6\xi + 18, & L_2^2(\xi) &= 12\xi^2 - 96\xi + 144, \end{aligned} \quad (3.198)$$

Returning to Eq. (195), we see that the natural quantization of the radial equation (193) has brought us a new integer quantum number n . To understand its range, we should notice that according to Eq. (197), the highest power of terms in the polynomial L_{p+q} is $(p + q)$, and hence, according to Eq. (196), that of L_p^q is p , so that the highest power in the polynomial participating in Eq. (195) is $(n - l - 1)$. Since the power cannot be negative to avoid the unphysical divergence of wavefunctions at $r \rightarrow 0$, the radial quantum number n has to obey the restriction $n \geq l + 1$. Since l , as we already know, may take values $l = 0, 1, 2, \dots$, we may conclude n may only take the following values:

⁷⁹ In Eqs. (196)-(197), p and q are non-negative integers, with no relation whatsoever to the particle's momentum or electric charge. Sorry for this notation, but it is absolutely common, and can hardly result in any confusion.

⁸⁰ Named after the same B. O. Rodrigues, and belonging to the same class as his other famous result, Eq. (165) for the Legendre polynomials.

$$n = 1, 2, 3, \dots \quad (3.199)$$

What makes this relation very important is the following, most surprising result: the eigenenergies corresponding to the wavefunctions (179), which are indexed with three quantum numbers:

$$\psi_{n,l,m} = \mathcal{R}_{n,l}(r)Y_l^m(\theta, \varphi), \quad (3.200)$$

depend *only on one of them*, n :

$$\varepsilon = \varepsilon_n = -\frac{1}{2n^2}, \quad \text{i.e. } E_n = -\frac{E_0}{2n^2} = -\frac{1}{2n^2} \frac{m}{\hbar} \left(\frac{C}{\hbar} \right)^2. \quad (3.201)$$

i.e. agree with Bohr's formula (1.12). Because of this reason, n is usually called the *principal quantum number*, and the above relation between it and the "more subordinate" orbital quantum number l is rewritten as

$$l \leq n - 1. \quad (3.202)$$

Together with the inequality (162), this gives us the following, very important hierarchy of the three quantum numbers involved in the Bohr atom problem:

$$1 \leq n \leq \infty \Rightarrow 0 \leq l \leq n - 1 \Rightarrow -l \leq m \leq +l. \quad (3.203)$$

Bohr
atom:
quantum
numbers

Taking into account the $(2l+1)$ -degeneracy related to the magnetic number m , and using the well-known formula for the arithmetic progression,⁸¹ we see that the n^{th} energy level (201) has the following *orbital degeneracy*:

$$g = \sum_{l=0}^{n-1} (2l+1) \equiv 2 \sum_{l=0}^{n-1} l + \sum_{l=0}^{n-1} 1 = 2 \frac{n(n-1)}{2} + n \equiv n^2. \quad (3.204)$$

Due to its importance for atoms, let us spell out the hierarchy (203) of a few lowest-energy states, using the traditional state notation, in which the value of n is followed by the letter that denotes the value of l :

$$n = 1: \quad l = 0 \quad (\text{one } 1s \text{ state}) \quad m = 0. \quad (3.205)$$

$$\begin{aligned} n = 2: \quad l = 0 &\quad (\text{one } 2s \text{ state}) & m = 0, \\ &\quad l = 1 & (\text{three } 2p \text{ states}) & m = 0, \pm 1. \end{aligned} \quad (3.206)$$

$$\begin{aligned} n = 3: \quad l = 0 &\quad (\text{one } 3s \text{ state}) & m = 0, \\ &\quad l = 1 & (\text{three } 3p \text{ states}) & m = 0, \pm 1, \\ &\quad l = 2 & (\text{five } 3d \text{ states}) & m = 0, \pm 1, \pm 2. \end{aligned} \quad (3.207)$$

Figure 22 shows plots of the radial functions (195) of the listed states. The most important of them is of course the ground ($1s$) state with $n = 1$ and hence $E = -E_0/2$. According to Eqs. (195) and (198), its radial function is just a simple decaying exponent

$$\mathcal{R}_{1,0}(r) = \frac{2}{r_0^{3/2}} e^{-r/r_0}, \quad (3.208)$$

Ground
state:
radial
function

⁸¹ See, e.g., MA Eq. (2.5a).

while its angular distribution is uniform – see Eq. (174). The gap between the ground energy and the energy $E = -E_0/8$ of the lowest excited states (with $n = 2$) in a hydrogen atom (in which $E_0 = E_H \approx 27.2$ eV) is as large as ~ 10 eV, so that their thermal excitation requires temperatures as high as $\sim 10^5$ K, and the overwhelming part of all hydrogen atoms in the visible Universe are in their ground state. Since the atomic hydrogen makes up about 75% of the “normal” matter,⁸² we are very fortunate that such simple formulas as Eqs. (174) and (208) describe the atomic states prevalent in Mother Nature!

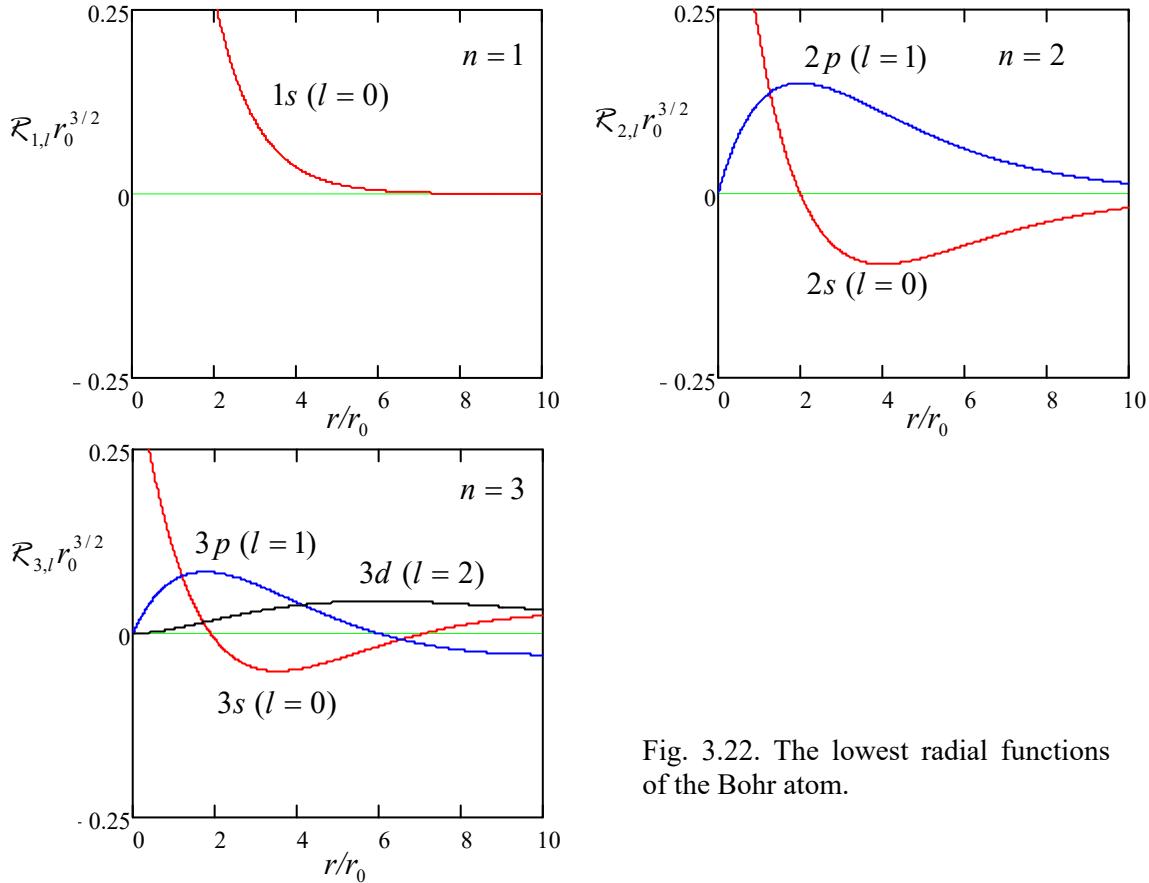

Fig. 3.22. The lowest radial functions of the Bohr atom.

According to Eqs. (195) and (198), the radial functions of the lowest excited states, $2s$ (with $n = 2$ and $l = 0$), and $2p$ (with $n = 2$ and $l = 1$) are also not too complicated:

$$\mathcal{R}_{2,0}(r) = \frac{1}{(2r_0)^{3/2}} \left(2 - \frac{r}{r_0} \right) e^{-r/2r_0}, \quad \mathcal{R}_{2,1}(r) = \frac{1}{(2r_0)^{3/2}} \frac{r}{3^{1/2} r_0} e^{-r/2r_0}, \quad (3.209)$$

with the former of these states ($2s$) having a uniform angular distribution, and the three latter ($2p$) states, with different $m = 0, \pm 1$, having simple angular distributions, which differ only by their spatial orientation – see Eq. (175) and the second row of Fig. 20. The most important trend here, clearly visible from the comparison of the two top panels of Fig. 22 as well, is a larger radius of the decay exponent in

⁸² Excluding the so-far hypothetical *dark matter* and *dark energy*.

the radial functions ($2r_0$ for $n = 2$ instead of r_0 for $n = 1$), and hence a larger radial extension of the states. This trend is confirmed by the following general formula:⁸³

$$\langle r \rangle_{n,l} = \frac{r_0}{2} [3n^2 - l(l+1)]. \quad (3.210)$$

The second important trend is that at a fixed n , the orbital quantum number l determines how fast does the wavefunction change with r near the origin, and how much it oscillates in the radial direction at larger values of r . For example, the $2s$ eigenfunction $\mathcal{R}_{2,0}(r)$ is different from zero at $r = 0$, and “makes one wiggle” (has one root) in the radial direction, while the eigenfunctions $2p$ equal zero at $r = 0$ but do not cross the horizontal axis after that. Instead, those wavefunctions oscillate as the functions of an angle – see the second row of Fig. 20. The same trend is clearly visible for $n = 3$ (see the bottom panel of Fig. 22), and continues for the higher values of n .

The states with $l = l_{\max} \equiv n - 1$ may be viewed as crude analogs of the circular motion of a particle in a plane whose orientation defines the quantum number m . On the other hand, the best classical image of the s -state ($l = 0$) is a purely radial, spherically-symmetric motion of the particle to and from the attracting center. (The latter image is especially imperfect because the motion needs to happen simultaneously in all radial directions.) The classical language becomes reasonable only for the highly degenerate *Rydberg states*, with $n \gg 1$, whose linear superpositions may be used to compose wave packets closely following the classical (circular or elliptic) trajectories of the particle – just as was discussed in Sec. 2.2 for the free 1D motion.

Besides Eq. (210), mathematics gives us several other simple relations for the radial functions $\mathcal{R}_{n,l}$ (and, since the spherical harmonics are normalized to 1, for the eigenfunctions as the whole), including those that we will use later in the course:⁸⁴

$$\left\langle \frac{1}{r} \right\rangle_{n,l} = \frac{1}{n^2 r_0}, \quad \left\langle \frac{1}{r^2} \right\rangle_{n,l} = \frac{1}{n^3 (l + \frac{1}{2}) r_0^2}, \quad \left\langle \frac{1}{r^3} \right\rangle_{n,l} = \frac{1}{n^3 l (l + \frac{1}{2}) (l + 1) r_0^3}. \quad (3.211)$$

In particular, the first of these formulas means that for *any* eigenfunction $\psi_{n,l,m}$, with all its complicated radial and angular dependencies, there is a simple relation between the potential and full energies:

$$\langle U \rangle_{n,l} = -C \left\langle \frac{1}{r} \right\rangle_{n,l} = -\frac{C}{n^2 r_0} = -\frac{E_0}{n^2} = 2E_n, \quad (3.212)$$

so that the average kinetic energy of the particle, $\langle T \rangle_{n,l} = E_n - \langle U \rangle_{n,l}$, is equal to $E_n - 2E_n = |E_n| > 0$.

As in the several previous cases we have met, simple results (201), (210)-(212) are in sharp contrast with the rather complicated expressions for the corresponding eigenfunctions. Historically this contrast gave an additional motivation for the development of more general approaches to quantum mechanics, that would replace, or at least complement our brute-force (wave-mechanics) analysis. A discussion of such an approach will be the main topic of the next chapter.

⁸³ Note that even at the largest value of l , equal to $(n - 1)$, the second term $l(l + 1)$ in Eq. (210) is equal to $(n^2 - n)$, and hence cannot over-compensate the first term $3n^2$.

⁸⁴ The first of these relations may be readily proved using the Heller-Feynman theorem (see Chapter 1); this proof will be offered for the reader’s exercise after a more general form of this theorem has been proved in Chapter 6.

Rather strikingly, the above classification of the quantum numbers, with minor steals from the later chapters of this course, allows a semi-quantitative explanation of the whole system of chemical elements. The “only” two additions we need are the following facts:

(i) due to their unavoidable interaction with relatively low-temperature environments, atoms tend to relax into their lowest-energy state, and

(ii) due to the Pauli principle (valid for electrons as the Fermi particles), each *orbital eigenstate* discussed above may be occupied by two electrons with opposite spins.

Of course, atomic electrons do interact, so that their quantitative description requires quantum mechanics of multiparticle systems, which is rather complex. (Its main concepts will be discussed in Chapter 8.) However, the lion’s share of this interaction is reduced to simple electrostatic *screening*, i.e. a partial compensation of the electric charge of the atomic nucleus, as felt by a particular electron, by other electrons of the atom. This screening changes quantitative results (such as the energy scale E_0) dramatically; however, the quantum number hierarchy, and hence their classification, is not affected.

The hierarchy of atoms is most often represented as the famous *periodic table of chemical elements*,⁸⁵ whose simple version is shown in Fig. 23. (The table in Fig. 24 presents a sequential list of the elements and their electron configurations, following the convention already used in Eqs. (205)-(207), with the additional upper index showing the number of electrons with the indicated values of quantum numbers n and l .) The number in each table’s cell, and in the first column of the list, is the so-called *atomic number Z*, which physically is the number of protons in the particular atomic nucleus, and hence the number of electrons in an electrically-neutral atom.

Fig. 3. 23. The periodic table of elements, showing their atomic numbers and chemical symbols, as well as their color-coded basic physical/chemical properties at the so-called *ambient* (meaning usual laboratory) conditions.

⁸⁵ Also called the *Mendeleev table*, after Dmitri Ivanovich Mendeleev who put forward the concept of the quasi-periodicity of chemical element properties as functions of Z phenomenologically in 1869. (The explanation of this periodicity had to wait for 60 more years until the advent of quantum mechanics in the late 1920s.)

Fig. 3.24. Atomic electron configurations. The upper index shows the number of electrons in the states with the indicated quantum numbers n (the first digit) and l (letter-coded as was discussed above).

The simplest atom, with $Z = 1$, is hydrogen (chemical symbol H) – the only atom for that the theory discussed above is quantitatively correct.⁸⁶ According to Eq. (191), the $1s$ ground state of its only electron corresponds to the quantum number values $n = 1$, $l = 0$, and $m = 0$ – see Eq. (205). In most versions of the periodic table, the cell of H is placed in the top left corner.

In the next atom, helium (symbol He, $Z = 2$), the same orbital quantum state ($1s$) is filled with two electrons. As will be discussed in detail in Chapter 8, electrons of the same atom are actually *indistinguishable*, so that their quantum states are not independent and may be *entangled*. These factors are important for several properties of helium atoms (and heavier elements as well); however, a bit counter-intuitively, for the atom classification purposes, they are not crucial, and we may pretend that two electrons of a helium atom just have “opposite spins”. Due to the twice higher electric charge of the nucleus of the helium atom, i.e. the twice higher value of the constant C in Eq. (190), resulting in a 4-fold increase of the constant E_0 given by Eq. (192), the binding energy of each electron is crudely 4 times higher than that of the hydrogen atom – though the electron interaction decreases it by about 25% – see Sec. 8.2. This is why taking one electron away (i.e. the *positive ionization* of a helium atom) requires relatively high energy, ~ 23.4 eV, which is not available in the usual chemical reactions. On the other hand, a neutral helium atom cannot bind one more electron (i.e. form a *negative ion*) either. As a result, the helium, and all other elements with fully completed electron *shells* (the term meaning the sets of states with eigenenergies well separated from higher energy levels) is a chemically inert *noble gas*, thus starting the whole right-most column of the periodic table, allocated for such elements.

The situation changes rather dramatically as we move to the next element, lithium (Li), with $Z = 3$ electrons. Two of them are still accommodated by the inner shell with $n = 1$ (listed in Fig. 24 as the *helium shell* [He]), but the third one has to reside in the next shell with $n = 2$, $l = 0$, and $m = 0$, i.e. in the $2s$ state. According to Eq. (201), the binding energy of this electron is much lower, especially if we take into account that according to Eqs. (210)-(211), the $1s$ electrons of the [He] shell are much closer to the nucleus and almost completely compensate two-thirds of its electric charge $+3e$. As a result, the $2s$ -state electron is approximately, but reasonably well described by Eq. (201) with $Z = 1$ and $n = 2$, giving binding energy close to just 3.4 eV (experimentally, ~ 5.39 eV), so that a lithium atom can give out that electron rather easily – to either an atom/ion of another element to form a chemical compound, or to the common conduction band of the solid-state lithium; as a result, at the ambient conditions, it is a typical *alkali metal*. The similarity of chemical properties of lithium and hydrogen, with the *chemical valence* of one,⁸⁷ places Li as the starting element of the second *period* (row), with the first period limited to only H and He – see Fig. 23.

In the next element, beryllium (symbol Be, $Z = 4$), the $2s$ state ($n = 2$, $l = 0$, $m = 0$) houses one more electron, with the “opposite spin”. Due to the higher electric charge of the nucleus, $Q = +4e$, with only half of it compensated by $1s$ electrons of the [He] shell, the binding energy of the $2s$ electrons is somewhat higher than that in lithium, so that the ionization energy increases to ~ 9.32 eV. As a result, beryllium is also chemically active with the valence of two, but not as active as lithium, and is also is metallic in its solid-state phase, but with a lower electric conductivity than lithium.

⁸⁶ Besides very small *fine-structure* and *hyperfine-splitting* corrections – to be discussed, respectively, in Chapters 6 and 8.

⁸⁷ The chemical valence (or “valency”) is a not very precise term describing the number of atom’s electrons involved in chemical reactions. For the same atom, especially with a large number of electrons in its outer, unfilled shell, this number may depend on the chemical compound formed. (For example, the valence of iron is two in the *ferrous oxide*, FeO, and three in the *ferric oxide*, Fe₂O₃.)

Moving in this way along the second row of the periodic table (from $Z = 3$ to $Z = 10$), we see a gradual filling of the rest of the total $2n^2 = 2 \times 2^2 = 8$ different electron states of the $n = 2$ shell (see Eq. (204), with the additional spin degeneracy factor of 2), including two $2s$ states with $m = 0$, and six $2p$ states with $m = 0, \pm 1$,⁸⁸ with a gradually growing ionization potential (up to ~ 21.6 eV in Ne with $Z = 10$), i.e. a growing reluctance to conduct electricity or form *positive* ions. However, the last elements of the row, such as oxygen (O, with $Z = 8$) and especially fluorine (F, with $Z = 9$) can readily pick up extra electrons to fill up their $2p$ states, i.e. form *negative* ions. As a result, these elements are chemically active, with a double valence for oxygen and a single valence for fluorine. However, the final element of this row, neon, has its $n = 2$ shell completely full, and cannot form a stable negative ion. This is why it is a noble gas, like helium. Traditionally, in the periodic table, such elements are placed right under helium (Fig. 23), to emphasize the similarity of their chemical properties. But this necessitates making an at least 6-cell gap in the 1st row. (Actually, the gap is often made larger, to accommodate the next rows – keep reading.)

Period 3, i.e. the 3rd row of the table, starts exactly like period 2, with sodium (Na, with $Z = 11$), also a chemically active alkali metal whose atom features 10 electrons filling the shells with $n = 1$ and $n = 2$ (in Fig. 24, collectively called the neon shell [Ne]), plus one electron in the $3s$ state ($n = 3, l = 0, m = 0$), which may be again reasonably well described by the hydrogen atom theory – see, e.g., the red curve on the last panel of Fig. 22. Continuing along this row, we could naively expect that, according to Eq. (204), and with the account of double spin degeneracy, this period of the table should have $2n^2 = 2 \times 3^2 = 18$ elements, with a gradual, sequential filling of two $3s$ states, then six $3p$ states, and then ten $3d$ states. However, here we run into a big surprise: after argon (Ar, with $Z = 18$), a relatively inert element with the ionization energy of ~ 15.7 eV due to the fully filled $3s$ and $3p$ shells, the next element, potassium (K, with $Z = 19$) is an alkali metal again!

The reason for that is the difference of the actual electron energies from those of the hydrogen atom, which is due mostly to inter-electron interactions, and gradually accumulates with the growth of Z . It may be semi-quantitatively understood from the results of Sec. 6. In hydrogen-like atoms/ions, the electron state energies do not depend on the quantum number l (as well as m) – see Eq. (201). However, the orbital quantum number does affect the wavefunction of an electron. As Fig. 22 shows, the larger l the less the probability for an electron to be close to the nucleus, where its positive charge is less compensated by other electrons. As a result of this effect (and also the relativistic corrections to be discussed in Sec. 6.3), the electron's energy grows with l . Actually, this effect is visible already in period 2 of the table: it manifests itself in the filling order – the p states after the s states. However, for potassium (K, with $Z = 19$) and calcium (Ca, with $Z = 20$), the energies of the $3d$ states become so high that the energies of the two $4s$ states are lower, and the latter states are filled first. As described by Eq. (210), and also by the first of Eqs. (211), the effect of the principal number n on the distance from the nucleus is much stronger than that of l , so that the $4s$ wavefunctions of K and Ca are relatively far from the nucleus, and determine the chemical valence (equal to 1 and 2, correspondingly) of these elements. The next atoms, from Sc ($Z = 21$) to Zn ($Z = 30$), with the gradually filled “internal” $3d$ states, are the so-called *transition metals* whose (comparable) ionization energies and chemical properties are determined by the $4s$ electrons.

This fact is the origin of the difference between various forms of the “periodic” table. In its most popular option, shown in Fig. 23, K is used to start the next period 4, and then a new period is started

⁸⁸ The specific order of filling of the states within each shell follows the so-called *Hund rules* – see Sec. 8.3.

each time and only when the first electron with the next principal quantum number (n) appears.⁸⁹ This topology of the table provides a very clear match of the chemical properties of the first element of each period (an alkali metal), as well as its last element (a noble gas). It also automatically means making gaps in all previous rows. Usually, this gap is made between the atoms with completely filled s states and with those with the first electron in a p state, because here the properties of the elements make a somewhat larger step. (For example, the step from Be to B makes the material an insulator, but the step from Mg to Al makes a smaller difference.) As a result, the elements of the same column have only *approximately* similar chemical valences and physical properties.

In order to accommodate the lower, longer rows, such representation is inconvenient, because the whole table would be too broad. This is why the so-called *rare earth* elements, including *lanthanides* (with Z from 57 to 70, of the 6th row, with a gradual filling of the 4 f and 5 d states) and *actinides* (Z from 89 to 103, of the 7th row, with a gradual filling of the 5 f and 6 d states), are usually represented as outlet rows – see Fig. 23. This is quite acceptable for basic chemistry, because the chemical properties of the elements within each such group are rather close.

To summarize my very short review of this extremely important topic,⁹⁰ the “periodic table of elements” is not periodic in the strict sense of the word. Nevertheless, it has had an enormous historic significance for chemistry, as well as atomic and solid-state physics, and is still very convenient for many purposes. For our course, the most important aspect of its discussion is the surprising possibility to describe, at least for classification purposes, such a complex multi-electron system as an atom as a set of quasi-independent electrons in certain quantum states indexed with the same quantum numbers n , l , and m as those of the hydrogen atom. This fact enables the use of various *perturbation theories*, which give a more quantitative description of atomic properties. Some of these techniques will be reviewed in Chapters 6 and 8.

3.8. Spherically-symmetric scatterers

The machinery of the Legendre polynomials and the spherical Bessel functions, discussed in Sec. 6, may also be used for analysis of particle scattering by spherically-symmetric potentials (155) beyond the Born approximation (Sec. 3), provided that such a potential $U(r)$ is also localized, i.e. reduces sufficiently fast at $r \rightarrow \infty$. (The quantification of this condition is left for the reader’s exercise.)

Indeed, directing the z -axis along the propagation of the incident plane de Broglie wave ψ_i , and taking its origin in the center of the scatterer, we may expect the scattered wave ψ_s to be axially symmetric, so that its expansion in the series over the spherical harmonics includes only the terms with $m = 0$. Hence, the solution (64) of the stationary Schrödinger equation (63) in this case may be represented as⁹¹

$$\psi = \psi_i + \psi_s = a_i \left[e^{ikz} + \sum_{l=0}^{\infty} R_l(r) P_l(\cos \theta) \right], \quad (3.213)$$

⁸⁹ Another popular option is to return to the first column as soon an atom has one electron in the s state (like it is in Cu, Ag, and Au, in addition to the alkali metals).

⁹⁰ For a bit more detailed (but still succinct) discussion of the valence and other chemical aspects of atomic structure, I can recommend Chapter 5 of the very clear text by L. Pauling, *General Chemistry*, Dover, 1988.

⁹¹ The particular terms in this sum are frequently called *partial waves*.

where $k \equiv (2mE)^{1/2}/\hbar$ is defined by the energy E of the incident particle, while the radial functions $\mathcal{R}_l(r)$ have to satisfy Eq. (181), and be finite at $r \rightarrow 0$. At large distances $r \gg R$, where R is the effective radius of the scatterer, the potential $U(r)$ is negligible, and Eq. (181) is reduced to Eq. (183). In contrast to its analysis in Sec. 6, we should look for its solution using a linear superposition of the spherical Bessel functions of both kinds:

$$\mathcal{R}_l(r) = A_l j_l(kr) + B_l y_l(kr), \quad \text{at } r \gg R, \quad (3.214)$$

because Eq. (183) is now invalid at $r \rightarrow 0$, and our former argument for dropping the functions $y_l(kr)$ is no more valid. In Eq. (214), A_l and B_l are some complex coefficients, determined by the scattering potential $U(r)$, i.e. by the solution of Eq. (181) at $r \sim R$.

As the explicit expressions (186) show, the spherical Bessel functions $j_l(\xi)$ and $y_l(\xi)$ represent *standing* de Broglie waves, with equal real amplitudes, so that their simple linear combinations (called the *spherical Hankel functions of the first and second kind*),

$$h_l^{(1)}(\xi) \equiv j_l(\xi) + iy_l(\xi), \quad \text{and} \quad h_l^{(2)}(\xi) \equiv j_l(\xi) - iy_l(\xi), \quad (3.215)$$

represent *traveling* spherical waves propagating, respectively, from the origin (i.e. from the center of the scatterer), and toward the origin. In particular, at $\xi \gg 1, l$, i.e. at large distances $r \gg 1/k, l/k$,⁹²

$$h_l^{(1)}(kr) \rightarrow \frac{(-i)^{l+1}}{kr} e^{ikr} \quad h_l^{(2)}(kr) \rightarrow \frac{i^{l+1}}{kr} e^{-ikr}. \quad (3.216)$$

But using the same physical argument as at the beginning of Sec. 1, we may argue that in the case of a localized scatterer, there should be no latter waves at $r \gg R$; hence, we have to require the amplitude of the term proportional to $h_l^{(2)}$ to be zero. With the relations reciprocal to Eqs. (215),

$$j_l(\xi) = \frac{1}{2} [h_l^{(1)}(\xi) + h_l^{(2)}(\xi)], \quad y_l(\xi) = \frac{1}{2i} [h_l^{(1)}(\xi) - h_l^{(2)}(\xi)], \quad (3.217)$$

which enable us to rewrite Eq. (214) as

$$\begin{aligned} \mathcal{R}_l(r) &= \frac{A_l}{2} [h_l^{(1)}(\xi) + h_l^{(2)}(\xi)] + \frac{B_l}{2i} [h_l^{(1)}(\xi) - h_l^{(2)}(\xi)] \\ &\equiv \left(\frac{A_l - iB_l}{2} \right) h_l^{(1)}(\xi) + \left(\frac{A_l + iB_l}{2} \right) h_l^{(2)}(\xi), \end{aligned} \quad (3.218)$$

this means that the combination $(A_l + iB_l)$ has to be equal zero, so that $B_l = iA_l$. Hence we have just one unknown coefficient (say, A_l) for each l ,⁹³ and may rewrite Eq. (218) in an even simpler form:

$$\mathcal{R}_l(r) = A_l [j_l(kr) + iy_l(kr)] \equiv A_l h_l^{(1)}(kr), \quad \text{at } r \gg R, \quad (3.219)$$

Spherically-symmetric scatterer: A_l

⁹² For arbitrary l , this result may be confirmed using Eqs. (185) and the asymptotic formulas for the “usual” Bessel functions – see, e.g., EM Eqs. (2.135) and (2.152), valid for an arbitrary (not necessarily integer) index n .

⁹³ Moreover, using the conservation of the orbital momentum, to be discussed in Sec. 5.6, it is possible to show that this *complex* coefficient may be further reduced to just one *real* parameter, usually recast as the *partial phase shift* δ_l between the l^{th} spherical harmonics of the incident and scattered waves. However, I will not use this notion, because practical calculations are more physically transparent (and not more complex) without it.

and use Eqs. (213) and (216) to write the following expression for the scattered wave at large distances:

$$\psi_s \approx \frac{a_i}{kr} e^{ikr} \sum_{l=0}^{\infty} (-i)^{l+1} A_l P_l(\cos \theta), \quad \text{at } r \gg R, \frac{1}{k}, \frac{l}{k}. \quad (3.220)$$

Comparing this expression with the general Eq. (81), we see that for a spherically-symmetric, localized scatterer,

$$f = \frac{1}{k} \sum_{l=0}^{\infty} (-i)^{l+1} A_l P_l(\cos \theta), \quad (3.221)$$

so that the differential cross-section (84) is

$$\frac{d\sigma}{d\Omega} = \frac{1}{k^2} \left| \sum_{l=0}^{\infty} (-i)^{l+1} A_l P_l(\cos \theta) \right|^2 \equiv \frac{1}{k^2} \sum_{l,l'=0}^{\infty} i^{l'-l} A_l A_{l'}^* P_l(\cos \theta) P_{l'}(\cos \theta). \quad (3.222)$$

The last expression is more convenient for the calculation of the total cross-section (59):

$$\sigma = \oint \frac{d\sigma}{d\Omega} d\Omega = 2\pi \int_{-1}^{+1} d\Omega d(\cos \theta) = \frac{2\pi}{k^2} \sum_{l,l'=0}^{\infty} i^{l'-l} A_l A_{l'}^* \int_{-1}^{+1} P_l(\xi) P_{l'}(\xi) d\xi, \quad (3.223)$$

where $\xi \equiv \cos \theta$, because this result may be much simplified by using Eq. (167):⁹⁴

$$\sigma = \sum_{l=0}^{\infty} \sigma_l, \quad \text{with } \sigma_l = \frac{4\pi}{k^2} \frac{|A_l|^2}{2l+1}. \quad (3.224)$$

Hence the solution of the scattering problem is reduced to the calculation of the partial wave amplitudes A_l defined by Eq. (219) – and for the total cross-section, merely of their magnitudes. This task is much facilitated by using the following *Rayleigh formula* for the expansion of the incident plane wave's exponent into a series over the Legendre polynomials,⁹⁵

$$e^{ikz} \equiv e^{ikr \cos \theta} = \sum_{l=0}^{\infty} i^l (2l+1) j_l(kr) P_l(\cos \theta). \quad (3.225)$$

As the simplest example, let us calculate scattering by a completely opaque and “hard” (meaning sharp-boundary) sphere, which may be described by the following potential:

$$U(r) = \begin{cases} +\infty, & \text{for } r < R, \\ 0, & \text{for } R < r. \end{cases} \quad (3.226)$$

In this case, the total wavefunction has to vanish at $r \leq R$, and hence for the external problem ($r \geq R$) the sphere enforces the boundary condition $\psi = \psi_0 + \psi_s = 0$ for all values of θ , at $r = R$. With Eqs. (213), (220) and (225), this condition becomes

$$a_i \sum_{l=0}^{\infty} [\mathcal{R}_l(R) + i^l (2l+1) j_l(kR)] P_l(\cos \theta) = 0. \quad (3.227)$$

⁹⁴ Physically, this reduction of the double sum to a single one means that due to the orthogonality of the spherical harmonics, the total scattering probability flows due to each partial wave just add up.

⁹⁵ It may be proved using the Rodrigues formula (165) and integration by parts – the task left for the reader's exercise.

Due to the orthogonality of the Legendre polynomials, this condition may be satisfied for all angles θ only if all the coefficients before all $P_l(\cos\theta)$ vanish, i.e. if

$$\mathcal{R}_l(R) = -i^l (2l+1) j_l(kR). \quad (3.228)$$

On the other hand, for $r > R$, $U(r) = 0$, so that Eq. (183) is valid, and its outward-wave solution (219) has to be valid even at $r \rightarrow R$, giving

$$\mathcal{R}_l(R) = A_l [j_l(kR) + iy_l(kR)]. \quad (3.229)$$

Requiring the two last expressions to give the same result, we get

$$A_l = -i^l (2l+1) \frac{j_l(kR)}{j_l(kR) + iy_l(kR)}, \quad (3.230)$$

so that Eqs. (222) and (224) yield:

$$\frac{d\sigma}{d\Omega} = \frac{1}{k^2} \left| \sum_{l=0}^{\infty} (2l+1) \frac{j_l(kR)}{j_l(kR) + iy_l(kR)} P_l(\cos\theta) \right|^2, \quad \sigma_l = \frac{4\pi(2l+1)}{k^2} \frac{j_l^2(kR)}{j_l^2(kR) + y_l^2(kR)}. \quad (3.231)$$

As Fig. 25a shows, the first of these results describes an angular structure of the scattered de Broglie wave, which is qualitatively similar to that given by the Born approximation – cf. Eq. (98) and Fig. 10.

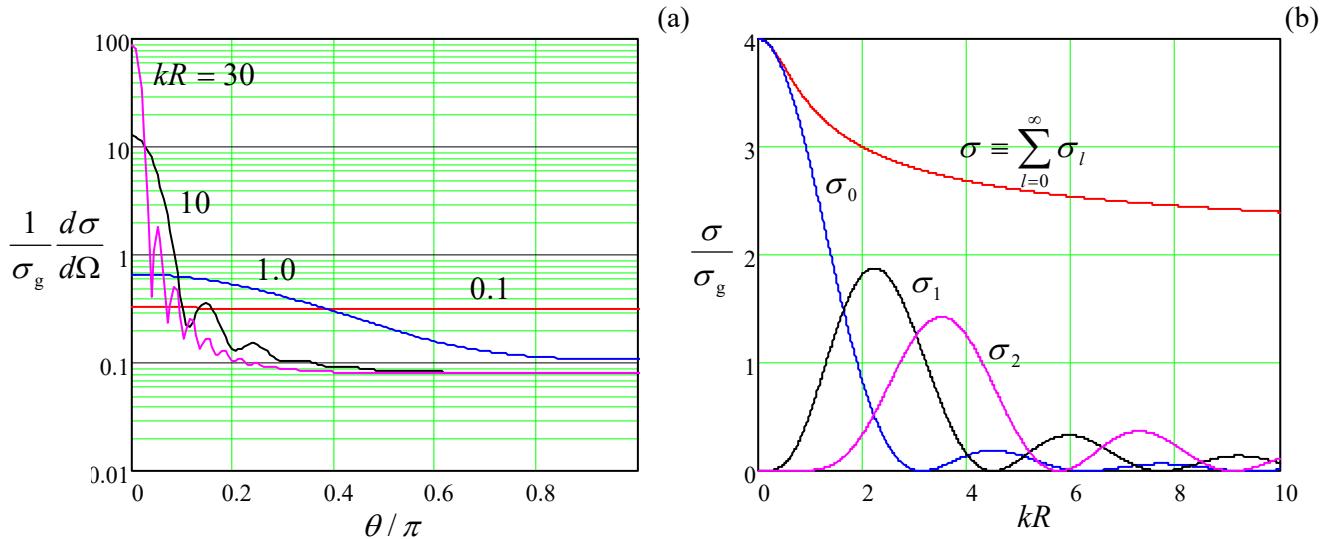

Fig. 3.25. Particle scattering by an opaque, hard sphere: (a) the differential cross-section normalized to the geometric cross-section $\sigma_g \equiv \pi R^2$ of the sphere, as a function of the scattering angle θ , and (b) the (similarly normalized) total cross-section and its lowest spherical components, as functions of the dimensionless product $kR \propto E^{1/2}$.

Namely, at low particle's energies ($kR \ll 1$), the scattering is essentially isotropic, while in the opposite, high-energy limit $kR \gg 1$, it is mostly confined to small angles $\theta \sim \pi/kR \ll 1$, and exhibits numerous local destructive-interference minima at angles $\theta_n \sim \pi n/kR$. However, in our current (exact!) theory, these minima are always finite, because the theory describes effective bending of the de Broglie waves along the back side of the sphere, which smears the interference pattern.

The same bending is also responsible for a rather counter-intuitive fact, described by the second of Eqs. (231) and clearly visible in Fig. 25b: even at $kR \rightarrow \infty$, the total cross-section σ of scattering tends to $2\sigma_g \equiv 2\pi R^2$, rather than to σ_g as in the purely-classical scattering theory. First discovered for optical wave scattering, this fact (common for all large non-absorbing scatterers) is sometimes interpreted as a manifestation of the so-called *wave extinction paradox*.

The fact that at $kR \ll 1$, the cross-section is also larger than σ_g , approaching $4\sigma_g$ at $kR \rightarrow 0$, is much less surprising, because in this limit the de Broglie wavelength $\lambda = 2\pi/k$ is much longer than the sphere's radius R , so that the wave's propagation is affected by the whole sphere.

The above analysis may be readily generalized to the case a step-like (*sharp* but finite) potential (97) – the problem left for the reader's exercise. On the other hand, for a finite and *smooth* scattering potential $U(r)$, plugging Eq. (225) into Eq. (213) and the result into Eq. (66), requiring the coefficients before each angular function $P_l(\cos\theta)$ to be balanced, and canceling the common coefficient a_0 , we get the following inhomogeneous generalization of Eq. (181) for the radial functions defined by Eq. (213):

$$[E - U(r)]\mathcal{R}_l + \frac{\hbar^2}{2mr^2} \left[\frac{d}{dr} \left(r^2 \frac{d}{dr} \right) - l(l+1) \right] \mathcal{R}_l(r) = U(r) i^l (2l+1) j_l(kr). \quad (3.232)$$

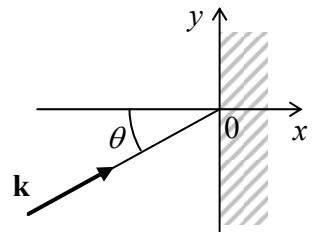

This differential equation has to be solved in the whole scatterer volume (i.e. for all $r \sim R$) with the boundary conditions for the functions $\mathcal{R}_l(r)$ to be finite at $r \rightarrow 0$, and to tend to the asymptotic form (219) at $r \gg R$. The last requirement enables the evaluation of the coefficients A_l that are needed for spelling out Eqs. (222) and (224). Unfortunately, due to the lack of time, I have to refer the reader interested in such cases to special literature.⁹⁶

3.9. Exercise Problems

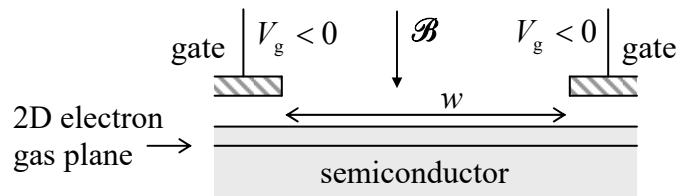

3.1. A particle of energy E is incident (in the figure on the right, within the plane of the drawing) on a sharp potential step:

$$U(\mathbf{r}) = \begin{cases} 0, & \text{for } x < 0, \\ U_0, & \text{for } 0 < x. \end{cases}$$

Calculate the particle reflection probability \mathcal{R} as a function of the incidence angle θ ; sketch and discuss this function for various magnitudes and signs of U_0 .

3.2.* Analyze how are the Landau levels (50) modified by an additional uniform electric field \mathcal{E} directed along the plane of the particle's motion. Contemplate the physical meaning of your result and its implications for the quantum Hall effect in a gate-defined Hall bar. (The area

⁹⁶ See, e.g., J. Taylor, *Scattering Theory*, Dover, 2006.

$l \times w$ of such a bar [see Fig. 6] is defined by metallic gate electrodes parallel to the 2D electron gas plane – see the figure on the right. The negative voltage V_g , applied to the gates, squeezes the 2D gas from the area under them into the complementary, Hall-bar part of the plane.)

3.3. Analyze how are the Landau levels (50) modified if a 2D particle is confined in an additional 1D potential well $U(x) = m\omega_0^2 x^2/2$.

3.4. Find the stationary states of a spinless, charged 3D particle moving in “crossed” (mutually perpendicular), uniform electric and magnetic fields, with $\mathcal{E} \ll c\mathcal{B}$. For such states, calculate the expectation values of the particle’s velocity in the direction perpendicular to both fields, and compare the result with the solution of the corresponding classical problem.

Hint: You may like to generalize Landau’s solution for 2D particles, discussed in Sec. 2.

3.5. Use the Born approximation to calculate the angular dependence and the total cross-section of scattering of an incident plane wave propagating along the x -axis, by the following pair of similar point inhomogeneities:

$$U(\mathbf{r}) = \mathcal{W} \left[\delta\left(\mathbf{r} - \mathbf{n}_z \frac{\mathbf{a}}{2}\right) + \delta\left(\mathbf{r} + \mathbf{n}_z \frac{\mathbf{a}}{2}\right) \right].$$

Analyze the results in detail. Derive the condition of the Born approximation’s validity for such delta-functional scatterers.

3.6. Complete the analysis of the Born scattering by a uniform spherical potential (97), started in Sec. 3, by calculation of its total cross-section. Analyze the result in the limits $kR \ll 1$ and $kR \gg 1$.

3.7. Use the Born approximation to calculate the differential cross-section of particle scattering by a very thin spherical shell, whose potential may be approximated as

$$U(r) = \mathcal{W} \delta(r - R).$$

Analyze the results in the limits $kR \ll 1$ and $kR \gg 1$, and compare them with those for a uniform sphere considered in Sec. 3.

3.8. Use the Born approximation to calculate the differential and total cross-sections of electron scattering by a screened Coulomb field of a point charge Ze , with the electrostatic potential

$$\phi(\mathbf{r}) = \frac{Ze}{4\pi\epsilon_0 r} e^{-\lambda r},$$

neglecting spin interaction effects, and analyze the result’s dependence on the screening parameter λ . Compare the results with those given by the classical (“Rutherford”) formula⁹⁷ for the unscreened Coulomb potential ($\lambda \rightarrow 0$), and formulate the condition of Born approximation’s validity in this limit.

3.9. A quantum particle with electric charge Q is scattered by a localized distributed charge with a spherically-symmetric density $\rho(r)$, and zero total charge. Use the Born approximation to calculate the

⁹⁷ See, e.g., CM Sec. 3.5, in particular Eq. (3.73).

differential cross-section of the *forward scattering* (with the scattering angle $\theta = 0$), and evaluate it for the scattering of electrons by a hydrogen atom in its ground state.

3.10. Reformulate the Born approximation for the 1D case. Use the result to find the scattering and transfer matrices of a “rectangular” (flat-top) scatterer

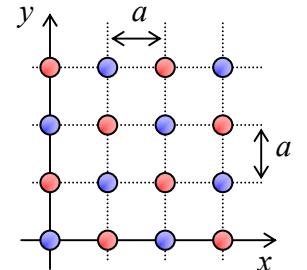

$$U(x) = \begin{cases} U_0, & \text{for } |x| < d/2, \\ 0, & \text{otherwise.} \end{cases}$$

Compare the results with those of the exact calculations carried out earlier in Chapter 2, and analyze how does their relationship change in the eikonal approximation.

3.11. In the tight-binding approximation, find the lowest stationary states of a particle placed into a system of three similar, weakly coupled potential wells located in the vertices of an equilateral triangle.

3.12. The figure on the right shows a fragment of a periodic 2D lattice, with the red and blue points showing the positions of different local potentials.

- (i) Find the reciprocal lattice and the 1st Brillouin zone of the system.
- (ii) Calculate the wave number k of the monochromatic de Broglie wave incident along axis x , at that the lattice creates the lowest-order diffraction peak within the $[x, y]$ plane, and the direction toward this peak.
- (iii) Semi-quantitatively, describe the evolution of the intensity of the peak when the local potentials, represented by the different points, become similar.

Hint: The *order of diffraction* on a multidimensional Bravais lattice is a somewhat ambiguous notion, usually associated with the sum of magnitudes of all integers l_j in Eq. (109), for the vector \mathbf{Q} that is equal to $\mathbf{q} \equiv \mathbf{k} - \mathbf{k}_i$.

3.13. For the 2D hexagonal lattice (Fig. 12b):

- (i) find the reciprocal lattice \mathbf{Q} and the 1st Brillouin zone;
- (ii) use the tight-binding approximation to calculate the dispersion relation $E(\mathbf{q})$ for a 2D particle moving through a potential profile with such periodicity, with an energy close to the energy of the axially-symmetric states quasi-localized at the potential minima;
- (iii) analyze and sketch (or plot) the resulting dispersion relation $E(\mathbf{q})$ inside the 1st Brillouin zone.

3.14. Complete the tight-binding-approximation calculation of the band structure of the honeycomb lattice, started at the end of Sec. 4. Analyze the results; in particular prove that the Dirac points \mathbf{q}_D are located in the corners of the 1st Brillouin zone, and express the velocity v_n participating in Eq. (122), in terms of the coupling energy δ_n . Show that the final results do not change if the quasi-localized wavefunctions are not axially-symmetric, but are proportional to $\exp\{im\varphi\}$ – as they are, with $m = 1$, for the $2p_z$ electrons of carbon atoms in graphene, that are responsible for its transport properties.

3.15. Examine basic properties of the so-called *Wannier functions* defined as

$$\phi_{\mathbf{R}}(\mathbf{r}) \equiv \text{const} \times \int_{\text{BZ}} \psi_{\mathbf{q}}(\mathbf{r}) e^{-i\mathbf{q}\cdot\mathbf{R}} d^3q,$$

where $\psi_{\mathbf{q}}(\mathbf{r})$ is the Bloch wavefunction (108), \mathbf{R} is any vector of the Bravais lattice, and the integration over the quasimomentum \mathbf{q} is extended over any (e.g., the first) Brillouin zone.

3.16. Evaluate the long-range interaction (the so-called *London dispersion force*) between two similar, electrically-neutral atoms or molecules, modeling each of them as an isotropic 3D harmonic oscillator with the electric dipole moment $\mathbf{d} = q\mathbf{s}$, where \mathbf{s} is the oscillator's displacement from its equilibrium position.

Hint: Represent the total Hamiltonian of the system as a sum of Hamiltonians of independent 1D harmonic oscillators, and calculate their total ground-state energy as a function of the distance between the dipoles.⁹⁸

3.17. Derive expressions for the stationary wavefunctions and the corresponding energies of a 2D particle of mass m , free to move inside a round disk of radius R . What is the degeneracy of each energy level? Calculate the five lowest energy levels with an accuracy better than 1%.

3.18. Calculate the ground-state energy of a 2D particle of mass m , localized in a very shallow flat-bottom potential well

$$U(\rho) = \begin{cases} -U_0, & \text{for } \rho < R, \\ 0, & \text{for } \rho > R, \end{cases} \quad \text{with } 0 < U_0 \ll \frac{\hbar^2}{mR^2}.$$

3.19. Estimate the energy E of the localized ground state of a particle of mass m , in an axially-symmetric 2D potential well of a finite radius R , with an arbitrary but very small potential $U(\rho)$. (Quantify this condition.)

3.20. Spell out the explicit form of the spherical harmonics $Y_4^0(\theta, \varphi)$ and $Y_4^4(\theta, \varphi)$.

3.21. Calculate $\langle x \rangle$ and $\langle x^2 \rangle$ in the ground states of the planar and spherical rotators of radius R . What can you say about $\langle p_x \rangle$ and $\langle p_x^2 \rangle$?

3.22. A spherical rotator, with $r \equiv (x^2 + y^2 + z^2)^{1/2} = R = \text{const}$, of mass m is in a state with the following wavefunction: $\psi = \text{const} \times (\frac{1}{3} + \sin^2 \theta)$. Calculate its energy.

3.23. According to the discussion at the beginning of Sec. 5, stationary wavefunctions of a 3D harmonic oscillator may be calculated as products of three 1D “Cartesian oscillators” – see, in particular Eq. (125), with $d = 3$. However, according to the discussion in Sec. 6, the wavefunctions of the type (200), proportional to the spherical harmonics Y_l^m , also describe stationary states of this spherically-symmetric system. Represent the wavefunctions (200) of:

⁹⁸ This explanation of the interaction between electrically-neutral atoms was put forward in 1930 by F. London, on the background of a prior (1928) work by C. Wang. Note that in some texts this interaction is (rather inappropriately) referred to as the “van der Waals force”, though it is only one, long-range component of the van der Waals model – see, e.g. SM Sec. 4.1.

- (i) the ground state of the oscillator, and
- (ii) each of its lowest excited states,

as linear combinations of products of 1D oscillator's stationary wavefunctions. Also, calculate the degeneracy of the n^{th} energy level of the oscillator.

3.24. Calculate the smallest depth U_0 of a spherical, flat-bottom potential well

$$U(\mathbf{r}) = \begin{cases} -U_0, & \text{for } r < R, \\ 0, & \text{for } R < r, \end{cases}$$

at that it has a bound (localized) stationary state. Does such a state exist for a very narrow and deep well $U(\mathbf{r}) = -w\delta(\mathbf{r})$, with a positive and finite w ?

3.25. A 3D particle of mass m is placed into a spherically-symmetric potential well with $-\infty < U(r) \leq U(\infty) = 0$. Relate its ground-state energy to that of a 1D particle of the same mass, moving in the following potential well:

$$U'(x) = \begin{cases} U(x), & \text{for } x \geq 0, \\ +\infty, & \text{for } x \leq 0. \end{cases}$$

In the light of the found relation, discuss the origin of the difference between the solutions of the previous problem and Problem 2.17.

3.26. Calculate the smallest value of the parameter U_0 , for that the following spherically-symmetric potential well,

$$U(r) = -U_0 e^{-r/R}, \quad \text{with } U_0, R > 0,$$

has a bound (localized) eigenstate.

Hint: You may like to introduce the following new variables: $f \equiv rR$ and $\xi \equiv Ce^{-r/2R}$, with an appropriate choice of the constant C .

3.27. A particle moving in a certain central potential $U(r)$ has a stationary state with the following wavefunction:

$$\psi = Cr^\alpha e^{-\beta r} \cos \theta,$$

where C , α , and $\beta > 0$ are constants. Calculate:

- (i) the probabilities of all possible values of the quantum numbers m and l , and
- (ii) the confining potential and the state's energy.

3.28. Use the variational method to estimate the ground-state energy of a particle of mass m , moving in the following spherically-symmetric potential:

$$U(\mathbf{r}) = ar^4.$$

3.29. Use the variational method, with the trial wavefunction $\psi_{\text{trial}} = A/(r + a)^b$, where both $a > 0$ and $b > 1$ are fitting parameters, to estimate the ground-state energy of the hydrogen-like atom/ion with the nuclear charge $+Ze$. Compare the solution with the exact result.

3.30. Calculate the energy spectrum of a particle moving in a monotonic, but otherwise arbitrary attractive spherically-symmetric potential $U(r) < 0$, in the approximation of very large orbital quantum numbers l . Formulate the quantitative condition(s) of validity of your theory. Check that for the Coulomb potential $U(r) = -C/r$, your result agrees with Eq. (201).

Hint: Try to solve Eq. (181) approximately, introducing the same new function, $f(r) \equiv r\mathcal{R}(r)$, that was already used in Sec. 1 and in the solutions of a few earlier problems.

3.31. An electron had been in the ground state of a hydrogen-like atom/ion with nuclear charge Ze , when the charge suddenly changed to $(Z + 1)e$.⁹⁹ Calculate the probabilities for the electron of the changed system to be:

- (i) in the ground state, and
- (ii) in the lowest excited state.

3.32. Due to a very short pulse of an external force, the nucleus of a hydrogen-like atom/ion, initially at rest in its ground state, starts moving with velocity v . Calculate the probability W_g that the atom remains in its ground state. Evaluate the energy to be given, by the pulse, to a hydrogen atom in order to reduce W_g to 50%.

3.33. Calculate $\langle x^2 \rangle$ and $\langle p_x^2 \rangle$ in the ground state of a hydrogen-like atom/ion. Compare the results with Heisenberg's uncertainty relation. What do these results tell about the electron's velocity in the system?

3.34. Use the Hellmann-Feynman theorem (see Problem 1.5) to prove:

- (i) the first of Eqs. (211), and
- (ii) the fact that for a spinless particle in an arbitrary spherically-symmetric attractive potential $U(r)$, the ground state is always an s -state (with the orbital quantum number $l = 0$).

3.35. For the ground state of a hydrogen atom, calculate the expectation values of \mathcal{E} and \mathcal{E}^2 , where \mathcal{E} is the electric field created by the atom, at distances $r \gg r_0$ from its nucleus. Interpret the resulting relation between $\langle \mathcal{E} \rangle^2$ and $\langle \mathcal{E}^2 \rangle$, at the same observation point.

3.36. Calculate the condition at that a particle of mass m , moving in the field of a very thin spherically-symmetric shell, with

$$U(\mathbf{r}) = w\delta(r - R),$$

and $w < 0$, has at least one localized ("bound") stationary state.

⁹⁹ Such a fast change happens, for example, at the beta-decay, when one of the nucleus' neutrons spontaneously turns into a proton, emitting a high-energy electron and a neutrino, which leave the system very fast (instantly on the atomic time scale), and do not affect directly the atom transition's dynamics.

3.37. Calculate the lifetime of the lowest metastable state of a particle in the same spherical-shell potential as in the previous problem, but now with $w > 0$, for sufficiently large w . (Quantify this condition.)

3.38. A particle of mass m and energy E is incident on a very thin spherical shell of radius R , whose localized states were the subject of two previous problems, with an arbitrary “weight” w .

(i) Derive general expressions for the differential and total cross-sections of scattering for this geometry.

(ii) Spell out the contribution σ_0 to the total cross-section σ , due to the spherically-symmetric component of the scattered de Broglie wave.

(iii) Analyze the result for σ_0 in the limits of very small and very large magnitudes of w , for both signs of this parameter. In particular, in the limit $w \rightarrow +\infty$, relate the result to the metastable state’s lifetime τ calculated in the previous problem.

3.39. Calculate the spherically-symmetric contribution σ_0 to the total cross-section of particle scattering by a uniform sphere of radius R , described by the following potential:

$$U(r) = \begin{cases} U_0, & \text{for } r < R, \\ 0, & \text{otherwise,} \end{cases}$$

with an arbitrary U_0 . Analyze the result in detail, and give an interpretation of its most remarkable features.

3.40. Use the finite difference method with the step $h = a/2$ to calculate as many energy levels as possible, for a particle confined to the interior of:

- (i) a square with side a , and
- (ii) a cube with side a ,

with hard walls. For the square, repeat the calculations, using a finer step: $h = a/3$. Compare the results for different values of h with each other and with the exact formulas.

Hint: It is advisable to either first solve (or review the solution of) the similar 1D Problem 1.15, or start from reading about the finite difference method.¹⁰⁰ Also: try to exploit the symmetry of the systems.

¹⁰⁰ See, e.g., CM Sec. 8.5 or EM Sec. 2.11.

Chapter 4. Bra-ket Formalism

The objective of this chapter is to describe Dirac's "bra-ket" formalism of quantum mechanics, which not only overcomes some inconveniences of wave mechanics but also allows a natural description of such intrinsic properties of particles as their spin. In the course of the formalism's discussion, I will give only a few simple examples of its application, leaving more involved cases for the following chapters.

4.1. Motivation

As the reader could see from the previous chapters of these notes, wave mechanics gives many results of primary importance. Moreover, it is mostly sufficient for many applications, for example, solid-state electronics and device physics. However, in the course of our survey, we have filed several grievances about this approach. Let me briefly summarize these complaints:

- (i) Attempts to analyze the *temporal* evolution of quantum systems, beyond the trivial time behavior of the stationary states, described by Eq. (1.62), run into technical difficulties. For example, we could derive Eq. (2.151) describing the metastable state's decay and Eq. (2.181) describing the quantum oscillations in coupled wells, only for the simplest potential profiles, though it is intuitively clear that such simple results should be common for all problems of this kind. Solving such problems for more complex potential profiles would entangle the time evolution analysis with the calculation of the spatial distribution of the evolving wavefunctions – which (as we could see in Secs. 2.9 and 3.6) may be rather complex even for simple time-independent potentials. Some separation of the spatial and temporal dependencies is possible using perturbation approaches (to be discussed in Chapter 6), but even those would lead, in the wavefunction language, to very cumbersome formulas.
- (ii) The last statement can also be made concerning other issues that are conceptually addressable within the wave mechanics, e.g., the Feynman path integral approach, coupling to the environment, etc. Pursuing them in the wave mechanics language would lead to formulas so bulky that I had postponed their discussion until we would have a more compact formalism on hand.
- (iii) In the discussion of several key problems (for example the harmonic oscillator and spherically-symmetric potentials), we have run into rather complicated eigenfunctions coexisting with very simple energy spectra – that infer some simple background physics. It is very important to get this physics revealed.
- (iv) In the wave-mechanics postulates formulated in Sec. 1.2, the quantum mechanical operators of the coordinate and momentum are treated rather unequally – see Eqs. (1.26b). However, some key expressions, e.g., for the fundamental eigenfunction of a free particle,

$$\exp\left\{i\frac{\mathbf{p}\cdot\mathbf{r}}{\hbar}\right\}, \quad (4.1)$$

or the harmonic oscillator's Hamiltonian,

$$\hat{H} = \frac{1}{2m}\hat{p}^2 + \frac{m\omega_0^2}{2}\hat{r}^2, \quad (4.2)$$

just beg for a similar treatment of coordinates and momenta.

However, the strongest motivation for a more general formalism comes from wave mechanics' conceptual inability to describe elementary particles' *spins*¹ and other internal quantum degrees of freedom, such as quark flavors or lepton numbers. In this context, let us review the basic facts on spin (which is very representative and experimentally the most accessible of all internal quantum numbers), to understand what a more general formalism has to explain – as a minimum.

Figure 1 shows the conceptual scheme of the simplest spin-revealing experiment, first conceived by Otto Stern in 1921 and implemented by Walther Gerlach in 1922. A collimated beam of electrons from a natural source, such as a heated cathode, is passed through a gap between the poles of a strong magnet, whose magnetic field \mathcal{B} , (in Fig. 1, directed along the z -axis) is nonuniform, so that both \mathcal{B}_z and $d\mathcal{B}_z/dz$ are not equal to zero. The experiment shows that the beam splits into two beams of equal intensity.

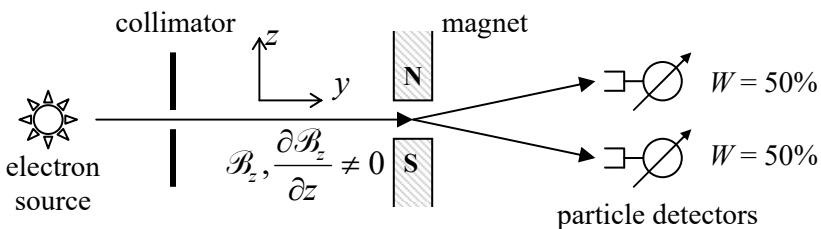

Fig. 4.1. The simplest Stern-Gerlach experiment.

This result may be semi-quantitatively explained on classical if somewhat phenomenological grounds, by assuming that each electron has an intrinsic, permanent magnetic dipole moment \mathbf{m} . Indeed, classical electrodynamics² tells us that the potential energy U of a magnetic dipole in an external magnetic field \mathcal{B} is equal to $(-\mathbf{m} \cdot \mathcal{B})$, so that the force acting on the electron,

$$\mathbf{F} = -\nabla U = -\nabla(-\mathbf{m} \cdot \mathcal{B}), \quad (4.3)$$

has a non-zero vertical component

$$F_z = -\frac{\partial}{\partial z}(-m_z \cdot \mathcal{B}_z) \equiv m_z \frac{\partial \mathcal{B}_z}{\partial z}. \quad (4.4)$$

Hence if we further assume that electron's magnetic moment may take only two equally probable discrete values of $m_z = \pm\mu$ (though such discreteness does not follow from any classical model of the particle), this may explain the original Stern-Gerlach effect qualitatively. The quantitative explanation of the beam splitting angle requires the magnitude of μ to be equal (or very close) to the so-called *Bohr magneton*³

$$\mu_B \equiv \frac{\hbar e}{2m_e} \approx 0.9274 \times 10^{-23} \frac{\text{J}}{\text{T}}. \quad (4.5)$$

Bohr
magneton

¹ To the best of my knowledge, the concept of spin as a measure of the internal rotation of a particle was first suggested by Ralph Kronig, then a 20-year-old student, in January 1925, a few months before two other students, G. Uhlenbeck and S. Goudsmit – to whom the idea is usually attributed. The concept was then accepted (rather reluctantly) and developed quantitatively by Wolfgang Pauli.

² See, e.g., EM Sec. 5.4, in particular Eq. (5.100).

³ A good mnemonic rule is that it is close to 1 K/T. In the Gaussian units, $\mu_B \equiv \hbar e/2m_e c \approx 0.9274 \times 10^{-20}$ erg/G.

However, as we will see below, this value cannot be explained by any internal motion of the electron, say its rotation about the z -axis. More importantly, this semi-classical phenomenology cannot explain, even qualitatively, other experimental results, for example those of the set of multi-stage Stern-Gerlach experiments shown in Fig. 2. In the first of the experiments, the electron beam is first passed through a magnetic field (and its gradient) oriented along the z -axis, just as in Fig. 1. Then one of the two resulting beams is absorbed (or removed from the setup in some other way), while the other one is passed through a similar but x -oriented field. The experiment shows that this beam is split again into two components of equal intensity. A classical explanation of this experiment would require an even more unnatural additional assumption that the initial electrons had random but discrete components of the magnetic moment simultaneously in *two* directions, z and x .

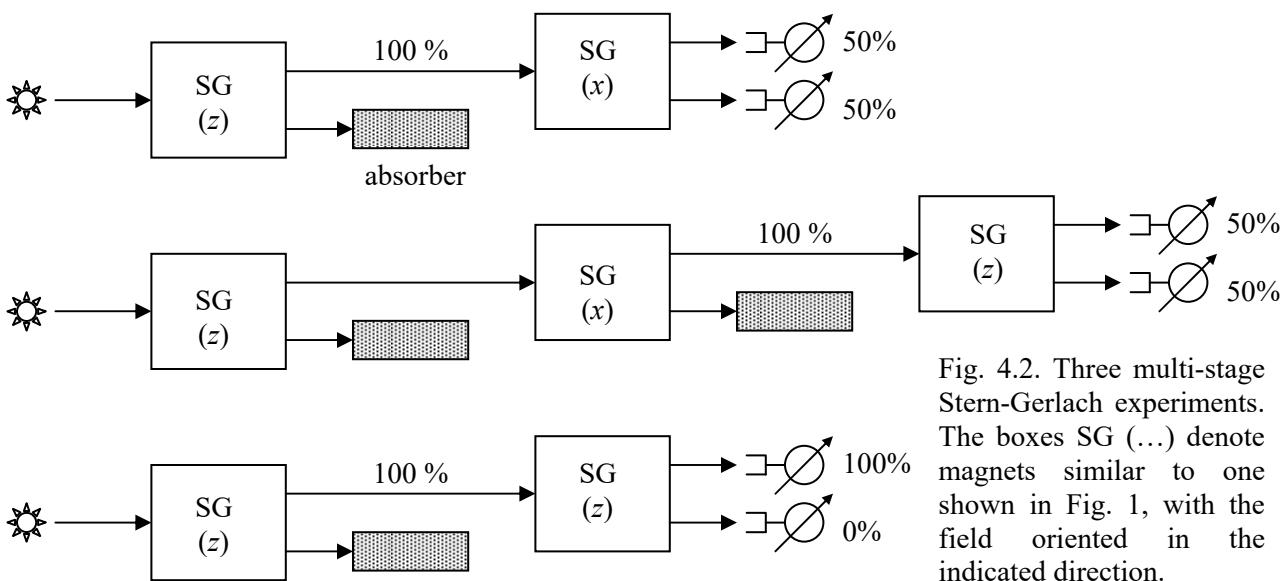

Fig. 4.2. Three multi-stage Stern-Gerlach experiments. The boxes SG (...) denote magnets similar to one shown in Fig. 1, with the field oriented in the indicated direction.

However, even this assumption cannot explain the results of the three-stage Stern-Gerlach experiment shown on the middle panel of Fig. 2. Here, the previous two-state setup is complemented with one more absorber and one more magnet, now with the z -orientation again. Completely counter-intuitively, it again gives two beams of equal intensity, as if we have not yet filtered out the electrons with m_z corresponding to the lower beam, at the first z -stage. The only way to save the classical explanation here is to say that maybe, electrons *somewhat* interact with the magnetic field so that the x -polarized (non-absorbed) beam becomes spontaneously depolarized again somewhere between the two last stages. But any hope for such an explanation is ruined by the control experiment shown on the bottom panel of Fig. 2, whose results indicate that no such depolarization happens.

We will see below that all these (and many more) results find a natural explanation in the so-called *matrix mechanics* pioneered by Werner Heisenberg, Max Born, and Pascual Jordan in 1925. However, the matrix formalism is rather inconvenient for the solution of most problems discussed in Chapters 1-3, and for a short time, it was eclipsed by E. Schrödinger's wave mechanics, which had been put forward just a few months later. However, very soon Paul Adrien Maurice Dirac introduced a more general *bra-ket formalism* of quantum mechanics, which provides a generalization of both approaches and proves their equivalence. Let me describe it, begging for the reader's patience, because (in a contrast with my usual style), I will not be able to give particular examples of its application for a while – until all the basic notions of the formalism have been introduced.

4.2. States, state vectors, and linear operators

The basic notion of the general formulation of quantum mechanics is the *quantum state* of a system.⁴ To get some gut feeling of this notion, if a quantum state α of a particle may be adequately described by wave mechanics, this description is given by the corresponding wavefunction $\Psi_\alpha(\mathbf{r}, t)$. Note, however, a quantum state as such is *not* a mathematical object,⁵ and can participate in mathematical formulas only as a “label” – e.g., the index of the wavefunction Ψ_α . On the other hand, such wavefunction is *not* a state, but a mathematical object (a complex function of space and time) giving a quantitative description of the state – just as the classical radius vector \mathbf{r}_α and velocity \mathbf{v}_α as real functions of time are mathematical objects describing the motion of the particle in its classical description – see Fig. 3. Similarly, in the Dirac formalism, a certain quantum state α is described by either of two mathematical objects, called the *state vectors*: the *ket-vector* $|\alpha\rangle$ and *bra-vector* $\langle\alpha|$,⁶ whose relationship is close to that between the wavefunction Ψ_α and its complex conjugate Ψ_α^* .

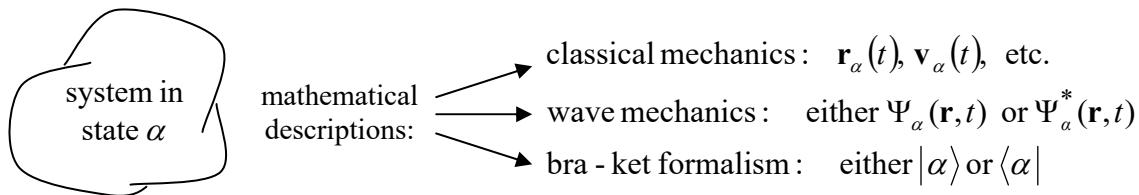

Fig. 4.3. Physical state of a system and its descriptions.

One should be cautious with the term “vector” here. The usual geometric vectors, such as \mathbf{r} and \mathbf{v} , are defined in the usual geometric (say, Euclidean) space. In contrast, the bra- and ket-vectors are defined in a more abstract *Hilbert space* – the full set of its possible bra- and ket-vectors of a given system.⁷ So, despite certain similarities with the geometric vectors, the bra- and ket-vectors are different mathematical objects, and we need to define the rules of their handling. The primary rules are essentially postulates and are justified only by the correct description of all experimental observations of the rule corollaries. While there is a general consensus among physicists what the corollaries are, there are many possible ways to carve from them the basic postulate sets. Just as in Sec. 1.2, I will not try too hard to beat the number of the postulates to the smallest possible minimum, trying instead to keep their physical meaning transparent.

(i) Ket-vectors. Let us start with *ket-vectors* – sometimes called just *kets* for short. Their most important property is the *linear superposition*. Namely, if several ket-vectors $|\alpha_j\rangle$ describe possible states of a quantum system, numbered by the index j , then any linear combination (*superposition*)

$$|\alpha\rangle = \sum_j c_j |\alpha_j\rangle, \quad (4.6)$$

Linear
superposition
of ket-vectors

⁴ An attentive reader could notice my smuggling the term “system” instead of “particle”, which was used in the previous chapters. Indeed, the bra-ket formalism allows the description of quantum systems much more complex than a single spinless particle that is a typical (though not the only possible) subject of wave mechanics.

⁵ As was expressed nicely by Asher Peres, one of the pioneers of the quantum information theory, “quantum phenomena do not occur in the Hilbert space, they occur in a laboratory”.

⁶ The terms *bra* and *ket* were suggested to reflect the fact that the pair $\langle\beta|$ and $|\alpha\rangle$ may be considered as the parts of the combinations like $\langle\beta|\alpha\rangle$ (see below), which remind expressions in the usual angle brackets.

⁷ I have to confess that this is a bit loose definition; it will be refined soon.

where c_j are any (possibly complex) c -numbers, also describes a possible state of the same system.⁸ Actually, since ket-vectors are new mathematical objects, the exact meaning of the right-hand side of Eq. (6) becomes clear only after we have postulated the following rules of summation of these vectors,

$$|\alpha_j\rangle + |\alpha_{j'}\rangle = |\alpha_{j'}\rangle + |\alpha_j\rangle, \quad (4.7)$$

and their multiplication by an arbitrary c -number:

$$c|\alpha_j\rangle = |\alpha_j\rangle c. \quad (4.8)$$

Note that in the set of wave mechanics postulates, the statements parallel to Eqs. (7) and (8) were unnecessary, because the wavefunctions are the usual (albeit complex) functions of space and time, and we know from the usual algebra that such relations are indeed valid.

As evident from Eq. (6), the complex coefficient c_j may be interpreted as the “weight” of the state α_j in the linear superposition α . One important particular case is $c_j = 0$, showing that the state α_j does not participate in the superposition α . The corresponding term of the sum (6), i.e. the product

Null-state vector

$$0|\alpha_j\rangle, \quad (4.9)$$

has a special name: the *null-state* vector. (It is important to avoid confusion between the null-state corresponding to vector (9), and the ground state of the system, which is frequently denoted by ket-vector $|0\rangle$. In some sense, the null-state does not exist at all, while the ground state not only does exist but frequently is the most important quantum state of the system.)

(ii) Bra-vectors and inner products. Bra-vectors $\langle\alpha|$, which obey the rules similar to Eqs. (7) and (8), are not new, independent objects: a ket-vector $|\alpha\rangle$ and the corresponding bra-vector $\langle\alpha|$ describe the same state. In other words, there is a *unique dual correspondence* between $|\alpha\rangle$ and $\langle\alpha|$,⁹ very similar (though not identical) to that between a wavefunction Ψ and its complex conjugate Ψ^* . The correspondence between these vectors is described by the following rule: if a ket-vector of a linear superposition is described by Eq. (6), then the corresponding bra-vector is

Linear superposition of bra-vectors

$$\langle\alpha| = \sum_j c_j^* \langle\alpha_j| = \sum_j \langle\alpha_j| c_j^*. \quad (4.10)$$

The mathematical convenience of using two types of vectors rather than just one becomes clear from the notion of their *inner product* (due to its second, shorthand form, also called the *short bracket*):

Short bracket (inner product)

$$(\langle\beta|)(\langle\alpha|) \equiv \langle\beta|\alpha\rangle, \quad (4.11)$$

which is a scalar c -number, in a certain but limited analogy with the scalar product of the usual geometric vectors. (For one difference, the product (11) may be a complex number.)

The main property of the inner product is its linearity with respect to any of its component vectors. For example, if a linear superposition α is described by the ket-vector (6), then

⁸ One may express the same statement by saying that the vector $|\alpha\rangle$ belongs to the same Hilbert space as all $|\alpha_j\rangle$.

⁹ Mathematicians like to say that the ket- and bra-vectors of the same quantum system are defined in two *isomorphic* Hilbert spaces.

$$\langle \beta | \alpha \rangle = \sum_j c_j \langle \beta | \alpha_j \rangle, \quad (4.12)$$

while if Eq. (10) is true, then

$$\langle \alpha | \beta \rangle = \sum_j c_j^* \langle \alpha_j | \beta \rangle. \quad (4.13)$$

In plain English, c -number factors may be moved either into or out of the inner products.

The second key property of the inner product is

$$\langle \alpha | \beta \rangle = \langle \beta | \alpha \rangle^*. \quad (4.14)$$

Inner product:: complex conjugate

It is compatible with Eq. (10); indeed, the complex conjugation of both parts of Eq. (12) gives:

$$\langle \beta | \alpha \rangle^* = \sum_j c_j^* \langle \beta | \alpha_j \rangle^* = \sum_j c_j^* \langle \alpha_j | \beta \rangle = \langle \alpha | \beta \rangle. \quad (4.15)$$

Finally, one more rule: the inner product of the bra- and ket-vectors describing the same state (called the *norm squared*) is real and non-negative,

$$\| \alpha \|^2 \equiv \langle \alpha | \alpha \rangle \geq 0. \quad (4.16)$$

State's norm squared

In order to give the reader some feeling about the meaning of this rule: we will see below that if some state α may be described by the wavefunction $\Psi_\alpha(\mathbf{r}, t)$, then

$$\langle \alpha | \alpha \rangle = \int \Psi_\alpha^* \Psi_\alpha d^3 r \geq 0. \quad (4.17)$$

Hence the role of the bra- and ket-vectors of the same state is very similar to that of complex-conjugate pairs of its wavefunctions.

(iii) Operators. One more key notion of the Dirac formalism is quantum-mechanical *linear operators*. Just as for the operators discussed in wave mechanics, the function of an operator is to “generate” of one state from another: if $|\alpha\rangle$ is a possible ket of the system, and \hat{A} is a legitimate¹⁰ operator, then the following combination,

$$\hat{A}|\alpha\rangle, \quad (4.18)$$

is also a ket-vector describing a possible state of the system, i.e. a ket-vector in the same Hilbert space as the initial vector $|\alpha\rangle$. An alternative formulation of the same rule is the following clarification of the notion of the Hilbert space: for the given set of linear operators of a system, its Hilbert state includes all vectors that may be obtained from each other using the operations of the type (18). In this context, let me note that the operator set, and hence the Hilbert space of a system, usually (if not always) implies its certain approximate model. For example, if the coupling of orbital degrees of freedom of a particle to its spin may be ignored (as it may be for a non-relativistic particle in the absence of an external magnetic

¹⁰ Here the term “legitimate” means “having a clear sense in the bra-ket formalism”. Some examples of “illegitimate” expressions are: $|\alpha\rangle \hat{A}$, $\hat{A} \langle \alpha|$, $|\alpha\rangle |\beta\rangle$, and $\langle \alpha| \langle \beta|$. Note, however, that the last two expressions may be legitimate if α and β are states of different systems, i.e. if their state vectors belong to different Hilbert spaces. We will run into such *direct products* of the bra- and ket-vectors (sometimes denoted, respectively, as $|\alpha\rangle \otimes |\beta\rangle$ and $\langle \alpha| \otimes \langle \beta|$) in Chapters 6-10.

field), we may describe the dynamics of the particle using spin operators only. In this case, the set of all possible spin vectors of the particle forms a Hilbert space separate from that of the orbital-state vectors of that particle.

As the adjective “linear” in the operator definition implies, the main rules governing the operators is their linearity with respect to both any superposition of vectors:

$$\hat{A}\left(\sum_j c_j |\alpha_j\rangle\right) = \sum_j c_j \hat{A}|\alpha_j\rangle, \quad (4.19)$$

and any superposition of operators:

$$\left(\sum_j c_j \hat{A}_j\right)|\alpha\rangle = \sum_j c_j \hat{A}_j|\alpha\rangle. \quad (4.20)$$

These rules are evidently similar to Eqs. (1.53)-(1.54) of wave mechanics.

The above rules imply that an operator “acts” on the ket-vector on its right; however, a combination of the type $\langle\alpha|\hat{A}$ is also legitimate and represents a new bra-vector. It is important that, generally, this vector does *not* represent the same state as the ket-vector (18); instead, the bra-vector isomorphic to the ket-vector (18) is

$$\langle\alpha|\hat{A}^\dagger. \quad (4.21)$$

Conjugate operator

This statement serves as the definition of the *Hermitian conjugate* (also called “Hermitian adjoint”) \hat{A}^\dagger of the initial operator \hat{A} . For an important class of operators, called the *Hermitian operators*, the conjugation is inconsequential, i.e. for them

$$\hat{A}^\dagger = \hat{A}. \quad (4.22)$$

Hermitian operator

(This equality, as well as any other operator equation below, means that these operators act similarly on any bra- or ket-vector of the given Hilbert space.)¹¹

To proceed further, we need one more additional postulate, sometimes called the *associative axiom of multiplication*: just as an ordinary product of scalars, *any* legitimate bra-ket expression, not including explicit summations, does not change from an insertion or removal of a pair of parentheses – meaning as usual that the operation inside them has to be performed first. The first two examples of this postulate are given by Eqs. (19) and (20), but the associative axiom is more general and means, for example, that

$$\langle\beta|\left(\hat{A}|\alpha\rangle\right) = \left(\langle\beta|\hat{A}\right)|\alpha\rangle \equiv \langle\beta|\hat{A}|\alpha\rangle, \quad (4.23)$$

Long bracket:
definition

This last equality serves as the definition of the last form, called the *long bracket* (evidently, also a scalar), with an operator sandwiched between a bra-vector and a ket-vector. This definition, when combined with the definition of the Hermitian conjugate and Eq. (14), yields an important corollary:

¹¹ If we consider *c*-numbers as a particular type of operators (which is legitimate for any Hilbert space), then according to Eqs. (11) and (21), for them the Hermitian conjugation is equivalent to the simple complex conjugation, so that only real *c*-numbers may be considered as a particular type of the Hermitian operators (22).

$$\langle \beta | \hat{A} | \alpha \rangle = \langle \beta | (\hat{A} | \alpha \rangle) = \left(\left(\langle \alpha | \hat{A}^\dagger \right) | \beta \rangle \right)^* = \left(\langle \alpha | \hat{A}^\dagger | \beta \rangle \right)^*, \quad (4.24)$$

which is most frequently rewritten as

$$\langle \alpha | \hat{A} | \beta \rangle^* = \langle \beta | \hat{A}^\dagger | \alpha \rangle. \quad (4.25)$$

Long bracket:
complex conjugate

The associative axiom also enables us to comprehend the following definition of one more, *outer* product of bra- and ket-vectors:

$$| \beta \rangle \langle \alpha |. \quad (4.26)$$

Outer
bra-ket
product

In contrast to the inner product (11), which is a *scalar*, this mathematical construct is an *operator*. Indeed, the associative axiom allows us to remove parentheses in the following expression:

$$(\langle \beta | \langle \alpha |) | \gamma \rangle = \langle \beta | \langle \alpha | \gamma \rangle. \quad (4.27)$$

But the last short bracket is just a scalar; hence the mathematical object (26), acting on a ket-vector (in this case, $|\gamma\rangle$), gives a new ket-vector, which is the essence of the operator's action. Very similarly,

$$\langle \delta | (\langle \beta | \langle \alpha |) = \langle \delta | \beta \rangle \langle \alpha | \quad (4.28)$$

– again a typical operator's action on a bra-vector. So, Eq. (26) defines an operator.

Now let us perform the following calculation. We may use the parentheses' insertion into the bra-ket equality following from Eq. (14),

$$\langle \gamma | \alpha \rangle \langle \beta | \delta \rangle = (\langle \delta | \beta \rangle \langle \alpha | \gamma \rangle)^*, \quad (4.29)$$

to transform it to the following form:

$$\langle \gamma | (\langle \alpha | \langle \beta |) | \delta \rangle = (\langle \delta | (\langle \beta | \langle \alpha |) | \gamma \rangle)^*. \quad (4.30)$$

Since this equality should be valid for any state vectors $\langle \gamma |$ and $| \beta \rangle$, its comparison with Eq. (25) gives the following operator equality

$$(\langle \alpha | \langle \beta |)^\dagger = | \beta \rangle \langle \alpha |. \quad (4.31)$$

Outer
product:
Hermitian
conjugate

This is the conjugate rule for outer products; it reminds the rule (14) for inner products but involves the Hermitian (rather than the usual complex) conjugation.

The associative axiom is also valid for the operator “multiplication”:

$$(\hat{A} \hat{B}) | \alpha \rangle = \hat{A} (\hat{B} | \alpha \rangle), \quad \langle \beta | (\hat{A} \hat{B}) = (\langle \beta | \hat{A}) \hat{B}, \quad (4.32)$$

showing that the action of an operator product on a state vector is nothing more than the sequential action of its operands. However, we have to be careful with the operator products; generally, they do not commute: $\hat{A} \hat{B} \neq \hat{B} \hat{A}$. This is why the *commutator* – the operator defined as

$$[\hat{A}, \hat{B}] \equiv \hat{A} \hat{B} - \hat{B} \hat{A}, \quad (4.33)$$

Commutator

is a non-trivial and very useful notion. Another similar notion is the *anticommutator*:¹²

$$\{\hat{A}, \hat{B}\} \equiv \hat{A}\hat{B} + \hat{B}\hat{A}. \quad (4.34)$$

Finally, the bra-ket formalism broadly uses two special operators. The *null-operator* $\hat{0}$ is defined by the following relations:

$$\hat{0}|\alpha\rangle \equiv 0|\alpha\rangle, \quad \langle\alpha|\hat{0} \equiv \langle\alpha|0, \quad (4.35)$$

where α is an arbitrary state; we may say that the null-operator “kills” *any* state, turning it into the null-state. Another useful notion is the *identity operator*, which is defined by the following action (or rather “inaction” :-)) on an arbitrary state vector:

$$\hat{I}|\alpha\rangle \equiv |\alpha\rangle, \quad \langle\alpha|\hat{I} \equiv \langle\alpha|. \quad (4.36)$$

These definitions show that the null-operator and the identity operator are Hermitian.

4.3. State basis and matrix representation

While some operations in quantum mechanics may be carried out in the general bra-ket formalism outlined above, many calculations are performed for quantum systems that feature a *full and orthonormal* set $\{u\} \equiv \{u_1, u_2, \dots, u_j, \dots\}$ of its states u_j , frequently called a *basis*. The first of these terms means that any possible state vector of the system (i.e. of its Hilbert space) may be represented as a unique sum of the type (6) or (10) over its basis vectors:

$$|\alpha\rangle = \sum_j \alpha_j |u_j\rangle, \quad \langle\alpha| = \sum_j \alpha_j^* \langle u_j|, \quad (4.37)$$

so that, in particular, if α is one of the basis states, say $u_{j'}$, then $\alpha_j = \delta_{jj'}$. The second term means that

$$\langle u_j | u_{j'} \rangle = \delta_{jj'}. \quad (4.38)$$

For the systems that may be described by wave mechanics, examples of the full orthonormal bases are represented by any full and orthonormal set of eigenfunctions calculated in the previous three chapters of this course – for the simplest example, see Eq. (1.87).

Due to the uniqueness of the expansion (37), the full set of the coefficients α_j involved in the expansion of a state α in certain basis $\{u\}$ gives its complete description – just as the Cartesian components A_x , A_y , and A_z of a usual geometric 3D vector \mathbf{A} in certain reference frame give its complete description. Still, let me emphasize some differences between such representations of the quantum-mechanical state vectors and 3D geometric vectors:

- (i) a quantum state basis may have a large or even infinite number of states u_j , and
- (ii) the expansion coefficients α_j may be complex.

¹² Another popular notation for the anticommutator (34) is $[\hat{A}, \hat{B}]_+$; it will not be used in these notes.

With these reservations in mind, the analogy with geometric vectors may be pushed further on. Let us inner-multiply both parts of the first of Eqs. (37) by a bra-vector $\langle u_j |$ and then transform the resulting relation using the linearity rules discussed in the previous section, and Eq. (38):

$$\langle u_{j'} | \alpha \rangle = \langle u_{j'} | \sum_j \alpha_j | u_j \rangle = \sum_j \alpha_j \langle u_{j'} | u_j \rangle = \alpha_{j'}. \quad (4.39)$$

Together with Eq. (14), this means that any of the expansion coefficients in Eq. (37) may be represented as an inner product:

$$\alpha_j = \langle u_j | \alpha \rangle, \quad \alpha_j^* = \langle \alpha | u_j \rangle; \quad (4.40)$$

Expansion coefficients as inner products

these important equalities relations are analogs of equalities $A_j = \mathbf{n}_j \cdot \mathbf{A}$ of the usual vector algebra, and will be used on numerous occasions in this course. With them, the expansions (37) may be rewritten as

$$|\alpha\rangle = \sum_j |u_j\rangle \langle u_j| \alpha \rangle \equiv \sum_j \hat{\Lambda}_j |\alpha\rangle, \quad \langle \alpha| = \sum_j \langle \alpha| u_j \rangle \langle u_j| \equiv \sum_j \langle \alpha| \hat{\Lambda}_j, \quad (4.41)$$

where

$$\hat{\Lambda}_j \equiv |u_j\rangle \langle u_j|. \quad (4.42)$$

Projection operator

Eqs. (41) show that $\hat{\Lambda}_j$ so defined is a legitimate linear operator. This operator, acting on any state vector of the type (37), singles out just one of its components, for example,

$$\hat{\Lambda}_j |\alpha\rangle = |u_j\rangle \langle u_j| \alpha \rangle = \alpha_j |u_j\rangle, \quad (4.43)$$

i.e. “kills” all components of the linear superposition but one. In the geometric analogy, such operator “projects” the state vector on the j^{th} “direction”, hence its name – the *projection operator*. Probably, the most important property of the projection operators, called the *closure* (or “completeness”) *relation*, immediately follows from Eq. (41): their sum over the full basis is equivalent to the identity operator

$$\sum_j |u_j\rangle \langle u_j| = \hat{I}. \quad (4.44)$$

Closure relation

This means in particular that we may insert the left-hand side of Eq. (44), for any basis, into any bra-ket relation, at any place – the trick that we will use again and again.

Now let us see how the expansions (37) transform the key notions introduced in the last section, starting from the short bracket (11), i.e. the inner product of two state vectors:

$$\langle \beta | \alpha \rangle = \sum_{j,j'} \langle u_j | \beta_j^* \alpha_{j'} | u_{j'} \rangle = \sum_{j,j'} \beta_j^* \alpha_{j'} \delta_{jj'} = \sum_j \beta_j^* \alpha_j. \quad (4.45)$$

Besides the complex conjugation, this expression is similar to the scalar product of the usual, geometric vectors. Now, let us explore the long bracket (23):

$$\langle \beta | \hat{A} | \alpha \rangle = \sum_{j,j'} \beta_j^* \langle u_j | \hat{A} | u_{j'} \rangle \alpha_{j'} = \sum_{j,j'} \beta_j^* A_{jj'} \alpha_{j'}. \quad (4.46)$$

Here, the last step uses the very important notion of *matrix elements* of the operator, defined as

Operator's
matrix
elements

$$A_{jj'} \equiv \langle u_j | \hat{A} | u_{j'} \rangle. \quad (4.47)$$

As evident from Eq. (46), the full set of the matrix elements completely characterizes the operator, just as the full set of the expansion coefficients (40) fully characterizes a quantum state. The term “matrix” means, first of all, that it is convenient to represent the full set of $A_{jj'}$ as a square table (*matrix*), with the linear dimension equal to the number of basis states u_j of the system under the consideration. By the way, this number (which may be infinite) is called the *dimensionality* of its Hilbert space.

As two simplest examples, all matrix elements of the null-operator, defined by Eqs. (35), are evidently equal to zero (in any basis), and hence it may be represented as a matrix of zeros (called the *null-matrix*):

Null
matrix

$$0 \equiv \begin{pmatrix} 0 & 0 & \dots \\ 0 & 0 & \dots \\ \dots & \dots & \dots \end{pmatrix}, \quad (4.48)$$

while for the identity operator \hat{I} , defined by Eqs. (36), we readily get

$$I_{jj'} = \langle u_j | \hat{I} | u_{j'} \rangle = \langle u_j | u_{j'} \rangle = \delta_{jj'}, \quad (4.49)$$

i.e. its matrix (naturally called the *identity matrix*) is diagonal – also in any basis:

Identity
matrix

$$I \equiv \begin{pmatrix} 1 & 0 & \dots \\ 0 & 1 & \dots \\ \dots & \dots & \dots \end{pmatrix}. \quad (4.50)$$

The convenience of the matrix language extends well beyond the representation of particular operators. For example, let us use the definition (47) to calculate matrix elements of a product of two operators:

$$(AB)_{jj''} = \langle u_j | \hat{A} \hat{B} | u_{j''} \rangle. \quad (4.51)$$

Matrix
element
of an
operator
product

Here we may use Eq. (44) for the first (but not the last!) time, inserting the identity operator between the two operators, and then expressing it via a sum of projection operators:

$$(AB)_{jj''} = \langle u_j | \hat{A} \hat{B} | u_{j''} \rangle = \langle u_j | \hat{A} \hat{I} \hat{B} | u_{j''} \rangle = \sum_{j'} \langle u_j | \hat{A} | u_{j'} \rangle \langle u_{j'} | \hat{B} | u_{j''} \rangle = \sum_{j'} A_{jj'} B_{j'j''}. \quad (4.52)$$

This result corresponds to the standard “row by column” rule of calculation of an arbitrary element of the matrix product

$$AB = \begin{pmatrix} A_{11} & A_{12} & \dots \\ A_{21} & A_{22} & \dots \\ \dots & \dots & \dots \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} & \dots \\ B_{21} & B_{22} & \dots \\ \dots & \dots & \dots \end{pmatrix}. \quad (4.53)$$

Hence a product of operators may be represented (in a fixed basis!) by that of their matrices (in the same basis).

This is so convenient that the same language is often used to represent not only long brackets,

$$\langle \beta | \hat{A} | \alpha \rangle = \sum_{j'} \beta_j^* A_{jj'} \alpha_{j'} = \left(\beta_1^*, \beta_2^*, \dots \right) \begin{pmatrix} A_{11} & A_{12} & \dots \\ A_{21} & A_{22} & \dots \\ \dots & \dots & \dots \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \dots \end{pmatrix}, \quad (4.54)$$

Long bracket as a matrix product

but even short brackets:

$$\langle \beta | \alpha \rangle = \sum_j \beta_j^* \alpha_j = \left(\beta_1^*, \beta_2^*, \dots \right) \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \dots \end{pmatrix}, \quad (4.55)$$

Short bracket as a matrix product

although these equalities require the use of non-square matrices: rows of (complex-conjugate!) expansion coefficients for the representation of bra-vectors, and columns of these coefficients for the representation of ket-vectors. With that, the mapping of quantum states and operators on matrices becomes completely general.

Now let us have a look at the outer product operator (26). Its matrix elements are just

$$(\langle \alpha | \beta \rangle)_{jj'} = \langle u_j | \alpha \rangle \langle \beta | u_{j'} \rangle = \alpha_j \beta_{j'}^*. \quad (4.56)$$

These are the elements of a very special square matrix, whose filling requires the knowledge of just $2N$ scalars (where N is the basis size), rather than N^2 scalars as for an arbitrary operator. However, a simple generalization of such an outer product may represent an arbitrary operator. Indeed, let us insert two identity operators (44), with different summation indices, on both sides of an arbitrary operator:

$$\hat{A} = \hat{I} \hat{A} \hat{I} = \left(\sum_j |u_j\rangle \langle u_j| \right) \hat{A} \left(\sum_{j'} |u_{j'}\rangle \langle u_{j'}| \right), \quad (4.57)$$

and then use the associative axiom to rewrite this expression as

$$\hat{A} = \sum_{j,j'} |u_j\rangle \langle u_j | \hat{A} | u_{j'} \rangle \langle u_{j'}|. \quad (4.58)$$

But the expression in the middle long bracket is just the matrix element (47), so that we may write

$$\hat{A} = \sum_{j,j'} |u_j\rangle A_{jj'} \langle u_{j'}|. \quad (4.59)$$

Operator via its matrix elements

The reader has to agree that this formula, which is a natural generalization of Eq. (44), is extremely elegant.

The matrix representation is so convenient that it makes sense to extend it to one level lower – from state vector products to the “bare” state vectors resulting from the operator’s action upon a given state. For example, let us use Eq. (59) to represent the ket-vector (18) as

$$|\alpha'\rangle \equiv \hat{A}|\alpha\rangle = \left(\sum_{j,j'} |u_j\rangle A_{jj'} \langle u_{j'}| \right) |\alpha\rangle = \sum_{j,j'} |u_j\rangle A_{jj'} \langle u_{j'}| \alpha\rangle. \quad (4.60)$$

According to Eq. (40), the last short bracket is just α_j , so that

$$|\alpha'\rangle = \sum_{j,j'} |u_j\rangle A_{jj'} \alpha_{j'} = \sum_j \left(\sum_{j'} A_{jj'} \alpha_{j'} \right) |u_j\rangle \quad (4.61)$$

But the expression in the parentheses is just the coefficient α'_j of the expansion (37) of the resulting ket-vector (60) in the same basis, so that

$$\alpha'_j = \sum_{j'} A_{jj'} \alpha_{j'} . \quad (4.62)$$

This result corresponds to the usual rule of multiplication of a matrix by a column, so that we may represent any ket-vector by its column matrix, with the operator's action looking like

$$\begin{pmatrix} \alpha'_1 \\ \alpha'_2 \\ \dots \end{pmatrix} = \begin{pmatrix} A_{11} & A_{12} & \dots \\ A_{21} & A_{22} & \dots \\ \dots & \dots & \dots \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \dots \end{pmatrix} . \quad (4.63)$$

Absolutely similarly, the operator action on the bra-vector (21), represented by its row-matrix, is

$$\left(\alpha'^*_1, \alpha'^*_2, \dots \right) = \left(\alpha^*_1, \alpha^*_2, \dots \right) \begin{pmatrix} \left(A^\dagger \right)_{11} & \left(A^\dagger \right)_{12} & \dots \\ \left(A^\dagger \right)_{21} & \left(A^\dagger \right)_{22} & \dots \\ \dots & \dots & \dots \end{pmatrix} . \quad (4.64)$$

By the way, Eq. (64) naturally raises the following question: what are the elements of the matrix on its right-hand side, or more exactly, what is the relation between the matrix elements of an operator and its Hermitian conjugate? The simplest way to answer it is to use Eq. (25) with two arbitrary states (say, u_j and $u_{j'}$) of the same basis in the role of α and β . Together with the orthonormality relation (38), this immediately gives¹³

$$\left(\hat{A}^\dagger \right)_{jj'} = \left(A_{j'j} \right)^* . \quad (4.65)$$

Hermitian
conjugate:
matrix
elements

Thus, the matrix of the Hermitian-conjugate operator is the *complex conjugated and transposed* matrix of the initial operator. This result exposes very clearly the difference between the Hermitian and the complex conjugation. It also shows that for the Hermitian operators, defined by Eq. (22),

$$A_{jj'} = A_{j'j}^*, \quad (4.66)$$

i.e. any pair of their matrix elements, symmetric with respect to the main diagonal, should be the complex conjugate of each other. As a corollary, their main-diagonal elements have to be real:

$$A_{jj} = A_{jj}^*, \quad \text{i.e. } \operatorname{Im} A_{jj} = 0. \quad (4.67)$$

¹³ For the sake of formula compactness, below I will use the shorthand notation in that the operands of this equality are just $A^\dagger_{jj'}$ and $A^*_{jj'}$. I believe that it leaves little chance for confusion, because the Hermitian conjugation sign \dagger may pertain only to an operator (or its matrix), while the complex conjugation sign $*$, to a scalar – say a matrix element.

In order to fully appreciate the special role played by Hermitian operators in quantum theory, let us introduce the key notions of *eigenstates* a_j (described by their *eigenvectors* $\langle a_j |$ and $| a_j \rangle$) and *eigenvalues* (*c-numbers*) A_j of an operator \hat{A} , both defined by the equation they have to satisfy:¹⁴

$$\hat{A} | a_j \rangle = A_j | a_j \rangle. \quad (4.68)$$

Let us prove that eigenvalues of any Hermitian operator are real,¹⁵

$$A_j = A_j^*, \quad \text{for } j = 1, 2, \dots, N, \quad (4.69)$$

while the eigenstates corresponding to different eigenvalues are orthogonal:

$$\langle a_j | a_{j'} \rangle = 0, \quad \text{if } A_j \neq A_{j'}. \quad (4.70)$$

The proof of both statements is surprisingly simple. Let us inner-multiply both sides of Eq. (68) by the bra-vector $\langle a_{j'} |$. On the right-hand side of the result, the eigenvalue A_j , as a *c-number*, may be taken out of the bracket, giving

$$\langle a_{j'} | \hat{A} | a_j \rangle = A_j \langle a_{j'} | a_j \rangle. \quad (4.71)$$

This equality has to hold for any pair of eigenstates, so that we may swap the indices in Eq. (71), and write the complex-conjugate of the result:

$$\langle a_j | \hat{A} | a_{j'} \rangle^* = A_{j'}^* \langle a_j | a_{j'} \rangle^*. \quad (4.72)$$

Now using Eqs. (14) and (25), together with the Hermitian operator's definition (22), we may transform Eq. (72) into the following form:

$$\langle a_{j'} | \hat{A} | a_j \rangle = A_{j'}^* \langle a_{j'} | a_j \rangle. \quad (4.73)$$

Subtracting this equation from Eq. (71), we get

$$0 = (A_j - A_{j'}^*) \langle a_{j'} | a_j \rangle. \quad (4.74)$$

There are two possibilities to satisfy this relation. If the indices j and j' are equal (denote the same eigenstate), then the bracket is the state's norm squared, and cannot be equal to zero. In this case, the left parentheses (with $j = j'$) have to be zero, proving Eq. (69). On the other hand, if j and j' correspond to different eigenvalues of A , the parentheses cannot equal zero (we have just proved that all A_j are real!), and hence the state vectors indexed by j and j' should be orthogonal, e.g., Eq. (70) is valid.

As will be discussed below, these properties make Hermitian operators suitable, in particular, for the description of physical observables.

Operator:
eigenstates
and
eigenvalues

Hermitian
operator:
eigenvalues

Hermitian
operator:
eigenvectors

¹⁴ This equation should look familiar to the reader – see the stationary Schrödinger equation (1.60), which was the focus of our studies in the first three chapters. We will see soon that that equation is just a particular (coordinate) representation of Eq. (68) for the Hamiltonian as the operator of energy.

¹⁵ The reciprocal statement is also true: if all eigenvalues of an operator are real, it is Hermitian (in any basis). This statement may be readily proved by applying Eq. (93) below to the case when $A_{kk'} = A_k \delta_{kk'}$, with $A_k^* = A_k$.

4.4. Change of basis, and matrix diagonalization

From the discussion of the last section, it may look that the matrix language is fully similar to, and in many instances more convenient than the general bra-ket formalism. In particular, Eqs. (54)-(55) and (63)-(64) show that any part of any bra-ket expression may be directly mapped on the similar matrix expression, with the only slight inconvenience of using not only columns but also rows (with their elements complex-conjugated), for state vector representation. This invites the question: why do we need the bra-ket language at all? The answer is that the elements of the matrices depend on the particular choice of the basis set, very much like the Cartesian components of a usual geometric vector depend on the particular choice of reference frame orientation (Fig. 4), and very frequently, at problem solution, it is convenient to use two or more different basis sets for the same system. (Just a bit more patience – numerous examples will follow soon.)

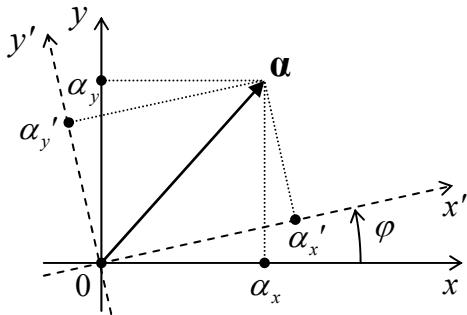

Fig. 4.4. The transformation of components of a 2D vector at a reference frame's rotation.

With this motivation, let us explore what happens at the transform from one basis, $\{u\}$, to another one, $\{v\}$ – both full and orthonormal. First of all, let us prove that for each such pair of bases, and an arbitrary numbering of the states of each base, there exists such an operator \hat{U} that, first,

$$|v_j\rangle = \hat{U}|u_j\rangle, \quad (4.75)$$

and, second,

$$\hat{U}\hat{U}^\dagger = \hat{U}^\dagger\hat{U} = \hat{I}. \quad (4.76)$$

(Due to the last property,¹⁶ \hat{U} is called a *unitary operator*, and Eq. (75), a *unitary transformation*.)

A very simple proof of both statements may be achieved by construction. Indeed, let us take

$$\hat{U} \equiv \sum_{j'} |v_{j'}\rangle \langle u_{j'}|, \quad (4.77)$$

- an evident generalization of Eq. (44). Then, using Eq. (38), we obtain

$$\hat{U}|u_j\rangle = \sum_{j'} |v_{j'}\rangle \langle u_{j'}|u_j\rangle = \sum_{j'} |v_{j'}\rangle \delta_{jj'} = |v_j\rangle, \quad (4.78)$$

so that Eq. (75) has been proved. Now, applying Eq. (31) to each term of the sum (77), we get

$$\hat{U}^\dagger \equiv \sum_{j'} |u_{j'}\rangle \langle v_{j'}|, \quad (4.79)$$

¹⁶ An alternative way to express Eq. (76) is to write $\hat{U}^\dagger = \hat{U}^{-1}$, but I will try to avoid this language.

so that

$$\hat{U}\hat{U}^\dagger = \sum_{j,j'} |v_j\rangle\langle u_j|u_{j'}\rangle\langle v_{j'}| = \sum_{j,j'} |v_j\rangle\delta_{jj'}\langle v_{j'}| = \sum_j |v_j\rangle\langle v_j|. \quad (4.80)$$

But according to the closure relation (44), the last expression is just the identity operator, so that one of Eqs. (76) has been proved. (The proof of the second equality is absolutely similar.) As a by-product of our proof, we have also got another important expression – Eq. (79). It implies, in particular, that while, according to Eq. (75), the operator \hat{U} performs the transform from the “old” basis u_j to the “new” basis v_j , its Hermitian adjoint \hat{U}^\dagger performs the reciprocal transform:

$$\hat{U}^\dagger |v_j\rangle = \sum_{j'} |u_{j'}\rangle\delta_{jj'} = |u_j\rangle. \quad (4.81)$$

Reciprocal basis transform

Now let us see how do the matrix elements of the unitary transform operators look like. Generally, as was discussed above, the operator’s elements may depend on the basis we calculate them in, so let us be specific – at least initially. For example, let us calculate the desired matrix elements $U_{jj'}$ in the “old” basis $\{u\}$, using Eq. (77):

$$U_{jj'}|_{in\ u} \equiv \langle u_j | \hat{U} | u_{j'} \rangle = \langle u_j | \left(\sum_{j''} |v_{j''}\rangle\langle u_{j''}| \right) | u_{j'} \rangle = \langle u_j | \sum_{j''} |v_{j''}\rangle\delta_{j''j'} = \langle u_j | v_{j'} \rangle. \quad (4.82)$$

Now performing a similar calculation in the “new” basis $\{v\}$, we get

$$U_{jj'}|_{in\ v} \equiv \langle v_j | \hat{U} | v_{j'} \rangle = \langle v_j | \left(\sum_{j''} |v_{j''}\rangle\langle u_{j''}| \right) | v_{j'} \rangle = \sum_{j''} \delta_{jj''} \langle u_{j''} | v_{j'} \rangle = \langle u_j | v_{j'} \rangle. \quad (4.83)$$

Surprisingly, the result is the same! This is of course true for the Hermitian conjugate (79) as well:

$$U_{jj'}^\dagger|_{in\ u} = U_{jj'}^\dagger|_{in\ v} = \langle v_j | u_{j'} \rangle. \quad (4.84)$$

These expressions may be used, first of all, to rewrite Eq. (75) in a more direct form. Applying the first of Eqs. (41) to any state $v_{j'}$ of the “new” basis, and then Eq. (82), we get

$$|v_{j'}\rangle = \sum_j |u_j\rangle\langle u_j|v_{j'}\rangle = \sum_j U_{jj'}|u_j\rangle. \quad (4.85)$$

Basis transforms: matrix form

Similarly, the reciprocal transform is

$$|u_{j'}\rangle = \sum_j |v_j\rangle\langle v_j|u_{j'}\rangle = \sum_j U_{jj'}^\dagger|v_j\rangle. \quad (4.86)$$

These formulas are very convenient for applications; we will use them already in this section.

Next, we may use Eqs. (83)-(84) to express the effect of the unitary transform on the expansion coefficients α_j of the vectors of an *arbitrary* state α , defined by Eq. (37). As a reminder, in the “old” basis $\{u\}$ they are given by Eqs. (40). Similarly, in the “new” basis $\{v\}$,

$$\alpha_j|_{in\ v} = \langle v_j | \alpha \rangle. \quad (4.87)$$

Again inserting the identity operator in its closure form (44) with the internal index j' , and then using Eqs. (84) and (40), we get

$$\alpha_j|_{\text{in } v} = \left\langle v_j \left| \left(\sum_{j'} |u_{j'}\rangle \langle u_{j'}| \right) \right| \alpha \right\rangle = \sum_{j'} \langle v_j | u_{j'} \rangle \langle u_{j'} | \alpha \rangle = \sum_{j'} U_{jj'}^\dagger \langle u_{j'} | \alpha \rangle = \sum_{j'} U_{jj'}^\dagger \alpha_{j'}|_{\text{in } u}. \quad (4.88)$$

The reciprocal transform is performed by matrix elements of the operator \hat{U} :

$$\alpha_j|_{\text{in } u} = \sum_{j'} U_{jj'} \alpha_{j'}|_{\text{in } v}. \quad (4.89)$$

So, if the transform (75) from the “old” basis $\{u\}$ to the “new” basis $\{v\}$ is performed by a unitary operator, the change (88) of state vectors components at this transformation requires its Hermitian conjugate. This fact is similar to the transformation of components of a usual vector at coordinate frame rotation. For example, for a 2D vector whose actual position in space is fixed (Fig. 4):

$$\begin{pmatrix} \alpha_x' \\ \alpha_y' \end{pmatrix} = \begin{pmatrix} \cos \varphi & \sin \varphi \\ -\sin \varphi & \cos \varphi \end{pmatrix} \begin{pmatrix} \alpha_x \\ \alpha_y \end{pmatrix}, \quad (4.90)$$

but the reciprocal transform is performed by a different matrix, which may be obtained from that participating in Eq. (90) by the replacement $\varphi \rightarrow -\varphi$. This replacement has a clear geometric sense: if the “new” reference frame $\{x', y'\}$ is obtained from the “old” frame $\{x, y\}$ by a *councclockwise* rotation by angle φ , the reciprocal transformation requires angle $-\varphi$. (In this analogy, the unitary property (76) of the unitary transform operators corresponds to the equality of the determinants of both rotation matrices to 1.)

Due to the analogy between expressions (88) and (89) on one hand, and our old friend Eq. (62) on the other hand, it is tempting to skip indices in these new results by writing

$$|\alpha\rangle_{\text{in } v} = \hat{U}^\dagger |\alpha\rangle_{\text{in } u}, \quad |\alpha\rangle_{\text{in } u} = \hat{U} |\alpha\rangle_{\text{in } v}. \quad (\text{SYMBOLIC ONLY!}) \quad (4.91)$$

Since the matrix elements of \hat{U} and \hat{U}^\dagger do not depend on the basis, such language is not too bad and is mnemonically useful. However, since in the bra-ket formalism (or at least its version presented in this course), the state vectors are basis-independent, Eq. (91) has to be treated as a symbolic one, and should not be confused with the strict Eqs. (88)-(89), and with the rigorous basis-independent vector and operator equalities discussed in Sec. 2.

Now let us use the same trick of identity operator insertion, repeated twice, to find the transformation rule for matrix elements of an arbitrary operator:

$$A_{jj'}|_{\text{in } v} \equiv \langle v_j | \hat{A} | v_{j'} \rangle = \left\langle v_j \left| \left(\sum_k |u_k\rangle \langle u_k| \right) \hat{A} \left(\sum_{k'} |u_{k'}\rangle \langle u_{k'}| \right) \right| v_{j'} \right\rangle = \sum_{k,k'} U_{jk}^\dagger A_{kk'}|_{\text{in } u} U_{kj'}; \quad (4.92)$$

Matrix
elements'
transforms

absolutely similarly, we may also get

$$A_{jj'}|_{\text{in } u} \equiv \sum_{k,k'} U_{jk} A_{kk'}|_{\text{in } v} U_{kj'}^\dagger. \quad (4.93)$$

In the spirit of Eq. (91), we may represent these results symbolically as well, in a compact form:

$$\hat{A}|_{\text{in } v} = \hat{U}^\dagger \hat{A}|_{\text{in } u} \hat{U}, \quad \hat{A}|_{\text{in } u} = \hat{U} \hat{A}|_{\text{in } v} \hat{U}^\dagger. \quad (\text{SYMBOLIC ONLY!}) \quad (4.94)$$

As a sanity check, let us apply Eq. (93) to the identity operator:

$$\hat{I}|_{\text{in } v} = \left(\hat{U}^\dagger \hat{I} \hat{U} \right)_{\text{in } u} = \left(\hat{U}^\dagger \hat{U} \right)_{\text{in } u} = \hat{I}|_{\text{in } u} \quad (4.95)$$

- as it should be. One more (strict rather than symbolic) invariant of the basis change is the *trace* of any operator, defined as the sum of the diagonal terms of its matrix:

$$\text{Tr } \hat{A} \equiv \text{Tr } A \equiv \sum_j A_{jj}. \quad (4.96)$$

Operator's/
matrix'
trace

The (easy) proof of this fact, using previous relations, is left for the reader's exercise.

So far, I have implied that both state bases $\{u\}$ and $\{v\}$ are known, and the natural question is where does this information come from in quantum mechanics of actual physical systems. To get a partial answer to this question, let us return to Eq. (68), which defines the eigenstates and the eigenvalues of an operator. Let us assume that the eigenstates a_j of a certain operator \hat{A} form a full and orthonormal set, and calculate the matrix elements of the operator in the basis $\{a\}$ of these states, at their arbitrary numbering. For that, it is sufficient to inner-multiply both sides of Eq. (68), written for some index j' , by the bra-vector of an arbitrary state $a_{j'}$ of the same set:

$$\langle a_j | \hat{A} | a_{j'} \rangle = \langle a_j | A_{j'} | a_{j'} \rangle. \quad (4.97)$$

The left-hand side of this equality is the matrix element $A_{jj'}$ we are looking for, while its right-hand side is just $A_j \delta_{jj'}$. As a result, we see that the matrix is diagonal, with the diagonal consisting of the operator's eigenvalues:

$$A_{jj'} = A_j \delta_{jj'}. \quad (4.98)$$

Matrix
elements in
eigenstate
basis

In particular, in the eigenstate basis (but not necessarily in an arbitrary basis!), A_{jj} means the same as A_j . Thus the important problem of finding the eigenvalues and eigenstates of an operator is equivalent to the *diagonalization* of its matrix,¹⁷ i.e. finding the basis in which the operator's matrix acquires the diagonal form (98); then the diagonal elements are the eigenvalues, and the basis itself is the desirable set of eigenstates.

To see how this is done in practice, let us inner-multiply Eq. (68) by a bra-vector of the basis (say, $\{u\}$) in that we have happened to know the matrix elements A_{jj} :

$$\langle u_k | \hat{A} | a_j \rangle = \langle u_k | A_j | a_j \rangle. \quad (4.99)$$

On the left-hand side, we can (as usual :-) insert the identity operator between the operator \hat{A} and the ket-vector, and then use the closure relation (44) in the same basis $\{u\}$, while on the right-hand side, we can move the eigenvalue A_j (a *c*-number) out of the bracket, and then insert a summation over the same index as in the closure, compensating it with the proper Kronecker delta symbol:

$$\langle u_k | \hat{A} \sum_{k'} | u_{k'} \rangle \langle u_{k'} | a_j \rangle = A_j \sum_{k'} \langle u_{k'} | a_j \rangle \delta_{kk'}. \quad (4.100)$$

Moving out the signs of summation over k' , and using the definition (47) of the matrix elements, we get

¹⁷ Note that the expression "matrix diagonalization" is a very common but dangerous jargon. (Formally, a matrix is just a matrix, an ordered set of *c*-numbers, and cannot be "diagonalized".) It is OK to use this jargon if you remember clearly what it actually means – see the definition above.

$$\sum_{k'} (A_{kk'} - A_j \delta_{kk'}) \langle u_{k'} | a_j \rangle = 0. \quad (4.101)$$

But the set of such equalities, for all N possible values of the index k , is just a system of linear, homogeneous equations for unknown c -numbers $\langle u_k | a_j \rangle$. According to Eqs. (82)-(84), these numbers are nothing else than the matrix elements U_{kj} of a unitary matrix providing the required transformation from the initial basis $\{u\}$ to the basis $\{a\}$ that diagonalizes the matrix A . This system may be represented in the matrix form:

Matrix diagonalization

$$\begin{pmatrix} A_{11} - A_j & A_{12} & \dots \\ A_{21} & A_{22} - A_j & \dots \\ \dots & \dots & \dots \end{pmatrix} \begin{pmatrix} U_{1j} \\ U_{2j} \\ \dots \end{pmatrix} = 0, \quad (4.102)$$

and the condition of its consistency,

Characteristic equation for eigenvalues

$$\begin{vmatrix} A_{11} - A_j & A_{12} & \dots \\ A_{21} & A_{22} - A_j & \dots \\ \dots & \dots & \dots \end{vmatrix} = 0, \quad (4.103)$$

plays the role of the characteristic equation of the system. This equation has N roots A_j – the eigenvalues of the operator \hat{A} ; after they have been calculated, plugging any of them back into the system (102), we can use it to find N matrix elements U_{kj} ($k = 1, 2, \dots, N$) corresponding to this particular eigenvalue. However, since the equations (103) are homogeneous, they allow finding U_{kj} only to a constant multiplier. To ensure their normalization, i.e. enforce the unitary character of the matrix U , we may use the condition that all eigenvectors are normalized (just as the basis vectors are):

$$\langle a_j | a_j \rangle \equiv \sum_k \langle a_j | u_k \rangle \langle u_k | a_j \rangle \equiv \sum_k |U_{kj}|^2 = 1, \quad (4.104)$$

for each j . This normalization completes the diagonalization.¹⁸

Now (at last!) I can give the reader some examples. As a simple but very important case, let us diagonalize each of the operators described (in a certain two-function basis $\{u\}$, i.e. in two-dimensional Hilbert space) by the so-called *Pauli matrices*

Pauli matrices

$$\sigma_x \equiv \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y \equiv \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z \equiv \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (4.105)$$

Though introduced by a physicist, with a specific purpose to describe electron's spin, these matrices have a general mathematical significance, because together with the 2×2 identity matrix, they provide a full, linearly-independent system – meaning that an arbitrary 2×2 matrix may be represented as

$$\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} = bI + c_x \sigma_x + c_y \sigma_y + c_z \sigma_z, \quad (4.106)$$

¹⁸ A possible slight complication here is that the characteristic equation may give equal eigenvalues for certain groups of different eigenvectors. In such cases, the requirement of the mutual orthogonality of these *degenerate states* should be additionally enforced.

with a unique set of four *c*-number coefficients b , c_x , c_y , and c_z .

Since the matrix σ_z is already diagonal, with the evident eigenvalues ± 1 , let us start with diagonalizing the matrix σ_x . For it, the characteristic equation (103) is evidently

$$\begin{vmatrix} -A_j & 1 \\ 1 & -A_j \end{vmatrix} = 0, \quad \text{i.e. } A_j^2 - 1 = 0, \quad (4.107)$$

and has two roots, $A_{1,2} = \pm 1$. (Again, the state numbering is arbitrary!) So the eigenvalues of the matrix σ_x are the same as of the matrix σ_z . (The reader may readily check that the eigenvalues of the matrix σ_y are also the same.) However, the eigenvectors of the operators corresponding to these three matrices are different. To find them for σ_x , let us plug its first eigenvalue, $A_1 = +1$, back into equations (101) spelled out for this particular case ($j = 1$; $k, k' = 1, 2$):

$$\begin{aligned} -\langle u_1 | a_1 \rangle + \langle u_2 | a_1 \rangle &= 0, \\ \langle u_1 | a_1 \rangle - \langle u_2 | a_1 \rangle &= 0. \end{aligned} \quad (4.108)$$

These two equations are compatible (of course, because the used eigenvalue $A_1 = +1$ satisfies the characteristic equation), and any of them gives

$$\langle u_1 | a_1 \rangle = \langle u_2 | a_1 \rangle, \quad \text{i.e. } U_{11} = U_{21}. \quad (4.109)$$

With that, the normalization condition (104) yields

$$|U_{11}|^2 = |U_{21}|^2 = \frac{1}{2}. \quad (4.110)$$

Although the normalization is insensitive to the simultaneous multiplication of U_{11} and U_{21} by the same phase factor $\exp\{i\varphi\}$ with any real φ , it is convenient to keep the coefficients real, for example taking $\varphi = 0$, to get

$$U_{11} = U_{21} = \frac{1}{\sqrt{2}}. \quad (4.111)$$

Performing an absolutely similar calculation for the second characteristic value, $A_2 = -1$, we get $U_{12} = -U_{22}$, and we may choose the common phase to have

$$U_{12} = -U_{22} = \frac{1}{\sqrt{2}}, \quad (4.112)$$

so that the whole unitary matrix for diagonalization of the operator corresponding to σ_x is¹⁹

$$U_x = U_x^\dagger = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

(4.113)

Unitary matrix
diagonalizing
 σ_x

For what follows, it will be convenient to have this result expressed in the ket-relation form – see Eqs. (85)-(86):

$$|a_1\rangle = U_{11}|u_1\rangle + U_{21}|u_2\rangle = \frac{1}{\sqrt{2}}(|u_1\rangle + |u_2\rangle), \quad |a_2\rangle = U_{12}|u_1\rangle + U_{22}|u_2\rangle = \frac{1}{\sqrt{2}}(|u_1\rangle - |u_2\rangle), \quad (4.114a)$$

¹⁹ Note that though this particular unitary matrix is Hermitian, this is not true for an arbitrary choice of phases φ .

$$|u_1\rangle = U_{11}^\dagger |a_1\rangle + U_{21}^\dagger |a_2\rangle = \frac{1}{\sqrt{2}}(|a_1\rangle + |a_2\rangle), \quad |u_2\rangle = U_{12}^\dagger |a_1\rangle + U_{22}^\dagger |a_2\rangle = \frac{1}{\sqrt{2}}(|a_1\rangle - |a_2\rangle) \quad (4.114b)$$

Now let me show that these results are already sufficient to understand the Stern-Gerlach experiments described in Sec. 1 – but with two additional postulates. The first of them is that the interaction of a particle with the external magnetic field, besides that due to its orbital motion, may be described by the following *vector operator* of its spin dipole magnetic moment:²⁰

Spin
magnetic
moment

$$\hat{\mathbf{m}} = \gamma \hat{\mathbf{S}}, \quad (4.115a)$$

where the constant coefficient γ , specific for every particle type, is called the *gyromagnetic ratio*,²¹ and $\hat{\mathbf{S}}$ is the *vector operator of spin*, with three Cartesian components:

$$\hat{\mathbf{S}} = \mathbf{n}_x \hat{S}_x + \mathbf{n}_y \hat{S}_y + \mathbf{n}_z \hat{S}_z. \quad (4.115b)$$

Spin
vector
operator

Here $\mathbf{n}_{x,y,z}$ are the usual Cartesian unit vectors in the 3D geometric space (in the quantum-mechanics sense, just *c*-numbers, or rather “*c*-vectors”), while $\hat{S}_{x,y,z}$ are the “usual” (scalar) operators.

For the so-called *spin-½ particles* (including the electron), these components may be simply, as

$$\hat{S}_{x,y,z} = \frac{\hbar}{2} \hat{\sigma}_{x,y,z}, \quad (4.116a)$$

Spin-½
operator

expressed via those of the *Pauli vector operator* $\hat{\boldsymbol{\sigma}} \equiv \mathbf{n}_x \hat{\sigma}_x + \mathbf{n}_y \hat{\sigma}_y + \mathbf{n}_z \hat{\sigma}_z$, so that we may also write

$$\hat{\mathbf{S}} = \frac{\hbar}{2} \hat{\boldsymbol{\sigma}}. \quad (4.116b)$$

In turn, in the so-called *z-basis*, each Cartesian component of the latter operator is just the corresponding Pauli matrix (105), so that it may be also convenient to use the following 3D vector of these matrices:

Pauli
matrix
vector

$$\boldsymbol{\sigma} \equiv \mathbf{n}_x \sigma_x + \mathbf{n}_y \sigma_y + \mathbf{n}_z \sigma_z \equiv \begin{pmatrix} \mathbf{n}_z & \mathbf{n}_x - i\mathbf{n}_y \\ \mathbf{n}_x + i\mathbf{n}_y & -\mathbf{n}_z \end{pmatrix}. \quad (4.117)$$

The *z-basis*, in which such matrix representation of $\hat{\boldsymbol{\sigma}}$ is valid, is *defined* as an orthonormal basis of certain two states, commonly denoted \uparrow an \downarrow , in that the matrix of the operator $\hat{\sigma}_z$ is diagonal, with eigenvalues, respectively, $+1$ and -1 , and hence the matrix $S_z \equiv (\hbar/2)\sigma_z$ of \hat{S}_z is also diagonal, with the eigenvalues $+\hbar/2$ and $-\hbar/2$. Note that we do not “understand” what exactly the states \uparrow and \downarrow are,²² but

²⁰ This was the key point in the electron spin’s description, developed by W. Pauli in 1925-1927.

²¹ For the electron, with its negative charge $q = -e$, the gyromagnetic ratio is negative: $\gamma_e = -g_e e/2m_e$, where $g_e \approx 2$ is the dimensionless *g-factor*. Due to quantum-electrodynamic (relativistic) effects, this *g*-factor is slightly higher than 2: $g_e = 2(1 + \alpha/2\pi + \dots) \approx 2.002319304\dots$, where $\alpha \equiv e^2/4\pi\epsilon_0\hbar c \equiv (E_H/m_e c^2)^{1/2} \approx 1/137$ is the so-called *fine structure constant*. (The origin of its name will be clear from the discussion in Sec. 6.3.)

²² If you think about it, the word “understand” typically means that we can express a new, more complex notion in terms of those discussed earlier and considered “known”. In our current case, we cannot describe the spin states by some wavefunction $\psi(\mathbf{r})$, or any other mathematical notion discussed in the previous three chapters. The bracket formalism has been invented exactly to enable mathematical analyses of such “new” quantum states we do not

loosely associate them with some internal rotation of a spin- $\frac{1}{2}$ particle about the z -axis, with either positive or negative angular momentum component S_z . However, attempts to use such classical interpretation for quantitative predictions runs into fundamental difficulties – see Sec. 6 below.

The second necessary postulate describes the general relation between the bra-ket formalism and experiment. Namely, in quantum mechanics, each real observable A is represented by a Hermitian operator $\hat{A} = \hat{A}^\dagger$, and the result of its measurement,²³ in a quantum state α described by a linear superposition of the eigenstates a_j of the operator,

$$|\alpha\rangle = \sum_j \alpha_j |a_j\rangle, \quad \text{with } \alpha_j = \langle a_j | \alpha \rangle, \quad (4.118)$$

may be only one of the corresponding eigenvalues A_j .²⁴ Specifically, if the ket (118) and all eigenkets $|a_j\rangle$ are normalized to 1,

$$\langle \alpha | \alpha \rangle = 1, \quad \langle a_j | a_j \rangle = 1, \quad (4.119)$$

then the probability of a certain measurement outcome A_j is²⁵

$$W_j = |\alpha_j|^2 \equiv \alpha_j^* \alpha_j \equiv \langle \alpha | a_j \rangle \langle a_j | \alpha \rangle,$$

(4.120)

Quantum measurement postulate

This relation is evidently a generalization of Eq. (1.22) in wave mechanics. As a sanity check, let us assume that the set of the eigenstates a_j is full, and calculate the sum of the probabilities to find the system in one of these states:

$$\sum_j W_j = \sum_j \langle \alpha | a_j \rangle \langle a_j | \alpha \rangle = \langle \alpha | \hat{I} | \alpha \rangle = 1. \quad (4.121)$$

Now returning to the Stern-Gerlach experiment, conceptually the description of the first (z -oriented) experiment shown in Fig. 1 is the hardest for us, because the statistical ensemble describing the unpolarized electron beam at its input is *mixed* (“incoherent”), and cannot be described by a *pure* (“coherent”) superposition of the type (6) that have been the subject of our studies so far. (We will discuss such mixed ensembles in Chapter 7.) However, it is intuitively clear that its results are compatible with the description of the two output beams as sets of electrons in the pure states \uparrow and \downarrow , respectively. The absorber following that first stage (Fig. 2) just takes all spin-down electrons out of the picture, producing an output beam of polarized electrons in the definite \uparrow state. For such a beam, the probabilities (120) are $W_\uparrow = 1$ and $W_\downarrow = 0$. This is certainly compatible with the result of the “control” experiment shown on the bottom panel of Fig. 2: the repeated SG (z) stage does not split such a beam, keeping the probabilities the same.

initially “understand”. Gradually we get *accustomed* to these notions, and eventually, as we know more and more about their properties, start treating them as “known” ones.

²³ Here again, just like in Sec. 1.2, the statement implies the abstract notion of “ideal experiments”, deferring the discussion of real (physical) measurements until Chapter 10.

²⁴ As a reminder, at the end of Sec. 3 we have already proved that such eigenstates corresponding to different values A_j are orthogonal. If any of these values is degenerate, i.e. corresponds to several different eigenstates, they should be also selected orthogonal, in order for Eq. (118) to be valid.

²⁵ This key relation, in particular, explains the most common term for the (generally, complex) coefficients α_j , the *probability amplitudes*.

Now let us discuss the double Stern-Gerlach experiment shown on the top panel of Fig. 2. For that, let us represent the z -polarized beam in another basis – of the two states (I will denote them as \rightarrow and \leftarrow) in that, by definition, the matrix S_x is diagonal. But this is exactly the set we called $a_{1,2}$ in the σ_x matrix diagonalization problem solved above. On the other hand, the states \uparrow and \downarrow are exactly what we called $u_{1,2}$ in that problem, because in this basis, we know matrix σ explicitly – see Eq. (117). Hence, in the application to the electron spin problem, we may rewrite Eqs. (114) as

$$|\rightarrow\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle + |\downarrow\rangle), \quad |\leftarrow\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle - |\downarrow\rangle), \quad (4.122)$$

$$|\uparrow\rangle = \frac{1}{\sqrt{2}}(|\rightarrow\rangle + |\leftarrow\rangle), \quad |\downarrow\rangle = \frac{1}{\sqrt{2}}(|\rightarrow\rangle - |\leftarrow\rangle), \quad (4.123)$$

Relation between eigenvectors of S_x and S_z

Currently for us the first of Eqs. (123) is most important, because it shows that the quantum state of electrons entering the SG (x) stage may be represented as a coherent superposition of electrons with $S_x = +\hbar/2$ and $S_x = -\hbar/2$. Notice that the beams have equal probability amplitude moduli, so that according to Eq. (122), the split beams \rightarrow and \leftarrow have equal intensities, in accordance with experimental results. (The minus sign before the second ket-vector is of no consequence here, but it may have an impact on outcomes of other experiments – for example, if coherently split beams are brought together again.)

Now, let us discuss the most mysterious (from the classical point of view) multi-stage SG experiment shown on the middle panel of Fig. 2. After the second absorber has taken out all electrons in, say, the \leftarrow state, the remaining electrons, all in the state \rightarrow , are passed to the final, SG (z), stage. But according to the first of Eqs. (122), this state may be represented as a (coherent) linear superposition of the \uparrow and \downarrow states, with equal probability amplitudes. The final stage separates electrons in these two states into separate beams, with equal probabilities $W_\uparrow = W_\downarrow = \frac{1}{2}$ to find an electron in each of them, thus explaining the experimental results.

To conclude our discussion of the multistage Stern-Gerlach experiment, let me note that though it cannot be explained in terms of wave mechanics (which operates with *scalar* de Broglie waves), it has an analogy in classical theories of *vector* fields, such as the classical electrodynamics. Indeed, let a plane electromagnetic wave propagate normally to the plane of the drawing in Fig. 5, and pass through the linear polarizer 1.

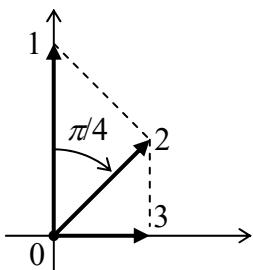

Fig. 4.5. A light polarization sequence similar to the three-stage Stern-Gerlach experiment shown on the middle panel of Fig. 2.

Similarly to the output of the initial SG (z) stages (including the absorbers) shown in Fig. 2, the output wave is linearly polarized in one direction – the vertical direction in Fig. 5. Now its electric field vector has no horizontal component – as may be revealed by the wave's full absorption in a perpendicular polarizer 3. However, let us pass the wave through polarizer 2 first. In this case, the

output wave does acquire a horizontal component, as can be, again, revealed by passing it through polarizer 3. If the angles between the polarization directions 1 and 2, and between 2 and 3, are both equal to $\pi/4$, each polarizer reduces the wave amplitude by a factor of $\sqrt{2}$, and hence the intensity by a factor of 2, exactly like in the multistage SG experiment, with the polarizer 2 playing the role of the SG (x) stage. The “only” difference is that the necessary angle is $\pi/4$, rather than by $\pi/2$ for the Stern-Gerlach experiment. In quantum electrodynamics (see Chapter 9 below), which confirms classical predictions for this experiment, this difference may be interpreted by that between the *integer* spin of electromagnetic field quanta (photons) and the *half-integer* spin of electrons.

4.5. Observables: Expectation values and uncertainties

After this particular (and hopefully inspiring) example, let us discuss the general relation between the Dirac formalism and experiment in more detail. The expectation value of an observable over *any* statistical ensemble (not necessarily coherent) may be always calculated using the general statistical rule (1.37). For the particular case of a coherent superposition (118), we can combine that rule with Eq. (120) and the second of Eqs. (118):

$$\langle A \rangle = \sum_j A_j W_j = \sum_j \alpha_j^* A_j \alpha_j = \sum_j \langle \alpha | a_j \rangle A_j \langle a_j | \alpha \rangle \equiv \langle \alpha | \left(\sum_j |a_j \rangle A_j \langle a_j| \right) | \alpha \rangle. \quad (4.124)$$

Now using Eq. (59) for the particular case of the eigenstate basis $\{a\}$, for which Eq. (98) is valid, we arrive at a very simple and important formula²⁶

$$\langle A \rangle = \langle \alpha | \hat{A} | \alpha \rangle. \quad (4.125)$$

Expectation
value
as a long
bracket

This is a clear analog of the wave-mechanics formula (1.23) – and as we will see soon, may be used to derive it. A big advantage of Eq. (125) is that it does not explicitly involve the eigenvector set of the corresponding operator, and allows the calculation to be performed in any convenient basis.²⁷

For example, let us consider an arbitrary coherent state α of spin- $1/2$,²⁸ and calculate the expectation values of its components. The calculations are easiest in the z -basis because we know the matrix elements of the spin operator components in that basis. Representing the ket- and bra-vectors of the given state as linear superpositions of the corresponding vectors of the basis states \uparrow and \downarrow ,

$$|\alpha\rangle = \alpha_{\uparrow} |\uparrow\rangle + \alpha_{\downarrow} |\downarrow\rangle, \quad \langle \alpha | = \langle \uparrow | \alpha_{\uparrow}^* + \langle \downarrow | \alpha_{\downarrow}^*. \quad (4.126)$$

and plugging these expressions to Eq. (125) written for the observable S_z , we get

²⁶ This equality reveals the full beauty of Dirac’s notation. Indeed, initially in this chapter the quantum-mechanical brackets just *reminded* the angular brackets used for the statistical averaging. Now we see that in this particular (but most important) case, the angular brackets of these two types may be indeed *equal* to each other!

²⁷ Note also that Eq. (120) may be rewritten in a form similar to Eq. (125): $W_j = \langle \alpha | \hat{\Lambda}_j | \alpha \rangle$, where $\hat{\Lambda}_j$ is the operator (42) of the state’s projection upon the j^{th} eigenstate a_j .

²⁸ For clarity, the noun “spin- $1/2$ ” is used, here and below, to denote the spin degree of freedom of a spin- $1/2$ particle, independent of its orbital motion.

$$\begin{aligned}\langle S_z \rangle &= \left(\langle \uparrow | \alpha_{\uparrow}^* + \langle \downarrow | \alpha_{\downarrow}^* \right) \hat{S}_z \left(\alpha_{\uparrow} | \uparrow \rangle + \alpha_{\downarrow} | \downarrow \rangle \right) \\ &= \alpha_{\uparrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_z | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_z | \downarrow \rangle + \alpha_{\uparrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_z | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_z | \downarrow \rangle.\end{aligned}\quad (4.127)$$

Now there are two equivalent ways (both very simple) to calculate the long brackets in this expression. The first one is to represent each of them in the matrix form in the z -basis, in which the bra- and ket-vectors of states \uparrow and \downarrow are the matrix-rows $(1, 0)$ and $(0, 1)$, or similar matrix-columns – the exercise highly recommended to the reader. Another (perhaps more elegant) way is to use the general Eq. (59), in the z -basis, together with the spin- $1/2$ -specific Eqs. (116a) and (105) to write

$$\hat{S}_x = \frac{\hbar}{2} (\langle \uparrow | \langle \downarrow | + \langle \downarrow | \langle \uparrow |), \quad \hat{S}_y = -i \frac{\hbar}{2} (\langle \uparrow | \langle \downarrow | - \langle \downarrow | \langle \uparrow |), \quad \hat{S}_z = \frac{\hbar}{2} (\langle \uparrow | \langle \uparrow | - \langle \downarrow | \langle \downarrow |). \quad (4.128)$$

For our particular calculation, we may plug the last of these expressions into Eq. (127), and use the orthonormality conditions (38):

$$\langle \uparrow | \uparrow \rangle = \langle \downarrow | \downarrow \rangle = 1, \quad \langle \uparrow | \downarrow \rangle = \langle \downarrow | \uparrow \rangle = 0. \quad (4.129)$$

Both approaches give (of course) the same result:

$$\langle S_z \rangle = \frac{\hbar}{2} \left(\alpha_{\uparrow} \alpha_{\uparrow}^* - \alpha_{\downarrow} \alpha_{\downarrow}^* \right). \quad (4.130)$$

This particular result might be also obtained using Eq. (120) for the probabilities $W_{\uparrow} = \alpha_{\uparrow} \alpha_{\uparrow}^*$ and $W_{\downarrow} = \alpha_{\downarrow} \alpha_{\downarrow}^*$, namely:

$$\langle S_z \rangle = W_{\uparrow} \left(+ \frac{\hbar}{2} \right) + W_{\downarrow} \left(- \frac{\hbar}{2} \right) = \alpha_{\uparrow} \alpha_{\uparrow}^* \left(+ \frac{\hbar}{2} \right) + \alpha_{\downarrow} \alpha_{\downarrow}^* \left(- \frac{\hbar}{2} \right). \quad (4.131)$$

The formal way (127), based on using Eq. (125), has, however, an advantage of being applicable, without any change, to finding the observables whose operators are *not* diagonal in the z -basis, as well. In particular, absolutely similar calculations give

$$\langle S_x \rangle = \alpha_{\uparrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_x | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_x | \downarrow \rangle + \alpha_{\uparrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_x | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_x | \downarrow \rangle = \frac{\hbar}{2} \left(\alpha_{\uparrow} \alpha_{\downarrow}^* + \alpha_{\downarrow} \alpha_{\uparrow}^* \right), \quad (4.132)$$

$$\langle S_y \rangle = \alpha_{\uparrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_y | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_y | \downarrow \rangle + \alpha_{\uparrow} \alpha_{\downarrow}^* \langle \downarrow | \hat{S}_y | \uparrow \rangle + \alpha_{\downarrow} \alpha_{\uparrow}^* \langle \uparrow | \hat{S}_y | \downarrow \rangle = i \frac{\hbar}{2} \left(\alpha_{\uparrow} \alpha_{\downarrow}^* - \alpha_{\downarrow} \alpha_{\uparrow}^* \right), \quad (4.133)$$

Let us have a good look at a particular spin state, for example the spin-up state \uparrow . According to Eq. (126), in this state $\alpha_{\uparrow} = 1$ and $\alpha_{\downarrow} = 0$, so that Eqs. (130)-(133) yield:

$$\langle S_z \rangle = \frac{\hbar}{2}, \quad \langle S_x \rangle = \langle S_y \rangle = 0. \quad (4.134)$$

Now let us use the same Eq. (125) to calculate the spin component uncertainties. According to Eqs. (105) and (116)-(117), the operator of each spin component squared is equal to $(\hbar/2)^2 \hat{I}$, so that the general Eq. (1.33) yields

$$(\delta S_z)^2 = \langle S_z^2 \rangle - \langle S_z \rangle^2 = \langle \uparrow | \hat{S}_z^2 | \uparrow \rangle - \left(\frac{\hbar}{2} \right)^2 = \left(\frac{\hbar}{2} \right)^2 \langle \uparrow | \hat{I} | \uparrow \rangle - \left(\frac{\hbar}{2} \right)^2 = 0, \quad (4.135a)$$

$$(\delta S_x)^2 = \langle S_x^2 \rangle - \langle S_x \rangle^2 = \langle \uparrow | \hat{S}_x^2 | \uparrow \rangle - 0 = \left(\frac{\hbar}{2} \right)^2 \langle \uparrow | \hat{I} | \uparrow \rangle = \left(\frac{\hbar}{2} \right)^2, \quad (4.135b)$$

$$(\delta S_y)^2 = \langle S_y^2 \rangle - \langle S_y \rangle^2 = \langle \uparrow | \hat{S}_y^2 | \uparrow \rangle - 0 = \left(\frac{\hbar}{2} \right)^2 \langle \uparrow | \hat{I} | \uparrow \rangle = \left(\frac{\hbar}{2} \right)^2. \quad (4.135c)$$

While Eqs. (134) and (135a) are compatible with the classical notion of the angular momentum of magnitude $\hbar/2$ being directed exactly along the z -axis, this correspondence should not be overstretched, because such classical picture cannot explain Eqs. (135b) and (135c). The best (but still imprecise!) classical image I can offer is the spin vector \mathbf{S} oriented, on average, in the z -direction, but still having its x - and y -components strongly “wobbling” (fluctuating) about their zero average values.

It is straightforward to verify that in the x -polarized and y -polarized states the situation is similar, with the corresponding change of axis indices. Thus, in neither of these states all three spin components have definite values. Let me show that this is not just an occasional fact, but reflects the perhaps most profound property of quantum mechanics, the *uncertainty relations*. For that, let us consider two measurable observables, A and B , of the same quantum system. There are two possibilities here. If the operators corresponding to these observables commute,

$$[\hat{A}, \hat{B}] = 0, \quad (4.136)$$

then all matrix elements of the commutator in any orthogonal basis (in particular, in the basis of eigenstates a_j of the operator \hat{A}) have to equal zero:

$$\langle a_j | [\hat{A}, \hat{B}] | a_{j'} \rangle \equiv \langle a_j | \hat{A} \hat{B} | a_{j'} \rangle - \langle a_j | \hat{B} \hat{A} | a_{j'} \rangle = 0. \quad (4.137)$$

In the first bracket of the middle expression, let us act by the (Hermitian!) operator \hat{A} on the bra-vector, while in the second one, on the ket-vector. According to Eq. (68), such action turns the operators into the corresponding eigenvalues, which may be taken out of the long brackets, so that we get

$$A_j \langle a_j | \hat{B} | a_{j'} \rangle - A_{j'} \langle a_j | \hat{B} | a_{j'} \rangle \equiv (A_j - A_{j'}) \langle a_j | \hat{B} | a_{j'} \rangle = 0. \quad (4.138)$$

This means that if all eigenstates of operator \hat{A} are non-degenerate (i.e. $A_j \neq A_{j'}$ if $j \neq j'$), the matrix of operator \hat{B} has to be diagonal in the basis $\{a\}$, i.e., the eigenstate sets of the operators \hat{A} and \hat{B} coincide. Such pairs of observables (and their operators) that share their eigenstates, are called *compatible*. For example, in the wave mechanics of a particle, its momentum (1.26) and kinetic energy (1.27) are compatible, sharing their eigenfunctions (1.29). Now we see that this is not occasional, because each Cartesian component of the kinetic energy is proportional to the square of the corresponding component of the momentum, and any operator commutes with an arbitrary integer power of itself:

$$[\hat{A}, \hat{A}^n] \equiv \left[\hat{A}, \underbrace{\hat{A} \hat{A} \dots \hat{A}}_n \right] = \hat{A} \underbrace{\hat{A} \hat{A} \dots \hat{A}}_n - \underbrace{\hat{A} \hat{A} \dots \hat{A}}_n \hat{A} = 0. \quad (4.139)$$

Now, what if operators \hat{A} and \hat{B} do *not* commute? Then the following *general uncertainty relation* is valid:

General uncertainty relation

$$\delta A \delta B \geq \frac{1}{2} \left| \langle [\hat{A}, \hat{B}] \rangle \right|, \quad (4.140)$$

where all expectation values are for the same but arbitrary state of the system. The proof of Eq. (140) may be divided into two steps, the first one proving the so-called *Schwartz inequality* for any two possible states, say α and β :²⁹

Schwartz inequality

$$\langle \alpha | \alpha \rangle \langle \beta | \beta \rangle \geq |\langle \alpha | \beta \rangle|^2. \quad (4.141)$$

Its proof may be readily achieved by applying the postulate (16) – that the norm of any legitimate state of the system cannot be negative – to the state with the following ket-vector:

$$|\delta\rangle \equiv |\alpha\rangle - \frac{\langle \beta | \alpha \rangle}{\langle \beta | \beta \rangle} |\beta\rangle, \quad (4.142)$$

where α and β are possible, non-null states of the system, so that the denominator in Eq. (142) is not equal to zero. For this case, Eq. (16) gives

$$\left(\langle \alpha | - \frac{\langle \alpha | \beta \rangle}{\langle \beta | \beta \rangle} \langle \beta | \right) \left(|\alpha\rangle - \frac{\langle \beta | \alpha \rangle}{\langle \beta | \beta \rangle} |\beta\rangle \right) \geq 0. \quad (4.143)$$

Opening the parentheses, we get

$$\langle \alpha | \alpha \rangle - \frac{\langle \alpha | \beta \rangle}{\langle \beta | \beta \rangle} \langle \beta | \alpha \rangle - \frac{\langle \beta | \alpha \rangle}{\langle \beta | \beta \rangle} \langle \alpha | \beta \rangle + \frac{\langle \alpha | \beta \rangle \langle \beta | \alpha \rangle}{\langle \beta | \beta \rangle^2} \langle \beta | \beta \rangle \geq 0. \quad (4.144)$$

After the cancellation of one inner product $\langle \beta | \beta \rangle$ in the numerator and the denominator of the last term, it cancels with the 2nd (or the 3rd) term. What remains is the Schwartz inequality (141).

Now let us apply this inequality to states

$$|\alpha\rangle \equiv \hat{A}|\gamma\rangle \quad \text{and} \quad |\beta\rangle \equiv \hat{B}|\gamma\rangle, \quad (4.145)$$

where, in both relations, γ is the same (but otherwise arbitrary) possible state of the system, and the deviation operators are defined similarly to the deviations of the observables (see Sec. 1.2):

$$\hat{\tilde{A}} \equiv \hat{A} - \langle \hat{A} \rangle, \quad \hat{\tilde{B}} \equiv \hat{B} - \langle \hat{B} \rangle. \quad (4.146)$$

With this substitution, and taking into account again that the observable operators \hat{A} and \hat{B} are Hermitian, Eq. (141) yields

$$\langle \gamma | \hat{\tilde{A}}^2 | \gamma \rangle \langle \gamma | \hat{\tilde{B}}^2 | \gamma \rangle \geq \left| \langle \gamma | \hat{\tilde{A}} \hat{\tilde{B}} | \gamma \rangle \right|^2. \quad (4.147)$$

Since the state γ is arbitrary, we may use Eq. (125) to rewrite this relation as an operator inequality:

²⁹ This inequality is the quantum-mechanical analog of the usual vector algebra's result $\alpha^2 \beta^2 \geq |\alpha \cdot \beta|^2$.

$$\delta A \delta B \geq \left| \langle \hat{A} \hat{B} \rangle \right|. \quad (4.148)$$

Actually, this is already an uncertainty relation, even “better” (stronger) than its standard form (140); moreover, it is more convenient in some cases. To prove Eq. (140), we need a couple of more steps. First, let us notice that the operator product participating in Eq. (148) may be recast as

$$\hat{A} \hat{B} = \frac{1}{2} \left\{ \hat{A}, \hat{B} \right\} - \frac{i}{2} \hat{C}, \quad \text{where } \hat{C} \equiv i \left[\hat{A}, \hat{B} \right]. \quad (4.149)$$

Any anticommutator of Hermitian operators, including that in Eq. (149), is a Hermitian operator, and its eigenvalues are purely real, so that its expectation value (in any state) is also purely real. On the other hand, the commutator part of Eq. (149) is just

$$\hat{C} \equiv i \left[\hat{A}, \hat{B} \right] = i \left(\hat{A} - \langle A \rangle \right) \left(\hat{B} - \langle B \rangle \right) - i \left(\hat{B} - \langle B \rangle \right) \left(\hat{A} - \langle A \rangle \right) = i \left(\hat{A} \hat{B} - \hat{B} \hat{A} \right) = i \left[\hat{A}, \hat{B} \right]. \quad (4.150)$$

Second, according to Eqs. (52) and (65), the Hermitian conjugate of any product of the Hermitian operators \hat{A} and \hat{B} is just the product of these operators swapped. Using the fact, we may write

$$\hat{C}^\dagger = \left(i \left[\hat{A}, \hat{B} \right] \right)^\dagger = -i (\hat{A} \hat{B})^\dagger + i (\hat{B} \hat{A})^\dagger = -i \hat{B} \hat{A} + i \hat{A} \hat{B} = i \left[\hat{A}, \hat{B} \right] = \hat{C}, \quad (4.151)$$

so that the operator \hat{C} is also Hermitian, i.e. its eigenvalues are also real, and thus its expectation value is purely real as well. As a result, the square of the expectation value of the operator product (149) may be represented as

$$\left\langle \hat{A} \hat{B} \right\rangle^2 = \left\langle \frac{1}{2} \left\{ \hat{A}, \hat{B} \right\} \right\rangle^2 + \left\langle \frac{1}{2} \hat{C} \right\rangle^2. \quad (4.152)$$

Since the first term on the right-hand side of this equality cannot be negative, we may write

$$\left\langle \hat{A} \hat{B} \right\rangle^2 \geq \left\langle \frac{1}{2} \hat{C} \right\rangle^2 = \left\langle \frac{i}{2} \left[\hat{A}, \hat{B} \right] \right\rangle^2, \quad (4.153)$$

and hence continue Eq. (148) as

$$\delta A \delta B \geq \left| \langle \hat{A} \hat{B} \rangle \right| \geq \frac{1}{2} \left| \langle \left[\hat{A}, \hat{B} \right] \rangle \right|, \quad (4.154)$$

thus proving Eq. (140).

For the particular case of operators \hat{x} and \hat{p}_x (or a similar pair of operators for another Cartesian coordinate), we may readily combine Eq. (140) with Eq. (2.14b) and to prove the original Heisenberg’s uncertainty relation (2.13). For the spin- $\frac{1}{2}$ operators defined by Eq. (116)-(117), it is very simple (and highly recommended to the reader) to show that

$$[\hat{\sigma}_j, \hat{\sigma}_{j'}] = 2i \varepsilon_{jj'j''} \hat{\sigma}_{j''}, \quad \text{i.e. } [\hat{S}_j, \hat{S}_{j'}] = i \varepsilon_{jj'j''} \hbar \hat{S}_{j''}, \quad (4.155)$$

Spin- $\frac{1}{2}$:
commutation
relations

where $\varepsilon_{jj'j''}$ is the *Levi-Civita permutation symbol* – see, e.g., MA Eq. (13.2). As a result, the uncertainty relations (140) for all Cartesian components of spin- $\frac{1}{2}$ systems are similar, for example

$$\delta S_x \delta S_y \geq \frac{\hbar}{2} |\langle S_z \rangle|, \text{ etc.} \quad (4.156)$$

Spin- $\frac{1}{2}$:
uncertainty
relations

In particular, as we already know, in the \uparrow state the right-hand side of this relation equals $(\hbar/2)^2 > 0$, so that neither of the uncertainties δS_x , δS_y can equal zero. As a reminder, our direct calculation earlier in this section has shown that each of these uncertainties is equal to $\hbar/2$, i.e. their product is equal to the lowest value allowed by the uncertainty relation (156) – just as the Gaussian wave packets (2.16) provide the lowest possible value of the product $\delta x \delta p_x$, allowed by the Heisenberg relation (2.13).

4.6. Quantum dynamics: Three pictures

So far in this chapter, I shied away from the discussion of the system's dynamics, implying that the bra- and ket-vectors were just their “snapshots” at a certain instant t . Now we are sufficiently prepared to examine their evolution in time. One of the most beautiful features of quantum mechanics is that this evolution may be described using either of three alternative “pictures”, giving exactly the same final results for the expectation values of all observables.

From the standpoint of our wave-mechanics experience, the *Schrödinger picture* is the most natural one. In this picture, the operators corresponding to time-independent observables (e.g., to the Hamiltonian function H of an isolated system) are also constant in time, while the bra- and ket-vectors evolve in time as

$$\langle \alpha(t) | = \langle \alpha(t_0) | \hat{u}^\dagger(t, t_0), \quad | \alpha(t) \rangle = \hat{u}(t, t_0) | \alpha(t_0) \rangle. \quad (4.157a)$$

Here $\hat{u}(t, t_0)$ is the *time-evolution operator*, which obeys the following differential equation:

$$i\hbar \frac{\partial}{\partial t} \hat{u} = \hat{H} \hat{u}, \quad (4.157b)$$

where \hat{H} is the Hamiltonian operator of the system – which is always Hermitian: $\hat{H}^\dagger = \hat{H}$, and t_0 is the initial moment of time. (Note that Eqs. (157) remain valid even if the Hamiltonian depends on time explicitly.) Differentiating the second of Eqs. (157a) over time t , and then using Eq. (157b) twice, we can merge these two relations into a single equation, without explicit use of the time-evolution operator:

$i\hbar \frac{\partial}{\partial t} | \alpha(t) \rangle = \hat{H} | \alpha(t) \rangle,$

(4.158)

Schrödinger
equation

which is frequently more convenient. (However, for some purposes the notion of the time-evolution operator, together with Eq. (157b), are useful – as we will see in a minute.) While Eq. (158) is a very natural generalization of the wave-mechanical equation (1.25), and is also frequently called the *Schrödinger equation*,³⁰ it still should be considered as a new, more general postulate, which finds its final justification (as it is usual in physics) in the agreement of its corollaries with experiment – more exactly, in the absence of a single credible contradiction to an experiment.

Starting the discussion of Eq. (158), let us first consider the case of a time-independent Hamiltonian, whose eigenstates a_n and eigenvalues E_n obey Eq. (68) for this operator:³¹

$$\hat{H} | a_n \rangle = E_n | a_n \rangle, \quad (4.159)$$

³⁰ Moreover, we will be able to *derive* Eq. (1.25) from Eq. (158) – see below.

³¹ I have switched the state index notation from j to n , which was used for numbering stationary states in Chapter 1, to emphasize the special role played by the stationary states a_n in quantum dynamics.

and hence are also time-independent. (Similarly to the wavefunctions ψ_n defined by Eq. (1.60), a_n are called the *stationary states* of the system.) Let us use Eqs. (158)-(159) to calculate the law of time evolution of the expansion coefficients α_n (i.e. the probability amplitudes) defined by Eq. (118), in a stationary state basis, using Eq. (158):

$$\dot{\alpha}_n(t) = \frac{d}{dt} \langle a_n | \alpha(t) \rangle = \langle a_n | \frac{d}{dt} | \alpha(t) \rangle = \langle a_n | \frac{1}{i\hbar} \hat{H} | \alpha(t) \rangle = \frac{E_n}{i\hbar} \langle a_n | \alpha(t) \rangle = -\frac{i}{\hbar} E_n \alpha_n. \quad (4.160)$$

This is the same simple equation as Eq. (1.61), and its integration, with the initial moment t_0 taken for 0, yields a similar result – cf. Eq. (1.62), just with the initial time t_0 rather than 0:

$$\alpha_n(t) = \alpha_n(t_0) \exp\left\{-\frac{i}{\hbar} E_n t\right\}. \quad (4.161)$$

Time
evolution
of probability
amplitudes

In order to illustrate how this result works, let us consider the dynamics of a spin-½ in a time-independent, uniform external magnetic field \mathcal{B} . To construct the system's Hamiltonian, we may apply the correspondence principle to the classical expression for the energy of a magnetic moment \mathbf{m} in the external magnetic field \mathcal{B} ,³²

$$U = -\mathbf{m} \cdot \mathcal{B}. \quad (4.162)$$

In quantum mechanics, the operator corresponding to the moment \mathbf{m} is given by Eq. (115) (suggested by W. Pauli), so that the spin-field interaction is described by the so-called *Pauli Hamiltonian*, which may be, due to Eqs. (116)-(117), represented in several equivalent forms:

$$\hat{H} = -\hat{\mathbf{m}} \cdot \mathcal{B} \equiv -\gamma \hat{\mathbf{S}} \cdot \mathcal{B} \equiv -\gamma \frac{\hbar}{2} \hat{\mathbf{\sigma}} \cdot \mathcal{B}. \quad (4.163a)$$

Pauli
Hamiltonian:
operator

If the z -axis is aligned with the field's direction, this expression is reduced to

$$\hat{H} = -\gamma \mathcal{B} \hat{S}_z \equiv -\gamma \mathcal{B} \frac{\hbar}{2} \hat{\sigma}_z. \quad (4.163b)$$

According to Eq. (117), in the z -basis of the spin states \uparrow and \downarrow , the matrix of the operator (163b) is

$$H = -\frac{\gamma \hbar \mathcal{B}}{2} \sigma_z \equiv \frac{\hbar \Omega}{2} \sigma_z, \quad \text{where } \Omega \equiv -\gamma \mathcal{B}. \quad (4.164)$$

Pauli
Hamiltonian:
 z -basis matrix

The constant Ω so defined coincides with the classical frequency of the precession, about the z -axis, of an axially-symmetric rigid body (the so-called *symmetric top*), with an angular momentum \mathbf{S} and the magnetic moment $\mathbf{m} = \gamma \mathbf{S}$, induced by the external torque $\tau = \mathbf{m} \times \mathcal{B}$.³³ (For an electron, with its negative gyromagnetic ratio $\gamma_e = -g_e e / 2m_e$, neglecting the tiny difference of the g_e -factor from 2, we get

$$\Omega = \frac{e}{m_e} \mathcal{B}, \quad (4.165)$$

so that according to Eq. (3.48), the frequency Ω coincides with the electron's cyclotron frequency ω_c .)

³² See, e.g., EM Eq. (5.100). As a reminder, we have already used this expression for the derivation of Eq. (3).

³³ See, e.g., CM Sec. 4.5, in particular Eq. (4.72), and EM Sec. 5.5, in particular Eq. (5.114) and its discussion.

In order to apply the general Eq. (161) to this case, we need to find the eigenstates a_n and eigenenergies E_n of our Hamiltonian. However, with our (smart :-) choice of the z -axis, the Hamiltonian matrix is already diagonal:

$$H = \frac{\hbar\Omega}{2} \sigma_z \equiv \frac{\hbar\Omega}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (4.166)$$

meaning that the states \uparrow and \downarrow are the eigenstates of this system, with the eigenenergies, respectively,

Spin-½ in magnetic field: eigenenergies

$$E_{\uparrow} = +\frac{\hbar\Omega}{2} \quad \text{and} \quad E_{\downarrow} = -\frac{\hbar\Omega}{2}. \quad (4.167)$$

Note that their difference,

$$\Delta E \equiv |E_{\uparrow} - E_{\downarrow}| = \hbar|\Omega| = \hbar|\gamma\mathcal{B}|, \quad (4.168)$$

corresponds to the classical energy $2|m\mathcal{B}|$ of flipping a magnetic dipole with the moment's magnitude $m = \gamma\hbar/2$, oriented along the direction of the field \mathcal{B} . Note also that if the product $\gamma\mathcal{B}$ is positive, then Ω is negative, so that E_{\uparrow} is negative, while E_{\downarrow} is positive. This is in the agreement with the classical picture of a magnetic dipole **m** having negative potential energy when it is aligned with the external magnetic field \mathcal{B} – see Eq. (162) again.

So, for the time evolution of the probability amplitudes of these states, Eq. (161) immediately yields the following expressions:

$$\alpha_{\uparrow}(t) = \alpha_{\uparrow}(0) \exp\left\{-\frac{i}{2}\Omega t\right\}, \quad \alpha_{\downarrow}(t) = \alpha_{\downarrow}(0) \exp\left\{+\frac{i}{2}\Omega t\right\}, \quad (4.169)$$

allowing a ready calculation of the time evolution of the expectation values of any observable. In particular, we can calculate the expectation value of S_z as a function of time by applying Eq. (130) to the (arbitrary) time moment t :

$$\langle S_z \rangle(t) = \frac{\hbar}{2} \left[\alpha_{\uparrow}(t)\alpha_{\uparrow}^*(t) - \alpha_{\downarrow}(t)\alpha_{\downarrow}^*(t) \right] = \frac{\hbar}{2} \left[\alpha_{\uparrow}(0)\alpha_{\uparrow}^*(0) - \alpha_{\downarrow}(0)\alpha_{\downarrow}^*(0) \right] = \langle S_z \rangle(0). \quad (4.170)$$

Thus the expectation value of the spin component parallel to the applied magnetic field remains constant in time, regardless of the initial state of the system. However, this is not true for the components perpendicular to the field. For example, Eq. (132), applied to the moment t , gives

$$\langle S_x \rangle(t) = \frac{\hbar}{2} \left[\alpha_{\uparrow}(t)\alpha_{\downarrow}^*(t) + \alpha_{\downarrow}(t)\alpha_{\uparrow}^*(t) \right] = \frac{\hbar}{2} \left[\alpha_{\uparrow}(0)\alpha_{\downarrow}^*(0)e^{-i\Omega t} + \alpha_{\downarrow}(0)\alpha_{\uparrow}^*(0)e^{+i\Omega t} \right]. \quad (4.171)$$

Clearly, this expression describes sinusoidal oscillations with frequency (164). The amplitude and the phase of these oscillations depend on initial conditions. Indeed, solving Eqs. (132)-(133) for the probability amplitude products, we get the following relations:

$$\hbar\alpha_{\downarrow}(t)\alpha_{\uparrow}^*(t) = \langle S_x \rangle(t) + i\langle S_y \rangle(t), \quad \hbar\alpha_{\uparrow}(t)\alpha_{\downarrow}^*(t) = \langle S_x \rangle(t) - i\langle S_y \rangle(t), \quad (4.172)$$

valid for any time t . Plugging their values for $t = 0$ into Eq. (171), we get

$$\begin{aligned}\langle S_x \rangle(t) &= \frac{1}{2} [\langle S_x \rangle(0) + i\langle S_y \rangle(0)] e^{+i\Omega t} + \frac{1}{2} [\langle S_x \rangle(0) - i\langle S_y \rangle(0)] e^{-i\Omega t} \\ &\equiv \langle S_x \rangle(0) \cos \Omega t - \langle S_y \rangle(0) \sin \Omega t.\end{aligned}\quad (4.173)$$

An absolutely similar calculation using Eq. (133) gives

$$\langle S_y \rangle(t) = \langle S_y \rangle(0) \cos \Omega t + \langle S_x \rangle(0) \sin \Omega t. \quad (4.174)$$

These formulas show, for example, that if at moment $t = 0$ the spin's state was \uparrow , i.e. $\langle S_x \rangle(0) = \langle S_y \rangle(0) = 0$, then the oscillation amplitudes of the both “lateral” components of the spin vanish. On the other hand, if the spin was initially in the state \rightarrow , i.e. had the definite, largest possible value of S_x , equal to $\hbar/2$ (in classics, we would say “the spin- $\frac{1}{2}$ was oriented in the x -direction”), then both expectation values $\langle S_x \rangle$ and $\langle S_y \rangle$ oscillate in time³⁴ with this amplitude, and with the phase shift $\pi/2$ between them.

So, the quantum-mechanical results for the expectation values of the Cartesian components of spin- $\frac{1}{2}$ are indistinguishable from the classical results for the precession, with the frequency $\Omega = -\gamma \mathcal{B}$,³⁵ of a symmetric top with the angular momentum of magnitude $S = \hbar/2$, about the field's direction (our axis z), under the effect of an external torque $\tau = \mathbf{m} \times \mathcal{B}$ exerted by the field \mathcal{B} on the magnetic moment $\mathbf{m} = \gamma \mathbf{S}$. Note, however, that the classical language does not describe the large quantum-mechanical uncertainties of the components, obeying Eqs. (156), which are absent in the classical picture – at least when it starts from a definite orientation of the angular momentum vector. Also, as we have seen in Sec. 3.5, the component L_z of the angular momentum at the orbital motion of particles is always a multiple of \hbar – see, e.g., Eq. (3.139). As a result, the angular momentum of a spin- $\frac{1}{2}$ particle, with $S_z = \pm \hbar/2$, cannot be explained by any summation of orbital angular moments of its hypothetical components, i.e. by any internal rotation of the particle about its axis.

After this illustration, let us return to the discussion of the general Schrödinger equation (157b) and prove the following fascinating fact: it is possible to write the general solution of this *operator* equation. In the easiest case when the Hamiltonian is time-independent, this solution is an exact analog of Eq. (161),

$$\hat{u}(t, t_0) = \hat{u}(t_0, t_0) \exp\left\{-\frac{i}{\hbar} \hat{H}(t-t_0)\right\} = \exp\left\{-\frac{i}{\hbar} \hat{H}(t-t_0)\right\}. \quad (4.175)$$

To start its proof we should, first of all, understand what a function (in this particular case, the exponent) of an operator means. In the operator (and matrix) algebra, such nonlinear functions are *defined* by their Taylor expansions; in particular, Eq. (175) means that

³⁴ This is one more (hopefully, redundant :-) illustration of the difference between the averaging over the statistical ensemble and that over time: in Eqs. (170), (173)-(174), and also in quite a few relations below, only the former averaging has been performed, so the results are still functions of time.

³⁵ Note that according to this relation, the gyromagnetic ratio γ may be interpreted just as the angular frequency of the spin precession per unit magnetic field – hence the name. In particular, for electrons, $|\gamma_e| \approx 1.761 \times 10^{11} \text{ s}^{-1}\text{T}^{-1}$; for protons, the ratio is much smaller, $\gamma_p \equiv g_p e/2m_p \approx 2.675 \times 10^8 \text{ s}^{-1}\text{T}^{-1}$, mostly because of their larger mass m_p , at a g -factor of the same order as for the electron: $g_p \approx 5.586$. For heavier spin- $\frac{1}{2}$ particles, e.g., atomic nuclei with such spin, the values of γ are correspondingly smaller – e.g., $\gamma \approx 8.681 \times 10^6 \text{ s}^{-1}\text{T}^{-1}$ for the ${}^{57}\text{Fe}$ nucleus.

$$\begin{aligned}\hat{u}(t, t_0) &= \hat{I} + \sum_{k=1}^{\infty} \frac{1}{k!} \left[-\frac{i}{\hbar} \hat{H}(t-t_0) \right]^k \\ &\equiv \hat{I} + \frac{1}{1!} \left(-\frac{i}{\hbar} \right) \hat{H}(t-t_0) + \frac{1}{2!} \left(-\frac{i}{\hbar} \right)^2 \hat{H}^2(t-t_0)^2 + \frac{1}{3!} \left(-\frac{i}{\hbar} \right)^3 \hat{H}^3(t-t_0)^3 + \dots,\end{aligned}\quad (4.176)$$

where $\hat{H}^2 \equiv \hat{H}\hat{H}$, $\hat{H}^3 \equiv \hat{H}\hat{H}\hat{H}$, etc. Working with such series of operator products is not as hard as one could imagine, due to their regular structure. For example, let us differentiate both sides of Eq. (176) over t , at constant t_0 , at the last stage using this equality again – backward:

$$\begin{aligned}\frac{\partial}{\partial t} \hat{u}(t, t_0) &= \hat{0} + \frac{1}{1!} \left(-\frac{i}{\hbar} \right) \hat{H} + \frac{1}{2!} \left(-\frac{i}{\hbar} \right)^2 \hat{H}^2 2(t-t_0) + \frac{1}{3!} \left(-\frac{i}{\hbar} \right)^2 \hat{H}^3 3(t-t_0)^2 + \dots \\ &\equiv \left(-\frac{i}{\hbar} \right) \hat{H} \left[\hat{I} + \frac{1}{1!} \left(-\frac{i}{\hbar} \right) \hat{H}(t-t_0) + \frac{1}{2!} \left(-\frac{i}{\hbar} \right)^2 \hat{H}^2(t-t_0)^2 \right] + \dots \equiv -\frac{i}{\hbar} \hat{H} \hat{u}(t, t_0),\end{aligned}\quad (4.177)$$

so that the differential equation (158) is indeed satisfied. On the other hand, Eq. (175) also satisfies the initial condition

$$\hat{u}(t_0, t_0) = \hat{u}^\dagger(t_0, t_0) = \hat{I} \quad (4.178)$$

that immediately follows from the definition (157a) of the evolution operator. Thus, Eq. (175) indeed gives the (unique) solution for the time evolution operator – in the Schrödinger picture.

Now let us allow the operator \hat{H} to be a function of time, but with the condition that its “values” (in fact, operators) at different instants commute with each other:

$$[\hat{H}(t'), \hat{H}(t'')] = 0, \quad \text{for any } t', t''. \quad (4.179)$$

(An important non-trivial example of such a Hamiltonian is the time-dependent part of the Hamiltonian of a particle, due to the effect of a classical, time-dependent, but position-independent force $\mathbf{F}(t)$,

$$\hat{H}_F = -\mathbf{F}(t) \cdot \hat{\mathbf{r}}. \quad (4.180)$$

Indeed, the radius vector’s operator $\hat{\mathbf{r}}$ does not depend explicitly on time and hence commutes with itself, as well as with the c -numbers $\mathbf{F}(t')$ and $\mathbf{F}(t'')$.) In this case, it is sufficient to replace, in all the above formulas, the product $\hat{H}(t-t_0)$ with the corresponding integral over time; in particular, Eq. (175) is generalized as

$$\hat{u}(t, t_0) = \exp \left\{ -\frac{i}{\hbar} \int_{t_0}^t \hat{H}(t') dt' \right\}.$$

(4.181)

Evolution operator:
explicit expression

This replacement means that the first form of Eq. (176) should be replaced with

$$\hat{u}(t, t_0) = \hat{I} + \sum_{k=1}^{\infty} \frac{1}{k!} \left(-\frac{i}{\hbar} \right)^k \left(\int_{t_0}^t \hat{H}(t') dt' \right)^k$$

$$\equiv \hat{I} + \sum_{k=1}^{\infty} \frac{1}{k!} \left(-\frac{i}{\hbar} \right)^k \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \dots \int_{t_0}^{t_{k-1}} dt_k \hat{H}(t_1) \hat{H}(t_2) \dots \hat{H}(t_k). \quad (4.182)$$

The proof that Eq. (182) satisfies Eq. (158) is absolutely similar to the one carried out above.

We may now use Eq. (181) to show that the time-evolution operator remains unitary at any moment, even for a time-dependent Hamiltonian, if it satisfies Eq. (179). Indeed, Eq. (181) yields

$$\hat{u}(t, t_0) \hat{u}^\dagger(t, t_0) = \exp \left\{ -\frac{i}{\hbar} \int_{t_0}^t \hat{H}(t') dt' \right\} \exp \left\{ +\frac{i}{\hbar} \int_{t_0}^t \hat{H}(t'') dt'' \right\}. \quad (4.183)$$

Since each of these exponents may be represented with the Taylor series (182), and, thanks to Eq. (179), different components of these sums may be swapped at will, the expression (183) may be manipulated exactly as the product of *c*-number exponents, for example rewritten as

$$\hat{u}(t, t_0) \hat{u}^\dagger(t, t_0) = \exp \left\{ -\frac{i}{\hbar} \left[\int_{t_0}^t \hat{H}(t') dt' - \int_{t_0}^t \hat{H}(t'') dt'' \right] \right\} = \exp \{ \hat{0} \} = \hat{I}. \quad (4.184)$$

This property ensures, in particular, that the system state's normalization does not depend on time:

$$\langle \alpha(t) | \alpha(t) \rangle = \langle \alpha(t_0) | \hat{u}^\dagger(t, t_0) \hat{u}(t, t_0) | \alpha(t_0) \rangle = \langle \alpha(t_0) | \alpha(t_0) \rangle. \quad (4.185)$$

The most difficult cases for the explicit solution of Eq. (158) are those where Eq. (179) is violated.³⁶ It may be proven that in these cases the integral limits in the last form of Eq. (182) should be truncated, giving the so-called *Dyson series*

$$\hat{u}(t, t_0) = \hat{I} + \sum_{k=1}^{\infty} \frac{1}{k!} \left(-\frac{i}{\hbar} \right)^k \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \dots \int_{t_0}^{t_{k-1}} dt_k \hat{H}(t_1) \hat{H}(t_2) \dots \hat{H}(t_k). \quad (4.186)$$

Since we would not have time/space to use this relation in our course, I will skip its proof.³⁷

Let me now return to the general discussion of quantum dynamics to outline its alternative, *Heisenberg picture*. For its introduction, let us recall that according to Eq. (125), in quantum mechanics the expectation value of any observable *A* is a long bracket. Let us explore an even more general form of such bracket:

$$\langle \alpha | \hat{A} | \beta \rangle. \quad (4.187)$$

(In some applications, the states α and β may be different.) As was discussed above, in the Schrödinger picture the bra- and ket-vectors of the states evolve in time, while the operators of observables remain time-independent (if they do not explicitly depend on time), so that Eq. (187), applied to a moment *t*, may be represented as

$$\langle \alpha(t) | \hat{A}_S | \beta(t) \rangle, \quad (4.188)$$

where the index “S” is added to emphasize the Schrödinger picture. Let us apply the evolution law (157a) to the bra- and ket-vectors in this expression:

³⁶ We will run into such situations in Chapter 7, but will not need to apply Eq. (186) there.

³⁷ It may be found, for example, in Chapter 5 of J. Sakurai’s textbook – see References.

$$\langle \alpha(t) | \hat{A}_s | \beta(t) \rangle = \langle \alpha(t_0) | \hat{u}^\dagger(t, t_0) \hat{A}_s \hat{u}(t, t_0) | \beta(t_0) \rangle. \quad (4.189)$$

This equality means that if we form a long bracket with bra- and ket-vectors of the initial-time states, together with the following time-dependent *Heisenberg operator*³⁸

$$\hat{A}_H(t) \equiv \hat{u}^\dagger(t, t_0) \hat{A}_s \hat{u}(t, t_0) = \hat{u}^\dagger(t, t_0) \hat{A}_H(t_0) \hat{u}(t, t_0), \quad (4.190)$$

all experimentally measurable results will remain the same as in the Schrödinger picture:

$$\langle \alpha(t) | \hat{A} | \beta(t) \rangle = \langle \alpha(t_0) | \hat{A}_H(t, t_0) | \beta(t_0) \rangle. \quad (4.191)$$

For full clarity, let us see how does the Heisenberg picture work for the same simple (but very important!) problem of the spin-½ precession in a *z*-oriented magnetic field, described (in the *z*-basis) by the Hamiltonian matrix (164). In that basis, Eq. (157b) for the time-evolution operator becomes

$$i\hbar \frac{\partial}{\partial t} \begin{pmatrix} u_{11} & u_{12} \\ u_{21} & u_{22} \end{pmatrix} = \frac{\hbar\Omega}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} u_{11} & u_{12} \\ u_{21} & u_{22} \end{pmatrix} \equiv \frac{\hbar\Omega}{2} \begin{pmatrix} u_{11} & u_{12} \\ -u_{21} & -u_{22} \end{pmatrix}. \quad (4.192)$$

We see that in this simple case the differential equations for different matrix elements of the evolution operator matrix are decoupled, and readily solvable, using the universal initial conditions (178):³⁹

$$u(t, 0) = \begin{pmatrix} e^{-i\Omega t/2} & 0 \\ 0 & e^{i\Omega t/2} \end{pmatrix} \equiv I \cos \frac{\Omega t}{2} - i\sigma_z \sin \frac{\Omega t}{2}. \quad (4.193)$$

Now let us use them in Eq. (190) to calculate the Heisenberg-picture operators of spin components – still in the *z*-basis. Dropping the index “H” for the notation brevity (the Heisenberg-picture operators are clearly marked by their dependence on time anyway), we get

$$\begin{aligned} S_x(t) &= u^\dagger(t, 0) S_x(0) u(t, 0) = \frac{\hbar}{2} u^\dagger(t, 0) \sigma_x u(t, 0) \\ &= \frac{\hbar}{2} \begin{pmatrix} e^{i\Omega t/2} & 0 \\ 0 & e^{-i\Omega t/2} \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} e^{-i\Omega t/2} & 0 \\ 0 & e^{i\Omega t/2} \end{pmatrix} \\ &= \frac{\hbar}{2} \begin{pmatrix} 0 & e^{i\Omega t} \\ e^{-i\Omega t} & 0 \end{pmatrix} = \frac{\hbar}{2} (\sigma_x \cos \Omega t - \sigma_y \sin \Omega t) \equiv S_x(0) \cos \Omega t - S_y(0) \sin \Omega t. \end{aligned} \quad (4.194)$$

Absolutely similar calculations of the other spin components yield

³⁸ Note that this *strict* relation is similar in structure to the first of the *symbolic* Eqs. (94), with the state bases $\{v\}$ and $\{u\}$ loosely associated with the time moments, respectively, t and t_0 .

³⁹ We could of course use this solution, together with Eq. (157), to obtain all the above results for this system within the Schrödinger picture. In our simple case, the use of Eqs. (161) for this purpose was more straightforward, but in some cases, e.g., for some time-dependent Hamiltonians, an explicit calculation of the time-evolution matrix may be the best (or even only practicable) way to proceed.

$$\mathbf{S}_y(t) = \frac{\hbar}{2} \begin{pmatrix} 0 & -ie^{i\Omega t} \\ ie^{-i\Omega t} & 0 \end{pmatrix} = \frac{\hbar}{2} (\sigma_y \cos \Omega t + \sigma_x \sin \Omega t) \equiv \mathbf{S}_y(0) \cos \Omega t + \mathbf{S}_x(0) \sin \Omega t, \quad (4.195)$$

$$\mathbf{S}_z(t) = \frac{\hbar}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \frac{\hbar}{2} \sigma_z = S_z(0). \quad (4.196)$$

One practical advantage of these formulas is that they describe the system's evolution for *arbitrary* initial conditions, thus making the analysis of initial state effects very simple. Indeed, since in the Heisenberg picture the expectation values of observables are calculated using Eq. (191) (with $\beta = \alpha$), with time-independent bra- and ket-vectors, such averaging of Eqs. (194)-(196) immediately returns us to Eqs. (170), (173), and (174), which were obtained above in the Schrödinger picture. Moreover, these equations for the Heisenberg operators formally coincide with the classical equations of the torque-induced precession for *c*-number variables. (Below we will see that the same exact correspondence is valid for the Heisenberg picture of the orbital motion.)

In order to see that the last fact is by no means a coincidence, let us combine Eqs. (157b) and (190) to form an explicit differential equation of the Heisenberg operator's evolution. For that, let us differentiate Eq. (190) over time:

$$\frac{d}{dt} \hat{A}_H = \frac{\partial \hat{u}^\dagger}{\partial t} \hat{A}_S \hat{u} + \hat{u}^\dagger \frac{\partial \hat{A}_S}{\partial t} \hat{u} + \hat{u}^\dagger \hat{A}_S \frac{\partial \hat{u}}{\partial t}. \quad (4.197)$$

Plugging in the derivatives of the time evolution operator from Eq. (157b) and its Hermitian conjugate, and multiplying both sides of the equation by $i\hbar$, we get

$$i\hbar \frac{d}{dt} \hat{A}_H = -\hat{u}^\dagger \hat{H} \hat{A}_S \hat{u} + i\hbar \hat{u}^\dagger \frac{\partial \hat{A}_S}{\partial t} \hat{u} + \hat{u}^\dagger \hat{A}_S \hat{H} \hat{u}. \quad (4.198a)$$

If for the Schrödinger-picture's Hamiltonian the condition similar to Eq. (179) is satisfied, then, according to Eqs. (177) or (182), the Hamiltonian commutes with the time evolution operator and its Hermitian conjugate, and may be swapped with any of them.⁴⁰ Hence, we may rewrite Eq. (198a) as

$$i\hbar \frac{d}{dt} \hat{A}_H = -\hat{H} \hat{u}^\dagger \hat{A}_S \hat{u} + i\hbar \hat{u}^\dagger \frac{\partial \hat{A}_S}{\partial t} \hat{u} + \hat{u}^\dagger \hat{A}_S \hat{H} \hat{u} \equiv i\hbar \hat{u}^\dagger \frac{\partial \hat{A}_S}{\partial t} \hat{u} + [\hat{u}^\dagger \hat{A}_S \hat{u}, \hat{H}]. \quad (4.198b)$$

Now using the definition (190) again, for both terms on the right-hand side, we may write

$$i\hbar \frac{d}{dt} \hat{A}_H = i\hbar \left(\frac{\partial \hat{A}}{\partial t} \right)_H + [\hat{A}_H, \hat{H}].$$

(4.199)

Heisenberg
equation
of motion

This is the so-called *Heisenberg equation of motion*.

Let us see how this equation looks for the same problem of the spin-1/2 precession in a *z*-oriented, time-independent magnetic field, described in the *z*-basis by the Hamiltonian matrix (164), which does not depend on time. In this basis, Eq. (199) for the vector operator of spin reads⁴¹

⁴⁰ Due to the same reason, $\hat{H}_H \equiv \hat{u}^\dagger \hat{H}_S \hat{u} = \hat{u}^\dagger \hat{u} \hat{H}_S = \hat{H}_S$; this is why the Hamiltonian operator's index may be dropped in Eqs. (198)-(199).

$$i\hbar \begin{pmatrix} \dot{\mathbf{S}}_{11} & \dot{\mathbf{S}}_{12} \\ \dot{\mathbf{S}}_{21} & \dot{\mathbf{S}}_{22} \end{pmatrix} = \frac{\hbar\Omega}{2} \left[\begin{pmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} \\ \mathbf{S}_{21} & \mathbf{S}_{22} \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \right] = \hbar\Omega \begin{pmatrix} 0 & -\mathbf{S}_{12} \\ \mathbf{S}_{21} & 0 \end{pmatrix}. \quad (4.200)$$

Once again, the equations for different matrix elements are decoupled, and their solution is elementary:

$$\begin{aligned} \mathbf{S}_{11}(t) &= \mathbf{S}_{11}(0) = \text{const}, & \mathbf{S}_{22}(t) &= \mathbf{S}_{22}(0) = \text{const}, \\ \mathbf{S}_{12}(t) &= \mathbf{S}_{12}(0)e^{+i\Omega t}, & \mathbf{S}_{21}(t) &= \mathbf{S}_{21}(0)e^{-i\Omega t}. \end{aligned} \quad (4.201)$$

According to Eq. (190), the initial values of the Heisenberg-picture matrix elements are just the Schrödinger-picture ones, so that using Eq. (117) we may rewrite this solution in either of two forms:

$$\begin{aligned} \mathbf{S}(t) &= \frac{\hbar}{2} \left[\mathbf{n}_x \begin{pmatrix} 0 & e^{+i\Omega t} \\ e^{-i\Omega t} & 0 \end{pmatrix} + \mathbf{n}_y \begin{pmatrix} 0 & -ie^{+i\Omega t} \\ ie^{-i\Omega t} & 0 \end{pmatrix} + \mathbf{n}_z \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \right] \\ &\equiv \frac{\hbar}{2} \begin{pmatrix} \mathbf{n}_z & \mathbf{n}_-e^{+i\Omega t} \\ \mathbf{n}_+e^{-i\Omega t} & -\mathbf{n}_z \end{pmatrix}, \quad \text{where } \mathbf{n}_\pm \equiv \mathbf{n}_x \pm i\mathbf{n}_y. \end{aligned} \quad (4.202)$$

The simplicity of the last expression is spectacular. (Remember, it covers *any* initial conditions and *all* three spatial components of spin!) On the other hand, for some purposes the previous form may be more convenient; in particular, its Cartesian components give our earlier results (194)-(196).⁴²

One of the advantages of the Heisenberg picture is that it provides a more clear link between classical and quantum mechanics, found by P. Dirac. Indeed, analytical classical mechanics may be used to derive the following equation of time evolution of an arbitrary function $A(q_j, p_j, t)$ of the generalized coordinates q_j and momenta p_j of the system, and time t :⁴³

$$\frac{dA}{dt} = \frac{\partial A}{\partial t} - \{A, H\}_P, \quad (4.203)$$

where H is the classical Hamiltonian function of the system, and $\{....\}$ is the so-called *Poisson bracket* defined, for two arbitrary functions $A(q_j, p_j, t)$ and $B(q_j, p_j, t)$, as

Poisson
bracket

$$\{A, B\}_P \equiv \sum_j \left(\frac{\partial A}{\partial p_j} \frac{\partial B}{\partial q_j} - \frac{\partial A}{\partial q_j} \frac{\partial B}{\partial p_j} \right). \quad (4.204)$$

Comparing Eq. (203) with Eq. (199), we see that the correspondence between the classical and quantum mechanics (in the Heisenberg picture) is provided by the following symbolic relation

⁴¹ Using the commutation relations (155), this equation may be readily generalized to the case of an arbitrary magnetic field $\mathcal{B}(t)$ and an arbitrary state basis – the exercise highly recommended to the reader.

⁴² Note that the “values” of the same Heisenberg operator at different moments of time may or may not commute. For example, consider a free 1D particle, with the time-independent Hamiltonian $\hat{H} = \hat{p}^2/2m$. In this case, Eq. (199) yields the following equations: $i\hbar\dot{\hat{x}} = [\hat{x}, \hat{H}] = i\hbar\hat{p}/m$ and $i\hbar\dot{\hat{p}} = [\hat{p}, \hat{H}] = 0$, with simple solutions (similar to those for the classical motion): $\hat{p}(t) = \text{const} = \hat{p}(0)$ and $\hat{x}(t) = \hat{x}(0) + \hat{p}(0)t/m$, so that $[\hat{x}(0), \hat{x}(t)] = [\hat{x}(0), \hat{p}(0)]t/m \equiv [\hat{x}_S, \hat{p}_S]t/m = i\hbar t/m \neq 0$, for $t \neq 0$.

⁴³ See, e.g., CM Eq. (10.17). The notation there does not use the subscript “P” that is employed in Eqs. (203)-(205) to distinguish the classical Poisson bracket (204) from the quantum anticommutator (34).

$$\{A, B\}_P \leftrightarrow \frac{i}{\hbar} [\hat{A}, \hat{B}]. \quad (4.205)$$

This relation may be used, in particular, for finding appropriate operators for the system's observables, if their form is not immediately evident from the correspondence principle.

Finally, let us discuss one more alternative picture of quantum dynamics. It is also attributed to Dirac, and is called either the "Dirac picture", or (more frequently) the *interaction picture*. The last name stems from the fact that this picture is very useful for the *perturbative* (approximate) approaches to systems whose Hamiltonians may be partitioned into two parts,

$$\hat{H} = \hat{H}_0 + \hat{H}_{\text{int}}, \quad (4.206)$$

where \hat{H}_0 is the sum of relatively simple Hamiltonians of the component subsystems, while the second term in Eq. (206) represents their weak interaction. (Note, however, that all relations in the balance of this section are exact and not directly based on the interaction weakness.) In this case, it is natural to consider, together with the full operator $\hat{u}(t, t_0)$ of the system's evolution, which obeys Eq. (157b), a similarly defined unitary operator $\hat{u}_0(t, t_0)$ of evolution of the "unperturbed system" described by the Hamiltonian \hat{H}_0 alone:

$$i\hbar \frac{\partial}{\partial t} \hat{u}_0 = \hat{H}_0 \hat{u}_0, \quad (4.207)$$

and also the following *interaction evolution operator*,

$$\hat{u}_I \equiv \hat{u}_0^\dagger \hat{u}. \quad (4.208)$$

The motivation for these definitions become more clear if we insert the reciprocal relation,

$$\hat{u} \equiv \hat{u}_0 \hat{u}_0^\dagger \hat{u} = \hat{u}_0 \hat{u}_1, \quad (4.209)$$

and its Hermitian conjugate,

$$\hat{u}^\dagger = (\hat{u}_0 \hat{u}_1)^\dagger = \hat{u}_1^\dagger \hat{u}_0^\dagger, \quad (4.210)$$

into the basic Eq. (189):

$$\begin{aligned} \langle \alpha | \hat{A} | \beta \rangle &= \langle \alpha(t_0) | \hat{u}^\dagger(t, t_0) \hat{A}_S \hat{u}(t, t_0) | \beta(t_0) \rangle \\ &= \langle \alpha(t_0) | \hat{u}_1^\dagger(t, t_0) \hat{u}_0^\dagger(t, t_0) \hat{A}_S \hat{u}_0(t, t_0) \hat{u}_1(t, t_0) | \beta(t_0) \rangle. \end{aligned} \quad (4.211)$$

This relation shows that any long bracket (187), i.e. any experimentally verifiable result of quantum mechanics, may be expressed as

$$\langle \alpha | \hat{A} | \beta \rangle = \langle \alpha_I(t) | \hat{A}_I(t) | \beta_I(t) \rangle, \quad (4.212)$$

if we assume that both the state vectors and the operators depend on time, with the vectors evolving only due to the *interaction operator* \hat{u}_I ,

$$\langle \alpha_I(t) | \equiv \langle \alpha(t_0) | \hat{u}_I^\dagger(t, t_0), \quad | \beta_I(t) \rangle \equiv \hat{u}_I(t, t_0) | \beta(t_0) \rangle, \quad (4.213)$$

while the operators' evolution being governed by the *unperturbed operator* \hat{u}_0 :

$$\hat{A}_I(t) \equiv \hat{u}_0^\dagger(t, t_0) \hat{A}_S \hat{u}_0(t, t_0). \quad (4.214)$$

These relations describe the interaction picture of quantum dynamics. Let me defer an example of its use until the perturbative analysis of open quantum systems in Sec. 7.6, and end this section with a proof that the interaction evolution operator (208) satisfies the following natural equation,

$$i\hbar \frac{\partial}{\partial t} \hat{u}_I = \hat{H}_I \hat{u}_I, \quad (4.215)$$

where \hat{H}_I is the interaction Hamiltonian formed from \hat{H}_{int} in accordance with the same rule (214):

$$\hat{H}_I(t) \equiv \hat{u}_0^\dagger(t, t_0) \hat{H}_{\text{int}} \hat{u}_0(t, t_0). \quad (4.216)$$

The proof is very straightforward: first using the definition (208), and then Eqs. (157b) and the Hermitian conjugate of Eq. (207), we may write

$$\begin{aligned} i\hbar \frac{\partial}{\partial t} \hat{u}_I &\equiv i\hbar \frac{\partial}{\partial t} (\hat{u}_0^\dagger \hat{u}) \equiv i\hbar \frac{\partial \hat{u}_0^\dagger}{\partial t} \hat{u} + \hat{u}_0^\dagger i\hbar \frac{\partial \hat{u}}{\partial t} = -\hat{H}_0 \hat{u}_0^\dagger \hat{u} + \hat{u}_0^\dagger \hat{H} \hat{u} = -\hat{H}_0 \hat{u}_0^\dagger \hat{u} + \hat{u}_0^\dagger (\hat{H}_0 + \hat{H}_{\text{int}}) \hat{u} \\ &\equiv -\hat{H}_0 \hat{u}_0^\dagger \hat{u} + \hat{u}_0^\dagger \hat{H}_0 \hat{u} + \hat{u}_0^\dagger \hat{H}_{\text{int}} \hat{u} \equiv (-\hat{H}_0 \hat{u}_0^\dagger + \hat{u}_0^\dagger \hat{H}_0) \hat{u} + \hat{u}_0^\dagger \hat{H}_{\text{int}} \hat{u}. \end{aligned} \quad (4.217)$$

Since \hat{u}_0^\dagger may be represented as an integral of an exponent of \hat{H}_0 over time (similar to Eq. (181) relating \hat{u} and \hat{H}), these operators commute, so that the parentheses in the last form of Eq. (217) vanish. Now plugging \hat{u} from the last form of Eq. (209), we get the equation,

$$i\hbar \frac{\partial}{\partial t} \hat{u}_I = \hat{u}_0^\dagger \hat{H}_{\text{int}} \hat{u}_0 u_I \equiv (\hat{u}_0^\dagger \hat{H}_{\text{int}} \hat{u}_0) \hat{u}_I, \quad (4.218)$$

which is clearly equivalent to the combination of Eqs. (215) and (216).

As Eq. (215) shows, if the energy scale of the interaction H_{int} is much smaller than that of the background Hamiltonian H_0 , the interaction evolution operators \hat{u}_I and \hat{u}_I^\dagger , and hence the state vectors (213) evolve relatively slowly, without fast background oscillations. This is very convenient for the perturbative approaches to complex interacting systems, in particular to the “open” quantum systems that weakly interact with their environment – see Sec. 7.6.

4.7. Coordinate and momentum representations

Now let me show that in application to the orbital motion of a particle, the bra-ket formalism naturally reduces to the notions and postulates of wave mechanics, which were discussed in Chapter 1. For that, we first have to modify some of the above formulas for the case of a basis with a continuous spectrum of eigenvalues. In that case, it is more appropriate to replace discrete indices, such as j, j' , etc. broadly used above, with the corresponding eigenvalue – just as it was done earlier for functions of the wave vector – see, e.g., Eqs. (1.88), (2.20), etc. For example, the key Eq. (68), defining the eigenkets and eigenvalues of an operator, may be conveniently rewritten in the form

$$\hat{A}|a_A\rangle = A|a_A\rangle. \quad (4.219)$$

More substantially, all sums over such continuous eigenstate sets should be replaced with integrals. For example, for a full and orthonormal set of the continuous eigenstates $|a_A\rangle$, the closure relation (44) should be replaced with

$$\int dA |a_A\rangle\langle a_A| = \hat{I}, \quad (4.220)$$

Continuous spectrum:
closure relation

where the integral is over the whole interval of possible eigenvalues of the observable A .⁴⁴ Applying this relation to the ket-vector of an arbitrary state α , we get the following replacement of Eq. (37):

$$|\alpha\rangle \equiv \hat{I}|\alpha\rangle = \int dA |a_A\rangle\langle a_A|\alpha\rangle = \int dA \langle a_A|\alpha\rangle|a_A\rangle. \quad (4.221)$$

For the particular case when $|\alpha\rangle = |a_{A'}\rangle$, this relation requires that

$$\langle a_A|a_{A'}\rangle = \delta(A - A'); \quad (4.222)$$

Continuous spectrum:
state ortho-normality

this formula replaces the orthonormality condition (38).

According to Eq. (221), in the continuous case the bracket $\langle a_A|\alpha\rangle$ still the role of probability amplitude, i.e. a complex c -number whose modulus squared determines the state a_A 's probability – see the last form of Eq. (120). However, for a continuous observable, the probability to find the system exactly in a particular state is infinitesimal; instead, we should speak about the probability $dW = w(A)dA$ of finding the observable within a small interval $dA \ll A$ near the value A , with *probability density* $w(A) \propto |\langle a_A|\alpha\rangle|^2$. The coefficient in this relation may be found by making a similar change from the summation to integration in the normalization condition (121):

$$\int dA \langle \alpha|a_A\rangle\langle a_A|\alpha\rangle = 1. \quad (4.223)$$

Since the total probability of the system to be in *some* state should be equal to $\int w(A)dA$, this means that

$$w(A) = \langle \alpha|a_A\rangle\langle a_A|\alpha\rangle = |\langle \alpha|a_A\rangle|^2. \quad (4.224)$$

Continuous spectrum:
probability density

Now let us see how we can calculate the expectation values of continuous observables, i.e. their ensemble averages. If we speak about the same observable A whose eigenstates are used as the continuous basis (or any compatible observable), everything is simple. Indeed, inserting Eq. (224) into the general statistical relation

$$\langle A \rangle = \int w(A)AdA, \quad (4.225)$$

which is just the obvious continuous version of Eq. (1.37), we get

$$\langle A \rangle = \int \langle \alpha|a_A\rangle A \langle a_A|\alpha\rangle dA. \quad (4.226)$$

Inserting a delta-function to represent this expression as a formally double integral,

$$\langle A \rangle = \int dA \int dA' \langle \alpha|a_A\rangle A \delta(A - A') \langle a_{A'}|\alpha\rangle, \quad (4.227)$$

and using the continuous-spectrum version of Eq. (98),

⁴⁴ The generalization to cases when the eigenvalue spectrum consists of both a continuum interval plus some set of discrete values, is straightforward, though leads to somewhat cumbersome formulas.

$$\langle a_A | \hat{A} | a_{A'} \rangle = A \delta(A - A'), \quad (4.228)$$

we may write

$$\langle A \rangle = \int dA \int dA' \langle \alpha | a_A \rangle \langle a_A | \hat{A} | a_{A'} \rangle \langle a_{A'} | \alpha \rangle \equiv \langle \alpha | \hat{A} | \alpha \rangle, \quad (4.229)$$

so that Eq. (4.125) remains valid in the continuous-spectrum case without any changes.

The situation is a bit more complicated for the expectation values of an operator that does not commute with the basis-generating operator, because its matrix in that basis may not be diagonal. We will consider (and overcome :-) this technical difficulty very soon, but otherwise we are ready for a discussion of the relation between the bra-ket formalism and the wave mechanics. (For the notation simplicity I will discuss its 1D version; its generalization to 2D and 3D cases is straightforward.)

Let us postulate the (intuitively almost evident) existence of a quantum state basis, whose ket-vectors will be called $|x\rangle$, corresponding to a certain definite value x of the particle's coordinate. Writing the following trivial identity:

$$x|x\rangle = x|x\rangle, \quad (4.230)$$

and comparing this relation with Eq. (219), we see that they do not contradict each other if we assume that x on the left-hand side of this relation is the (Hermitian) operator \hat{x} of particle's coordinate, whose action on a ket- (or bra-) vector is just its multiplication by the c -number x . (This looks like a proof, but is actually a separate, independent postulate, no matter how plausible.) Hence we may consider vectors $|x\rangle$ as the eigenstates of the operator \hat{x} . Let me hope that the reader will excuse me if I do not pursue here a strict proof that this set is full and orthogonal,⁴⁵ so that we may apply to them Eq. (222):

$$\langle x | x' \rangle = \delta(x - x'). \quad (4.231)$$

Using this basis is called the *coordinate representation* – the term which was already used at the end of Sec. 1.1, but without explanation.

In the basis of the x -states, the inner product $\langle a_A | \alpha(t) \rangle$ becomes $\langle x | \alpha(t) \rangle$, and Eq. (223) takes the following form:

$$w(x, t) = \langle \alpha(t) | x \rangle \langle x | \alpha(t) \rangle \equiv \langle x | \alpha(t) \rangle^* \langle x | \alpha(t) \rangle. \quad (4.232)$$

Comparing this formula with the basic postulate (1.22) of wave mechanics, we see that they coincide if the wavefunction of a time-dependent state α is identified with that short bracket:⁴⁶

$$\Psi_\alpha(x, t) \equiv \langle x | \alpha(t) \rangle. \quad (4.233)$$

This key formula provides the desired connection between the bra-ket formalism and the wave mechanics, and should not be too surprising for the (thoughtful :-) reader. Indeed, Eq. (45) shows that any inner product of two state vectors describing two states is a measure of their coincidence – just as the scalar product of two geometric vectors is; the orthonormality condition (38) is a particular manifestation of this fact. In this language, the particular value (233) of a wavefunction Ψ_α at some

⁴⁵Such proof is rather involved mathematically, but physically this fact should be evident.

⁴⁶I do not quite like expressions like $\langle x | \Psi \rangle$ used in some papers and even textbooks. Of course, one is free to replace α with any other letter (Ψ including) to denote a quantum state, but then it is better not to use the same letter to denote the wavefunction, i.e. an inner product of two state vectors, to avoid confusion.

point x and moment t characterizes “how much of a particular coordinate x ” does the state α contain at time t . (Of course, this informal language is too crude to reflect the fact that $\Psi_\alpha(x, t)$ is a complex function, which has not only a modulus but also an argument – the quantum-mechanical phase.)

Now let us rewrite the most important formulas of the bra-ket formalism in the wave mechanics notation. Inner-multiplying both parts of Eq. (219) by the ket-vector $\langle x|$, and then inserting into the left-hand side of that relation the identity operator in the form (220) for coordinate x' , we get

$$\int dx' \langle x | \hat{A} | x' \rangle \langle x' | a_A \rangle = A \langle x | a_A \rangle, \quad (4.234)$$

i.e., using the wavefunction’s definition (233),

$$\int dx' \langle x | \hat{A} | x' \rangle \Psi_A(x') = A \Psi_A(x), \quad (4.235)$$

where, for the notation brevity, the time dependence of the wavefunction is just implied (with the capital Ψ serving as a reminder of this fact), and will be restored when needed.

For a general operator, we would have to stop here, because if it does not commute with the coordinate operator, its matrix in the x -basis is not diagonal, and the integral on the left-hand side of Eq. (235) cannot be worked out explicitly. However, virtually all quantum-mechanical operators discussed in this course⁴⁷ are (*space-*) *local*: they depend on only one spatial coordinate, say x . For such operators, the left-hand side of Eq. (235) may be further transformed as

$$\int \langle x | \hat{A} | x' \rangle \Psi(x') dx' = \int \langle x | x' \rangle \hat{A} \Psi(x') dx' \equiv \hat{A} \int \delta(x - x') \Psi(x') dx' = \hat{A} \Psi(x). \quad (4.236)$$

The first step in this transformation may appear as elementary as the last two, with the ket-vector $|x'\rangle$ swapped with the operator depending only on x ; however, due to the delta-functional character of the bracket (231), this step is, in fact, an additional postulate, so that the second equality in Eq. (236) essentially *defines* the coordinate representation of the local operator, whose explicit form still needs to be determined.

Let us consider, for example, the 1D version of the Hamiltonian (1.41),

$$\hat{H} = \frac{\hat{p}_x^2}{2m} + U(\hat{x}), \quad (4.237)$$

which was the basis of all our discussions in Chapter 2. Its potential-energy part U (which may be time-dependent as well) commutes with the operator \hat{x} , i.e. its matrix in the x -basis has to be diagonal. For such an operator, the transformation (236) is indeed trivial, and its coordinate representation is given merely by the *c*-number function $U(x)$.

The situation the momentum operator \hat{p}_x (and hence the kinetic energy $\hat{p}_x^2/2m$), not commuting with \hat{x} , is less evident. Let me show that its coordinate representation is given by the 1D version of Eq. (1.26), if we *postulate* that the commutation relation (2.14),

$$[\hat{x}, \hat{p}] = i\hbar \hat{I}, \quad \text{i.e. } \hat{x}\hat{p}_x - \hat{p}_x\hat{x} = i\hbar \hat{I}, \quad (4.238)$$

⁴⁷ The only substantial exception is the statistical operator $\hat{w}(x, x')$, to be discussed in Chapter 7.

is valid in *any* representation.⁴⁸ For that, let us consider the following matrix element, $\langle x | \hat{x}\hat{p}_x - \hat{p}_x\hat{x} | x' \rangle$. On one hand, we may use Eq. (238), and then Eq. (231), to write

$$\langle x | \hat{x}\hat{p}_x - \hat{p}_x\hat{x} | x' \rangle = \langle x | i\hbar\hat{I} | x' \rangle = i\hbar\langle x | x' \rangle = i\hbar\delta(x - x'). \quad (4.239)$$

On the other hand, since $\hat{x}|x'\rangle = x'|x'\rangle$ and $\langle x|\hat{x} = \langle x|x$, we may represent the same matrix element as

$$\langle x | \hat{x}\hat{p}_x - \hat{p}_x\hat{x} | x' \rangle = \langle x | x\hat{p}_x - \hat{p}_x x' | x' \rangle = (x - x')\langle x | \hat{p}_x | x' \rangle. \quad (4.240)$$

Comparing Eqs. (239) and (240), we get

$$\langle x | \hat{p}_x | x' \rangle = i\hbar \frac{\delta(x - x')}{x - x'}. \quad (4.241)$$

As it follows from the definition of the delta function,⁴⁹ all expressions involving it acquire final sense only at their integration, in our current case, at that described by Eq. (236). Plugging Eq. (241) into the left-hand side of that relation, we get

$$\int \langle x | \hat{p}_x | x' \rangle \Psi(x') dx' = i\hbar \int \frac{\delta(x - x')}{x - x'} \Psi(x') dx'. \quad (4.242)$$

Since the right-hand-part integral is contributed only by an infinitesimal vicinity of the point $x' = x$, we may calculate it by expanding the continuous wavefunction $\Psi(x')$ into the Taylor series in small $(x' - x)$, and keeping only two leading terms of the series, so that Eq. (242) is reduced to

$$\int \langle x | \hat{p}_x | x' \rangle \Psi(x') dx' = i\hbar \left[\Psi(x) \int \frac{\delta(x - x')}{x - x'} dx' - \int \delta(x - x') \frac{\partial \Psi(x')}{\partial x'} \Big|_{x'=x} dx' \right]. \quad (4.243)$$

Since the delta function may be always understood as an even function of its argument, in our case of $(x - x')$, the first term on the right-hand side is proportional to an integral of an odd function in symmetric limits and is equal to zero, and we get⁵⁰

$$\int \langle x | \hat{p}_x | x' \rangle \Psi(x') dx' = -i\hbar \frac{\partial \Psi}{\partial x}. \quad (4.244)$$

Comparing this expression with the right-hand side of Eq. (236), we see that in the coordinate representation we indeed get the 1D version of Eq. (1.26), which was used so much in Chapter 2,⁵¹

$$\hat{p}_x = -i\hbar \frac{\partial}{\partial x}. \quad (4.245)$$

⁴⁸ Another possible approach to the wave mechanics axiomatics is to *derive* Eg. (238) by *postulating* the form, $\hat{T}_X = \exp\{-ip_x X / \hbar\}$, of the operator that shifts any wavefunction by distance X along the axis x . In my approach, this expression will be *derived* when we need it (in Sec. 5.5), while Eq. (238) is *postulated*.

⁴⁹ If necessary, please revisit MA Sec. 14.

⁵⁰ One more useful expression of this type, which may be proved similarly, is $(\partial/\partial x)\delta(x - x') = \delta(x - x')\partial/\partial x'$.

⁵¹ This means, in particular, that in the sense of Eq. (236), the operator of differentiation is local, despite the fact that its action on a function f may be interpreted as the limit of the fraction $\Delta f / \Delta x$, involving *two* points. (In some axiomatic systems, local operators are *defined* as arbitrary polynomials of functions and their derivatives.)

It is straightforward to show (and is virtually evident) that the coordinate representation of any operator function $f(\hat{p}_x)$ is

$$f\left(-i\hbar \frac{\partial}{\partial x}\right). \quad (4.246)$$

In particular, this pertains to the kinetic energy operator in Eq. (237), so the coordinate representation of this Hamiltonian also takes the very familiar form:

$$\hat{H} = \frac{1}{2m} \left(-i\hbar \frac{\partial}{\partial x} \right)^2 + U(x, t) \equiv -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + U(x, t). \quad (4.247)$$

Now returning to the discussion of the general Eq. (235), and comparing its last form with that of Eq. (236), we see that for a local operator in the coordinate representation, the eigenproblem (219) takes the form

$$\hat{A}\Psi_\alpha(x) = A\Psi_\alpha(x), \quad (4.248)$$

Eigenproblem
in x-
representation

even if the operator \hat{A} does not commute with the operator \hat{x} . The most important case of this coordinate-representation form of the eigenproblem (68) is the familiar Eq. (1.60) for the eigenvalues E_n of the energy of a system with a time-independent Hamiltonian.

The operator locality also simplifies the expression for its expectation value. Indeed, plugging the closure relation in the form (231) into the general Eq. (125) twice (written in the first case for x and in the second case for x'), we get

$$\langle A \rangle = \int dx \int dx' \langle \alpha(t) | x \rangle \langle x | \hat{A} | x' \rangle \langle x' | \alpha(t) \rangle = \int dx \int dx' \Psi_\alpha^*(x, t) \langle x | \hat{A} | x' \rangle \Psi_\alpha(x', t). \quad (4.249)$$

Now, Eq. (236) reduces this result to just

$$\langle A \rangle = \int dx \int dx' \Psi_\alpha^*(x, t) \hat{A} \Psi_\alpha(x, t) \delta(x - x') \equiv \int \Psi_\alpha^*(x, t) \hat{A} \Psi_\alpha(x, t) dx. \quad (4.250)$$

i.e. to Eq. (1.23), which had to be postulated in Chapter 1.

Finally, let us discuss the time evolution of the wavefunction, in the Schrödinger picture. For that, we may use Eq. (233) to calculate the (partial) time derivative of the wavefunction of some state α :

$$i\hbar \frac{\partial \Psi_\alpha}{\partial t} = i\hbar \frac{\partial}{\partial t} \langle x | \alpha(t) \rangle. \quad (4.251)$$

Since the coordinate operator \hat{x} does not depend on time explicitly, its eigenstates x are stationary, and we can swap the time derivative and the time-independent bra-vector $\langle x |$. Now using the Schrödinger-picture equation (158), and then inserting the identity operator in the continuous form (220) of the closure relation, written for the coordinate eigenstates,

$$\int dx' |x'\rangle \langle x'| = \hat{I}, \quad (4.252)$$

we may continue to develop the right-hand side of Eq. (251) as

$$\langle x | i\hbar \frac{\partial}{\partial t} | \alpha(t) \rangle = \langle x | \hat{H} | \alpha(t) \rangle = \int dx' \langle x | \hat{H} | x' \rangle \langle x' | \alpha(t) \rangle = \int dx' \langle x | \hat{H} | x' \rangle \Psi_\alpha(x'), \quad (4.253)$$

If the Hamiltonian operator is local, we may apply Eq. (236) to the last expression, to get the familiar form (1.28) of the Schrödinger equation:

$$i\hbar \frac{\partial \Psi_\alpha}{\partial t} = \hat{H}\Psi_\alpha, \quad (4.254)$$

in which the coordinate representation of the operator \hat{H} is implied.

So, for the local operators that obey Eq. (236), we have been able to derive all the basic notions and postulates of the wave mechanics from the bra-ket formalism. Moreover, the formalism has allowed us to get the very useful equation (248) for an arbitrary local operator, which will be repeatedly used below. (In the first three chapters of this course, we have only used its particular case (1.60) for the Hamiltonian operator.)

Now let me deliver on my promise to develop a more balanced view at the monochromatic de Broglie waves (1), which would be more respectful to the evident $\mathbf{r} \leftrightarrow \mathbf{p}$ symmetry of the coordinate and momentum. Let us do this for the 1D case when the wave may be represented as

$$\psi_p(x) = a_p \exp\left\{i \frac{px}{\hbar}\right\}, \quad \text{for all } -\infty < x < +\infty. \quad (4.255)$$

(For the sake of brevity, from this point to the end of the section, I am dropping the index x in the notation of the momentum – just as it was done in Chapter 2.) Let us have a good look at this function. Since it satisfies Eq. (248) for the 1D momentum operator (245),

$$\hat{p}\psi_p = p\psi_p, \quad (4.256)$$

ψ_p is an eigenfunction of that operator. But this means that we can also write Eq. (219) for the corresponding ket-vector:

$$\hat{p}|p\rangle = p|p\rangle, \quad (4.257)$$

and according to Eq. (233), the wavefunction (255) may be represented as

$$\psi_p(x) = \langle x|p\rangle. \quad (4.258)$$

This expression is quite remarkable in its $x \leftrightarrow p$ symmetry – which may be pursued further on. Before doing that, however, we have to discuss the normalization of such wavefunctions. Indeed, in this case, the probability density $w(x)$ (18) is constant, so that its integral

$$\int_{-\infty}^{+\infty} w(x)dx = \int_{-\infty}^{+\infty} \psi_p(x)\psi_p^*(x)dx \quad (4.259)$$

diverges if $a_p \neq 0$. Earlier in the course, we discussed two ways to avoid this divergence. One is to use a very large but finite integration volume – see Eq. (1.31). Another way is to work with wave packets of the type (2.20), possibly of a very large length and hence a very narrow spread of the momentum values. Then the integral (259) may be required to equal 1 without any conceptual problem.

However, both these methods, convenient for the solution of many particular problems, violate the $x \leftrightarrow p$ symmetry and hence are inconvenient for our current conceptual discussion. Instead, let us continue to identify the eigenvectors $\langle p|$ and $|p\rangle$ of the momentum with the bra- and ket-vectors $\langle a_p|$ and

$|a_A\rangle$ of the general theory described at the beginning of this section. Then the normalization condition (222) becomes

$$\langle p | p' \rangle = \delta(p - p'). \quad (4.260)$$

Inserting the identity operator in the form (252), with the integration variable x' replaced by x , into the left-hand side of this equation, and using Eq. (258), we can translate this normalization rule to the wavefunction language:

$$\int dx \langle p | x \rangle \langle x | p' \rangle \equiv \int dx \psi_p^*(x) \psi_{p'}(x) = \delta(p - p'). \quad (4.261)$$

For the wavefunction (255), this requirement turns into the following condition:

$$a_p^* a_{p'} \int_{-\infty}^{+\infty} \exp\left\{i \frac{(p-p')x}{\hbar}\right\} dx \equiv |a_p|^2 2\pi\hbar \delta(p - p') = \delta(p - p'), \quad (4.262)$$

so that, finally, $a_p = e^{i\phi}/(2\pi\hbar)^{1/2}$, where ϕ is an arbitrary (real) phase, and Eq. (255) becomes⁵²

$$\psi_p(x) = \langle x | p \rangle = \frac{1}{(2\pi\hbar)^{1/2}} \exp\left\{i\left(\frac{px}{\hbar} + \phi\right)\right\}, \quad (4.263)$$

Now let us represent an arbitrary wavefunction $\psi(x)$ as a wave packet of the type (2.20), based on the wavefunctions (263), taking $\phi = 0$ for the notation brevity, because the phase may be incorporated into the (generally, complex) envelope function $\varphi(p)$:

$$\psi(x) = \frac{1}{(2\pi\hbar)^{1/2}} \int \varphi(p) \exp\left\{i \frac{px}{\hbar}\right\} dp. \quad (4.264)$$

x-
representation:
wavefunctions

From the mathematical point of view, this is just a 1D Fourier spatial transform, and its reciprocal is

$$\varphi(p) \equiv \frac{1}{(2\pi\hbar)^{1/2}} \int \psi(x) \exp\left\{-i \frac{px}{\hbar}\right\} dx. \quad (4.265)$$

p-
representation:
wavefunctions

These expressions are completely symmetric, and represent the same wave packet; this is why the functions $\psi(x)$ and $\varphi(p)$ are frequently called the *reciprocal representations* of a quantum state of the particle: respectively, its *coordinate (x-) and momentum (p-) representations*. Using Eq. (258), and Eq. (263) with $\phi = 0$, they may be recast into simpler forms,

$$\psi(x) = \int \varphi(p) \langle x | p \rangle dp, \quad \varphi(p) = \int \psi(x) \langle p | x \rangle dx, \quad (4.266)$$

in which the inner products satisfy the basic postulate (14) of the bra-ket formalism:

$$\langle p | x \rangle = \frac{1}{(2\pi\hbar)^{1/2}} \exp\left\{-i \frac{px}{\hbar}\right\} = \langle x | p \rangle^*. \quad (4.267)$$

⁵² Repeating such calculation for each Cartesian component of a plane monochromatic wave of arbitrary dimensionality d , we get $\psi_p = (2\pi\hbar)^{-d/2} \exp\{i(\mathbf{p} \cdot \mathbf{r}/\hbar + \phi)\}$.

Next, we already know that in the x -representation, i.e. in the usual wave mechanics, the coordinate operator \hat{x} is reduced to the multiplication by x , and the momentum operator is proportional to the partial derivative over the coordinate:

x-representation:
operators

$$\hat{x}|_{\text{in } x} = x, \quad \hat{p}|_{\text{in } x} = -i\hbar \frac{\partial}{\partial x}. \quad (4.268)$$

It is natural to guess that in the p -representation, the expressions for operators would be reciprocal:

p-representation:
operators

$$\hat{x}|_{\text{in } p} = +i\hbar \frac{\partial}{\partial p}, \quad \hat{p}|_{\text{in } p} = p, \quad (4.269)$$

with the only difference of one sign, which is due to the opposite signs of the Fourier exponents in Eqs. (264) and (265). The proof of Eqs. (269) is straightforward; for example, acting by the momentum operator on the arbitrary wavefunction (264), we get

$$\hat{p}\psi(x) = -i\hbar \frac{\partial}{\partial x} \psi(x) = \frac{1}{(2\pi\hbar)^{1/2}} \int \varphi(p) \left(-i\hbar \frac{\partial}{\partial x} \exp\left\{i \frac{px}{\hbar}\right\} \right) dp = \frac{1}{(2\pi\hbar)^{1/2}} \int p \varphi(p) \exp\left\{i \frac{px}{\hbar}\right\} dp, \quad (4.270)$$

and similarly for the operator \hat{x} acting on the function $\varphi(p)$. Comparing the final form of Eq. (270) with the initial Eq. (264), we see that the action of the operators (268) on the wavefunction ψ (i.e. the state's x -representation) gives the same results as the action of the operators (269) on the function φ (i.e. its p -representation).

It is illuminating to have one more, different look at this coordinate-momentum duality. For that, notice that according to Eqs. (82)-(84), we may consider the bracket $\langle x|p\rangle$ as an element of the (infinite-size) matrix U_{xp} of the unitary transform from the x -basis to the p -basis. Let us use this fact to derive the general operator transform rule that would be a continuous version of Eq. (92). Say, we want to calculate the general matrix element of some operator, known in the x -representation, in the p -representation:

$$\langle p|\hat{A}|p'\rangle. \quad (4.271)$$

Inserting two identity operators (252), written for x and x' , into this bracket, and then using Eq. (258) and its complex conjugate, and also Eq. (236) (again, valid only for space-local operators!), we get

$$\begin{aligned} \langle p|\hat{A}|p'\rangle &= \int dx \int dx' \langle p|x\rangle \langle x|\hat{A}|x'\rangle \langle x'|p'\rangle = \int dx \int dx' \psi_p^*(x) \langle x|\hat{A}|x'\rangle \psi_{p'}(x') \\ &= \frac{1}{2\pi\hbar} \int dx \int dx' \exp\left\{-i \frac{px}{\hbar}\right\} \delta(x-x') \hat{A} \exp\left\{+i \frac{p'x'}{\hbar}\right\} = \frac{1}{2\pi\hbar} \int dx \exp\left\{-i \frac{px}{\hbar}\right\} \hat{A} \exp\left\{+i \frac{p'x}{\hbar}\right\}. \end{aligned} \quad (4.272)$$

As a sanity check, for the momentum operator itself, this relation yields:

$$\langle p|\hat{p}|p'\rangle = \frac{1}{2\pi\hbar} \int dx \exp\left\{-i \frac{px}{\hbar}\right\} \left(-i\hbar \frac{\partial}{\partial x}\right) \exp\left\{i \frac{p'x}{\hbar}\right\} = \frac{p'}{2\pi\hbar} \int_{-\infty}^{+\infty} \exp\left\{i \frac{(p'-p)x}{\hbar}\right\} dx = p' \delta(p'-p). \quad (4.273)$$

Due to Eq. (257), this result is equivalent to the second of Eqs. (269).

From a thoughtful reader, I anticipate the following natural question: why is the momentum representation used much less frequently than the coordinate representation – i.e. wave mechanics? The answer is purely practical: besides the important special case of the 1D harmonic oscillator (to be

revisited in Sec. 5.4), in most systems the orbital-motion Hamiltonian (237) is not $x \leftrightarrow p$ symmetric, with the potential energy $U(\mathbf{r})$ typically being a more complex function than the kinetic energy $p^2/2m$. Because of that, it is easier to analyze such systems treating such potential energy operator just a c -number multiplier, as it is in the coordinate representation – as it was done in Chapters 1-3.

The most significant exception from this practice is the motion in a periodic potential in presence of a coordinate-independent external force $\mathbf{F}(t)$. As was discussed in Secs. 2.7 and 3.4, in such periodic systems the eigenenergies $E_n(\mathbf{q})$, playing the role of the effective kinetic energy of the particle, may be rather involved functions of its quasimomentum $\hbar\mathbf{q}$, while its effective potential energy $U_{\text{ef}} = -\mathbf{F}(t) \cdot \mathbf{r}$, due to the additional force $\mathbf{F}(t)$, is a very simple function of coordinates. This is why detailed analyses of the quantum effects briefly discussed in Sec. 2.8 (the Bloch oscillations, etc.) and also such statistical phenomena as drift, diffusion, etc.,⁵³ in solid-state theory are typically based on the momentum (or rather quasimomentum) representation.

4.8. Exercise problems

4.1. Prove that if \hat{A} and \hat{B} are linear operators, and C is a c -number, then:

- (i) $(\hat{A}^\dagger)^\dagger = \hat{A}$;
- (ii) $(C\hat{A})^\dagger = C^* \hat{A}^\dagger$;
- (iii) $(\hat{A}\hat{B})^\dagger = \hat{B}^\dagger \hat{A}^\dagger$;
- (iv) the operators $\hat{A}\hat{A}^\dagger$ and $\hat{A}^\dagger\hat{A}$ are Hermitian.

4.2. Prove that for any linear operators $\hat{A}, \hat{B}, \hat{C}$, and \hat{D} ,

$$[\hat{A}\hat{B}, \hat{C}\hat{D}] = \hat{A}\{\hat{B}, \hat{C}\}\hat{D} - \hat{A}\hat{C}\{\hat{B}, \hat{D}\} + \{\hat{A}, \hat{C}\}\hat{D}\hat{B} - \hat{C}\{\hat{A}, \hat{D}\}\hat{B}.$$

4.3. Calculate all possible binary products $\sigma_j\sigma_{j'}$ (for $j, j' = x, y, z$) of the Pauli matrices, defined by Eqs. (105), and their commutators and anticommutators (defined similarly to those of the corresponding operators). Summarize the results, using the Kronecker delta and Levi-Civita permutation symbols.⁵⁴

4.4. Calculate the following expressions,

- (i) $(\mathbf{c} \cdot \boldsymbol{\sigma})^n$, and then
- (ii) $(b\mathbf{I} + \mathbf{c} \cdot \boldsymbol{\sigma})^n$,

for the scalar product $\mathbf{c} \cdot \boldsymbol{\sigma}$ of the Pauli matrix vector $\boldsymbol{\sigma} \equiv \mathbf{n}_x\sigma_x + \mathbf{n}_y\sigma_y + \mathbf{n}_z\sigma_z$ by an arbitrary c -number geometric vector \mathbf{c} , where $n \geq 0$ is an integer, and b is an arbitrary scalar c -number.

Hint: For task (ii), you may like to use the binomial theorem,⁵⁵ and then transform the result in a way enabling you to use the same theorem backward.

⁵³ In this series, a brief discussion of these effects may be found in SM Chapter 6.

⁵⁴ See, e.g., MA Eqs. (13.1) and (13.2).

⁵⁵ See, e.g. MA Eq. (2.9).

4.5. Use the solution of the previous problem to derive Eqs. (2.191) for the transparency \mathcal{T} of a system of N similar, equidistant, delta-functional potential barriers.

4.6. Use the solution of Problem 4(i) to spell out the following matrix: $\exp\{i\theta \mathbf{n} \cdot \boldsymbol{\sigma}\}$, where $\boldsymbol{\sigma}$ is the 3D vector (117) of the Pauli matrices, \mathbf{n} is a c -number geometric vector of unit length, and θ is a c -number scalar.

4.7. Use the solution of Problem 4(ii) to calculate $\exp\{A\}$, where A is an arbitrary 2×2 matrix.

4.8. Express all elements of the matrix $B \equiv \exp\{A\}$ explicitly via those of the 2×2 matrix A . Spell out your result for the following matrices:

$$A = \begin{pmatrix} a & a \\ a & a \end{pmatrix}, \quad A' = \begin{pmatrix} i\varphi & i\varphi \\ i\varphi & i\varphi \end{pmatrix},$$

with real a and φ .

4.9. Prove that for arbitrary square matrices A and B ,

$$\text{Tr}(AB) = \text{Tr}(BA).$$

Is each diagonal element $(AB)_{jj}$ necessarily equal to $(BA)_{jj}$?

4.10. Calculate the trace of the following 2×2 matrix:

$$A \equiv (\mathbf{a} \cdot \boldsymbol{\sigma})(\mathbf{b} \cdot \boldsymbol{\sigma})(\mathbf{c} \cdot \boldsymbol{\sigma}),$$

where $\boldsymbol{\sigma}$ is the Pauli matrix vector, while \mathbf{a} , \mathbf{b} , and \mathbf{c} are arbitrary c -number vectors.

4.11. Prove that the matrix trace of an arbitrary operator does not change at its arbitrary unitary transformation.

4.12. Prove that for any two full and orthonormal bases $\{u\}$ and $\{v\}$ of the same Hilbert space,

$$\text{Tr}\left(\left|u_j\right\rangle\left\langle v_{j'}\right|\right) = \left\langle v_{j'}\left|u_j\right\rangle\right.$$

4.13. Is the 1D scattering matrix S , defined by Eq. (2.124), unitary? What about the 1D transfer matrix T defined by Eq. (2.125)?

4.14. Calculate the trace of the following matrix:

$$\exp\{i\mathbf{a} \cdot \boldsymbol{\sigma}\} \exp\{i\mathbf{b} \cdot \boldsymbol{\sigma}\},$$

where $\boldsymbol{\sigma}$ is the Pauli matrix vector, while \mathbf{a} and \mathbf{b} are c -number geometric vectors.

4.15. Prove the following vector-operator identity:

$$(\boldsymbol{\sigma} \cdot \hat{\mathbf{r}})(\boldsymbol{\sigma} \cdot \hat{\mathbf{p}}) = I \hat{\mathbf{r}} \cdot \hat{\mathbf{p}} + i\boldsymbol{\sigma} \cdot (\hat{\mathbf{r}} \times \hat{\mathbf{p}}),$$

where $\boldsymbol{\sigma}$ is the Pauli matrix vector, and I is the 2×2 identity matrix.

Hint: Take into account that the vector operators $\hat{\mathbf{r}}$ and $\hat{\mathbf{p}}$ are defined in the orbital-motion Hilbert space, different from that of the Pauli vector-matrix σ , and hence commute with it – even though they do not commute with each other.

4.16. Let A_j be eigenvalues of some operator \hat{A} . Express the following two sums,

$$\Sigma_1 \equiv \sum_j A_j, \quad \Sigma_2 \equiv \sum_j A_j^2,$$

via the matrix elements $A_{jj'}$ of this operator in an arbitrary basis.

4.17. Calculate $\langle \sigma_z \rangle$ of a spin- $1/2$ in the quantum state with the following ket-vector:

$$|\alpha\rangle = \text{const} \times (\left| \uparrow \right\rangle + \left| \downarrow \right\rangle + \left| \rightarrow \right\rangle + \left| \leftarrow \right\rangle),$$

where (\uparrow, \downarrow) and $(\rightarrow, \leftarrow)$ are the eigenstates of the Pauli matrices σ_z and σ_x , respectively.

Hint: Double-check whether your solution is general.

4.18. A spin- $1/2$ is fully polarized in the positive z -direction. Calculate the probabilities of the alternative outcomes of a perfect Stern-Gerlach experiment with the magnetic field oriented in an arbitrary different direction, performed on a particle in this spin state.

4.19. In a certain basis, the Hamiltonian of a two-level system is described by the matrix

$$H = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix}, \quad \text{with } E_1 \neq E_2,$$

while the operator of some observable A of this system, by the matrix

$$A = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}.$$

For the system's state with the energy definitely equal to E_1 , find the possible results of measurements of the observable A and the probabilities of the corresponding measurement outcomes.

4.20. Certain states $u_{1,2,3}$ form an orthonormal basis of a system with the following Hamiltonian

$$\hat{H} = -\delta (\left| u_1 \right\rangle \langle u_2 | + \left| u_2 \right\rangle \langle u_3 | + \left| u_3 \right\rangle \langle u_1 |) + \text{h.c.},$$

where δ is a real constant, and h.c. means the Hermitian conjugate of the previous expression. Calculate its stationary states and energy levels. Can you relate this system to any other(s) discussed earlier in the course?

4.21. Guided by Eq. (2.203), and by the solutions of Problems 3.11 and 4.20, suggest a Hamiltonian describing particle's dynamics in an infinite 1D chain of similar potential wells in the tight-binding approximation, in the bra-ket formalism. Verify that its eigenstates and eigenvalues correspond to those discussed in Sec. 2.7.

4.22. Calculate eigenvectors and eigenvalues of the following matrices:

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

4.23. A certain state γ is an eigenstate of each of two operators, \hat{A} and \hat{B} . What can be said about the corresponding eigenvalues a and b , if the operators anticommute?

4.24. Derive the differential equation for the time evolution of the expectation value of an observable, using both the Schrödinger picture and the Heisenberg picture of quantum dynamics.

4.25. At $t = 0$, a spin- $\frac{1}{2}$ whose interaction with an external field is described by the Hamiltonian

$$\hat{H} = \mathbf{c} \cdot \hat{\mathbf{\sigma}} \equiv c_x \hat{\sigma}_x + c_y \hat{\sigma}_y + c_z \hat{\sigma}_z$$

(where $c_{x,y,z}$ are real c -number constants, and $\hat{\sigma}_{x,y,z}$ are the Pauli operators), was in the state \uparrow , one of the two eigenstates of $\hat{\sigma}_z$. In the Schrödinger picture, calculate the time evolution of:

- (i) the ket-vector $|\alpha\rangle$ of the spin (in any time-independent basis you like),
- (ii) the probabilities to find the spin in the states \uparrow and \downarrow , and
- (iii) the expectation values of all three Cartesian components (\hat{S}_x , etc.) of the spin vector.

Analyze and interpret the results for the particular case $c_y = c_z = 0$.

Hint: Think about the best basis to use for the solution.

4.26. For the same system as in the previous problem, use the Heisenberg picture to calculate the time evolution of:

- (i) all three Cartesian components of the spin operator $\hat{S}_H(t)$, and
- (ii) the expectation values of the spin components.

Compare the latter results with those of the previous problem.

4.27. For the same system as in the two last problems, calculate matrix elements of the operator $\hat{\sigma}_z$ in the basis of the stationary states of the system.

4.28. In the Schrödinger picture of quantum dynamics, certain three operators satisfy the following commutation relation:

$$[\hat{A}, \hat{B}] = \hat{C}.$$

What is their relation in the Heisenberg picture, at a certain time instant t ?

4.29. Prove the Bloch theorem given by either Eq. (3.107) or Eq. (3.108).

Hint: Consider the *translation operator* $\hat{\tau}_{\mathbf{R}}$ defined by the following result of its action on an arbitrary function $f(\mathbf{r})$:

$$\hat{\tau}_{\mathbf{R}} f(\mathbf{r}) = f(\mathbf{r} + \mathbf{R}),$$

for the case when \mathbf{R} is an arbitrary vector of the Bravais lattice (3.106). In particular, analyze the commutation properties of this operator, and apply them to an eigenfunction $\psi(\mathbf{r})$ of the stationary Schrödinger equation for a particle moving in the 3D periodic potential described by Eq. (3.105).

4.30. A constant force F is applied to an (otherwise free) 1D particle of mass m . Calculate the stationary wavefunctions of the particle in:

- (i) the coordinate representation, and
- (ii) the momentum representation.

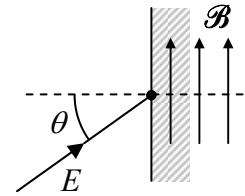

Discuss the relation between the results.

4.31. Use the momentum representation to re-solve the problem discussed at the beginning of Sec. 2.6, i.e. calculate the eigenenergy of a 1D particle of mass m , localized in a very short potential well of “weight” w .

4.32. The momentum representation of a certain operator of 1D orbital motion is p^{-1} . Find its coordinate representation.

4.33.* For a particle moving in a 3D periodic potential, develop the bra-ket formalism for the \mathbf{q} -representation, in which a complex amplitude similar to a_q in Eq. (2.234) (but generalized to 3D and all energy bands) plays the role of the wavefunction. In particular, calculate the operators \mathbf{r} and \mathbf{v} in this representation, and use the result to prove Eq. (2.237) for the 1D case in the low-field limit.

4.34. A uniform, time-independent magnetic field \mathcal{B} is induced in one semi-space, while the other semi-space is field-free, with a sharp, plane boundary between these two regions. A monochromatic beam of non-relativistic, electrically-neutral spin- $1/2$ particles with a gyromagnetic ratio $\gamma \neq 0$,⁵⁶ in a certain spin state and with a kinetic energy E , is incident on this boundary, from the field-free side, under angle θ – see figure on the right. Calculate the coefficient of particle reflection from the boundary.

⁵⁶ The fact that γ may be different from zero even for electrically-neutral particles, such as neutrons, is explained by the Standard Model of the elementary particles, in which a neutron “consists” (in a broad sense of the word) of three electrically-charged quarks with zero net charge.

Chapter 5. Some Exactly Solvable Problems

The objective of this chapter is to describe several relatively simple but very important applications of the bra-ket formalism, including a few core problems of wave mechanics we have already started to discuss in Chapters 2 and 3.

5.1. Two-level systems

The discussion of the bra-ket formalism in the previous chapter was peppered with numerous illustrations of its main concepts on the example of “spins-½” – systems with the smallest non-trivial (two-dimensional) Hilbert space, in which the bra- and ket-vectors of an arbitrary quantum state α may be represented as a linear superposition of just two basis vectors, for example

$$|\alpha\rangle = \alpha_{\uparrow}|\uparrow\rangle + \alpha_{\downarrow}|\downarrow\rangle, \quad (5.1)$$

where the states \uparrow and \downarrow were defined as the eigenstates of the Pauli matrix σ_z – see Eq. (4.105). For the genuine spin-½ particles, such as electrons, placed in a z -oriented time-independent magnetic field, these states are the stationary “spin-up” and “spin-down” stationary states of the Pauli Hamiltonian (4.163), with the corresponding two energy levels (4.167). However, an approximate but reasonable quantum description of some other important systems may also be given in such Hilbert space.

For example, as was discussed in Sec. 2.6, two weakly coupled space-localized orbital states of a spin-free particle are sufficient for an approximate description of its quantum oscillations between two potential wells. A similar coupling of two traveling waves explains the energy band splitting in the weak-potential approximation of the band theory – Sec. 2.7. As will be shown in the next chapter, in systems with time-independent Hamiltonians, such situation almost unavoidably appears each time when two energy levels are much closer to each other than to other levels. Moreover, as will be shown in Sec. 6.5, a similar truncated description is adequate even in cases when two levels E_n and $E_{n'}$ of an unperturbed system are not close to each other, but the corresponding states become coupled by an applied ac field of a frequency ω very close to the difference $(E_n - E_{n'})/\hbar$. Such *two-level systems* (alternatively called “spin-½-like” systems) are nowadays the focus of additional attention in the view of prospects of their use for quantum information processing and encryption.¹ This is why let me spend a bit more time reviewing the main properties of an arbitrary two-level system.

First, the most general form of the Hamiltonian of a two-level system is represented, in an arbitrary basis, by a 2×2 matrix

$$H = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix}. \quad (5.2)$$

According to the discussion in Secs. 4.3-4.5, since the Hamiltonian operator has to be Hermitian, the diagonal elements of the matrix H have to be real, and its off-diagonal elements be complex conjugates

¹ In the last context, to be discussed in Sec. 8.5, the two-level systems are usually called *qubits*.

of each other: $H_{21} = H_{12}^*$. As a result, we may not only represent H as a linear combination (4.106) of the identity matrix and the Pauli matrices but also reduce it to a more specific form:

$$H = bI + \mathbf{c} \cdot \boldsymbol{\sigma} = \begin{pmatrix} b + c_z & c_x - ic_y \\ c_x + ic_y & b - c_z \end{pmatrix} \equiv \begin{pmatrix} b + c_z & c_- \\ c_+ & b - c_z \end{pmatrix}, \quad c_\pm \equiv c_x \pm ic_y, \quad (5.3)$$

where the scalar b and the Cartesian components of the vector \mathbf{c} are *real* c -number coefficients:

$$b = \frac{H_{11} + H_{22}}{2}, \quad c_x = \frac{H_{12} + H_{21}}{2} \equiv \text{Re } H_{21}, \quad c_y = \frac{H_{21} - H_{12}}{2i} \equiv \text{Im } H_{21}, \quad c_z = \frac{H_{11} - H_{22}}{2}. \quad (5.4)$$

If such Hamiltonian does not depend on time, the corresponding characteristic equation (4.103) for the system's energy levels E_\pm ,

$$\begin{vmatrix} b + c_z - E & c_- \\ c_+ & b - c_z - E \end{vmatrix} = 0, \quad (5.5)$$

is a simple quadratic equation, with the following solutions:

$$E_\pm = b \pm c \equiv b \pm (c_+ c_- + c_z^2)^{1/2} \equiv b \pm (c_x^2 + c_y^2 + c_z^2)^{1/2} \equiv \frac{H_{11} + H_{22}}{2} \pm \left[\left(\frac{H_{11} - H_{22}}{2} \right)^2 + |H_{21}|^2 \right]^{1/2}. \quad (5.6)$$

The parameter $b \equiv (H_{11} + H_{22})/2$ evidently gives the average energy $E^{(0)}$ of the system, which does not contribute to the level splitting

$$\Delta E \equiv E_+ - E_- = 2c \equiv 2(c_x^2 + c_y^2 + c_z^2)^{1/2} \equiv \left[(H_{11} - H_{22})^2 + 4|H_{21}|^2 \right]^{1/2}. \quad (5.7)$$

So, the splitting is a hyperbolic function of the coefficient $c_z \equiv (H_{11} - H_{22})/2$. A plot of this function is the famous level-anticrossing diagram (Fig. 1), which has already been discussed in Sec. 2.7 in the particular context of the weak-potential limit of the 1D band theory.

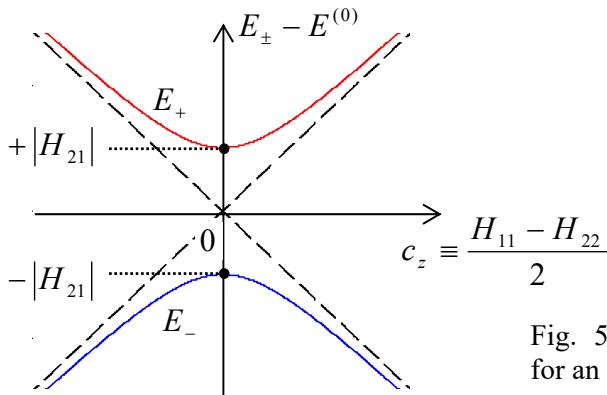

Fig. 5.1. The level-anticrossing diagram for an arbitrary two-level system.

The physics of the diagram becomes especially clear if the two states of the basis used to spell out the matrix (2), may be interpreted as the stationary states of two potentially independent subsystems, with the energies, respectively, H_{11} and H_{22} . (For example, in the case of two weakly coupled potential wells discussed in Sec. 2.6, these are the ground-state energies of two distant wells.) Then the off-diagonal elements $c_- \equiv H_{12}$ and $c_+ \equiv H_{21} = H_{12}^*$ describe the subsystem coupling, and the level

anticrossing diagram shows how do the eigenenergies of the coupled system depend (at fixed coupling) on the difference of the subsystem energies. As was already discussed in Sec. 2.7, the most striking feature of the diagram is that any non-zero coupling $|c_{\pm}| \equiv (c_x^2 + c_y^2)^{1/2}$ changes the topology of the eigenstate energies, creating a gap of the width ΔE .

As it follows from our discussions of particular two-level systems in Secs. 2.6 and 4.6, their dynamics also has a general feature – the quantum oscillations. Namely, if we put any two-level system into any initial state different from one of its eigenstates \pm , and then let it evolve on its own, the probability of its finding the system in any of the “partial” states exhibits oscillations with the frequency

$$\Omega = \frac{\Delta E}{\hbar} \equiv \frac{E_+ - E_-}{\hbar} = 2c, \quad (5.8)$$

lowest at the exact subsystem symmetry ($c_z = 0$, i.e. $H_{11} = H_{22}$), when it is proportional to the coupling strength: $\Omega_{\min} = 2|c_{\pm}|/\hbar \equiv 2|H_{12}|/\hbar = 2|H_{21}|/\hbar$.

In the case discussed in Sec. 2.6, these are the oscillations of a particle between the two coupled potential wells (or rather of the probabilities to find it in either well) – see, e.g., Eqs. (2.181). On the other hand, for a spin-½ particle in an external magnetic field, these oscillations take the form of spin precession in the plane normal to the field, with periodic oscillations of its Cartesian components (or rather their expectation values) – see, e.g., Eqs. (4.173)-(4.174). Some other examples of the quantum oscillations in two-level systems may be rather unexpected; for example, the ammonium molecule NH₃ (Fig. 2) has two symmetric states that differ by the inversion of the nitrogen atom relative to the plane of the three hydrogen atoms, which are weakly coupled due to quantum-mechanical tunneling of the nitrogen atom through the plane of the hydrogen atoms.² Since for this particular molecule, in the absence of external fields, the level splitting ΔE corresponds to an experimentally convenient frequency $\Omega/2\pi \approx 24$ GHz, it played an important historic role at the initial development of the atomic frequency standards and microwave quantum generators (*masers*) in the early 1950s,³ which paved the way toward laser technology.

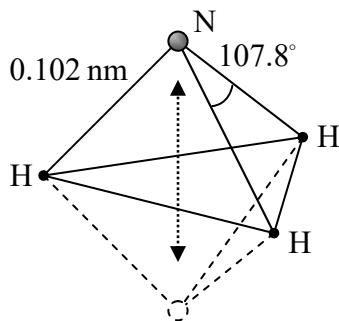

Fig. 5.2. An ammonia molecule and its inversion.

Now let us now discuss a very convenient geometric representation of an arbitrary state α of (any!) two-level system. As Eq. (1) shows, such state is completely described by two complex

² Since the hydrogen atoms are much lighter, it would be fairer to speak about the tunneling of their triangle around the (nearly immobile) nitrogen atom.

³ In particular, these molecules were used in the demonstration of the first maser by C. Townes' group in 1954.

coefficients (*c*-numbers) – say, α_{\uparrow} and α_{\downarrow} . If the vectors of the basis states \uparrow and \downarrow are normalized, then these coefficients must obey the following restriction:

$$W_{\Sigma} = \langle \alpha | \alpha \rangle = (\langle \uparrow | \alpha_{\uparrow}^* + \langle \downarrow | \alpha_{\downarrow}^* \rangle (\alpha_{\uparrow} | \uparrow \rangle + \alpha_{\downarrow} | \downarrow \rangle) = \alpha_{\uparrow}^* \alpha_{\uparrow} + \alpha_{\downarrow}^* \alpha_{\downarrow} = |\alpha_{\uparrow}|^2 + |\alpha_{\downarrow}|^2 = 1. \quad (5.9)$$

This requirement is automatically satisfied if we take the moduli of α_{\uparrow} and α_{\downarrow} equal to the sine and cosine of the same (real) angle. Thus we may write, for example,

$$\alpha_{\uparrow} = \cos \frac{\theta}{2} e^{i\gamma}, \quad \alpha_{\downarrow} = \sin \frac{\theta}{2} e^{i(\gamma+\varphi)}. \quad (5.10)$$

Moreover, according to the general Eq. (4.125), if we deal with just one system,⁴ the common phase factor $\exp\{i\gamma\}$ drops out of the calculation of any expectation value, so that we may take $\gamma = 0$, and Eq. (10) is reduced to

$$\alpha_{\uparrow} = \cos \frac{\theta}{2}, \quad \alpha_{\downarrow} = \sin \frac{\theta}{2} e^{i\varphi}. \quad (5.11)$$

Bloch
sphere
representation

The reason why the argument of these sine and cosine functions is usually taken in the form $\theta/2$, becomes clear from Fig. 3a: Eq. (11) conveniently maps each state α of a two-level system on a certain *representation point* on a unit-radius *Bloch sphere*,⁵ with the polar angle θ and the azimuthal angle φ .

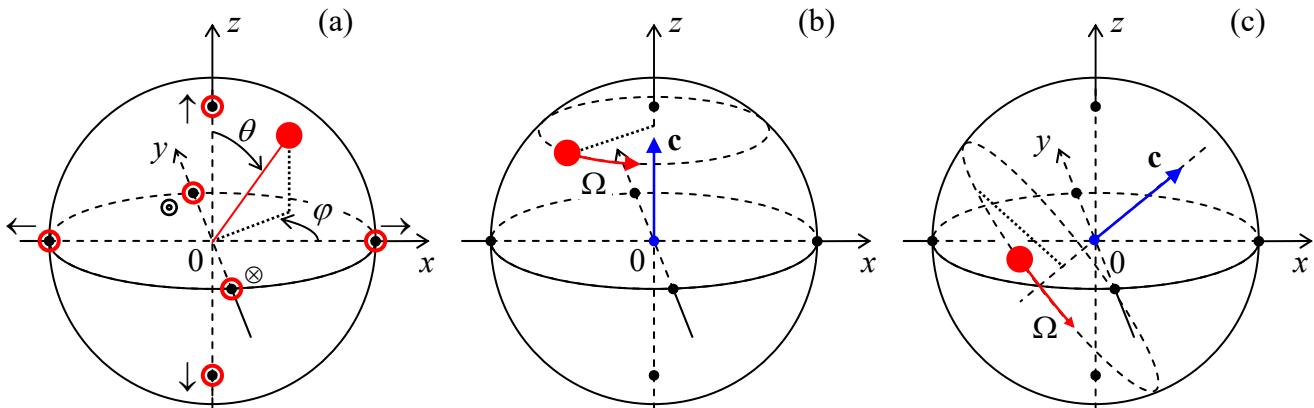

Fig. 5.3. The Bloch sphere: (a) the representation of an arbitrary state (solid red point) and the eigenstates of the Pauli matrices (dotted points), and (b, c) the two-level system's evolution: (b) in a constant “field” \mathbf{c} directed along the z -axis, and (c) in a field of arbitrary orientation.

In particular, the basis state \uparrow , described by Eq. (1) with $\alpha_{\uparrow} = 1$ and $\alpha_{\downarrow} = 0$, corresponds to the North Pole of the sphere ($\theta = 0$), while the opposite state \downarrow , with $\alpha_{\uparrow} = 0$ and $\alpha_{\downarrow} = 1$, to its South Pole ($\theta = \pi$). Similarly, the eigenstates \rightarrow and \leftarrow of the matrix σ_x , described by Eqs. (4.122), i.e. having $\alpha_{\uparrow} =$

⁴ If you need a reminder of why this condition is crucial, please revisit the discussion at the end of Sec. 1.6. Note also that the mutual phase shifts between different qubits are important, in particular, for quantum information processing (see Sec. 8.5 below), so that most discussions of these applications have to start from Eq. (10) rather than Eq. (11).

⁵ This representation was suggested in 1946 by the same Felix Bloch who has pioneered the energy band theory discussed in Chapters 2-3.

$1/\sqrt{2}$ and $\alpha_{\downarrow} = \pm 1/\sqrt{2}$, correspond to the equator ($\theta = \pi/2$) points with, respectively, $\varphi = 0$ and $\varphi = \pi$. Two more special points (denoted in Fig. 3a as \odot and \otimes) are also located on the sphere's equator, at $\theta = \pi/2$ and $\varphi = \pm\pi/2$; it is easy to check that they correspond to the eigenstates of the matrix σ_y (in the same z -basis).

To understand why such mutually perpendicular location of these three special point pairs on the Bloch sphere is not occasional, let us plug Eqs. (11) into Eqs. (4.131)-(4.133) for the expectation values of the spin- $1/2$ components. In terms of the Pauli vector operator (4.117), $\boldsymbol{\sigma} \equiv \mathbf{S}/(\hbar/2)$, the result is

$$\langle \sigma_x \rangle = \sin \theta \cos \varphi, \quad \langle \sigma_y \rangle = \sin \theta \sin \varphi, \quad \langle \sigma_z \rangle = \cos \theta, \quad (5.12)$$

showing that the radius vector of any representation point is just the expectation value of $\boldsymbol{\sigma}$.

Now let us use Eq. (3) to see how does the representation point moves in various cases, ignoring the term bI – which, again, describes the offset of the total energy of the system relative to some reference level, and does not affect its dynamics. First of all, according to Eq. (4.158), in the case $\mathbf{c} = 0$ (when the Hamiltonian operator turns to zero, and hence the state vectors do not depend on time) the point does not move at all, and its position is determined by initial conditions, i.e. by the system's preparation. If $\mathbf{c} \neq 0$, we may re-use some results of Sec. 4.6, obtained for the Pauli Hamiltonian (4.163a), which coincides with Eq. (3) if⁶

$$\mathbf{c} = -\gamma \mathcal{B} \frac{\hbar}{2}. \quad (5.13)$$

In particular, if the field \mathcal{B} , and hence the vector \mathbf{c} , is directed along the z -axis and is time-independent, Eqs. (4.170) and (4.173)-(4.174) show that the representation point $\langle \boldsymbol{\sigma} \rangle$ on the Bloch sphere rotates within a plane normal to this axis (see Fig. 3b) with the angular velocity

$$\frac{d\varphi}{dt} \equiv \Omega = -\gamma \mathcal{B}_z \equiv \frac{2c_z}{\hbar}. \quad (5.14)$$

Almost evidently, since the selection of the coordinate axes is arbitrary, this picture should remain valid for any orientation of the vector \mathbf{c} , with the representation point rotating, on the Bloch sphere, around its direction, with the angular speed $|\Omega| = 2c/\hbar$ – see Fig. 3c. This fact may be proved using any picture of the quantum dynamics, discussed in Sec. 4.6. Actually, the reader may already have done that by solving Problems 4.25 and 4.26, just to see that even for the particular, simple initial state of the system (\uparrow), the final results for the Cartesian components of the vector $\langle \boldsymbol{\sigma} \rangle$ are somewhat bulky. However, this description may be readily simplified, even for arbitrary time dependence of the “field” vector $\mathbf{c}(t)$ in Eq. (3), using the (geometric) vector language.

Indeed, let us rewrite Eq. (3) (again, with $b = 0$) in the operator form,

$$\hat{H} = \mathbf{c}(t) \cdot \hat{\boldsymbol{\sigma}}, \quad (5.15)$$

valid in an arbitrary basis. According to Eq. (4.199), the corresponding Heisenberg equation of motion for the j^{th} Cartesian components of the vector-operator $\hat{\boldsymbol{\sigma}}$ (which does not depend on time explicitly, so that $\partial \hat{\sigma} / \partial t = 0$) is

⁶ This correspondence justifies using the use of term “field” for the vector \mathbf{c} .

$$i\hbar\dot{\hat{\sigma}}_j = [\hat{\sigma}_j, \hat{H}] \equiv [\hat{\sigma}_j, \mathbf{c}(t) \cdot \hat{\boldsymbol{\sigma}}] \equiv \left[\hat{\sigma}_j, \sum_{j'=1}^3 c_{j'}(t) \hat{\sigma}_{j'} \right] \equiv \sum_{j'=1}^3 c_{j'}(t) [\hat{\sigma}_j, \hat{\sigma}_{j'}]. \quad (5.16)$$

Now using the commutation relations (4.155), which remain valid in any basis and in any picture of time evolution,⁷ we get

$$i\hbar\dot{\hat{\sigma}}_j = 2i \sum_{j'=1}^3 c_{j'}(t) \hat{\sigma}_{j''} \epsilon_{jj''}, \quad (5.17)$$

where j'' is the index, or the same set $\{1, 2, 3\}$, complementary to j and j' ($j'' \neq j, j'$), and $\epsilon_{jj''}$ is the Levi-Civita symbol.⁸ But it is straightforward to verify that the usual vector product of two 3D vectors may be represented in a similar Cartesian-component form:

$$(\mathbf{a} \times \mathbf{b})_j = \begin{vmatrix} \mathbf{n}_1 & \mathbf{n}_2 & \mathbf{n}_3 \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix}_j = \sum_{j'=1}^3 a_{j'} b_{j''} \epsilon_{jj''}, \quad (5.18)$$

As a result, Eq. (17) may be rewritten in a vector form – or rather several equivalent forms:

$$i\hbar\dot{\hat{\sigma}}_j = 2i[\mathbf{c}(t) \times \hat{\boldsymbol{\sigma}}]_j, \quad \text{i.e. } i\hbar\dot{\hat{\boldsymbol{\sigma}}} = 2i\mathbf{c}(t) \times \hat{\boldsymbol{\sigma}}, \quad \text{or } \dot{\hat{\boldsymbol{\sigma}}} = \frac{2}{\hbar} \mathbf{c}(t) \times \hat{\boldsymbol{\sigma}}, \quad \text{or } \dot{\hat{\boldsymbol{\sigma}}} = \boldsymbol{\Omega}(t) \times \hat{\boldsymbol{\sigma}}, \quad (5.19)$$

where the vector $\boldsymbol{\Omega}$ is defined as

$$\hbar\boldsymbol{\Omega}(t) \equiv 2\mathbf{c}(t) \quad (5.20)$$

– an evident generalization of Eq. (14).⁹ As we have seen in Sec. 4.6, any linear relation between two Heisenberg operators is also valid for the expectation values of the corresponding observables, so that the last form of Eq. (19) yields:

$$\langle \hat{\boldsymbol{\sigma}} \rangle = \boldsymbol{\Omega}(t) \times \langle \boldsymbol{\sigma} \rangle. \quad (5.21)$$

But this is the well-known kinematic formula¹⁰ for the rotation of a constant-length classical 3D vector $\langle \boldsymbol{\sigma} \rangle$ around the instantaneous direction of the vector $\boldsymbol{\Omega}(t)$, with the instantaneous angular velocity $\boldsymbol{\Omega}(t)$. So, the time evolution of the representation point on the Bloch sphere is quite simple, especially in the case of a time-independent \mathbf{c} , and hence $\boldsymbol{\Omega}$ – see Fig. 3c.¹¹ Note that it is sufficient to turn off the field to stop the precession instantly. (Since Eq. (21) is the first-order differential equation, the

⁷ Indeed, if some three operators in the Schrödinger picture are related as $[\hat{A}_S, \hat{B}_S] = \hat{C}_S$, then according to Eq. (4.190), in the Heisenberg picture:

$$[\hat{A}_H, \hat{B}_H] = [\hat{u}^\dagger \hat{A}_H \hat{u}, \hat{u}^\dagger \hat{B}_H \hat{u}] \equiv \hat{u}^\dagger \hat{A}_H \hat{u} \hat{u}^\dagger \hat{B}_H \hat{u} - \hat{u}^\dagger \hat{B}_H \hat{u} \hat{u}^\dagger \hat{A}_H \hat{u} \equiv \hat{u}^\dagger [\hat{A}_S, \hat{B}_S] \hat{u} \equiv \hat{u}^\dagger \hat{C}_S \hat{u} = \hat{C}_H.$$

⁸ See, e.g., MA Eq. (9.2). Note that in Eqs. (17)-(18) and similar expressions below, the condition $j'' \neq j, j'$ may be (and frequently is) replaced by the summation over not only j' , but also j'' , in their right-hand sides.

⁹ It is also easy to verify that in the particular case $\boldsymbol{\Omega} = \Omega \mathbf{n}_z$, Eqs. (19) are reduced, in the z -basis, to Eqs. (4.200) for the spin- $1/2$ vector matrix $\mathbf{S} = (\hbar/2)\boldsymbol{\sigma}$.

¹⁰ See, e.g., CM Sec. 4.1, in particular Eq. (4.8).

¹¹ The bulkiness of the solutions of Problems 4.25 and 4.26 (which were offered just as useful exercises in quantum dynamic formalisms) reflects the awkward expression of the resulting circular motion of the vector $\langle \boldsymbol{\sigma} \rangle$ (see Fig. 3c) via its Cartesian components.

representation point has no effective inertia.¹²⁾ Hence, changing the direction and the magnitude of the effective external field, it is possible to drive the representation point of a two-level system from any initial position to any final position on the Bloch sphere, i.e. make the system take any of its possible quantum states.

In the particular case of a spin- $\frac{1}{2}$ in a magnetic field $\mathcal{B}(t)$, it is more customary to use Eqs. (13) and (20) to rewrite Eq. (21) as the following equation for the expectation value of the spin vector $\mathbf{S} = (\hbar/2)\boldsymbol{\sigma}$:

$$\langle \dot{\mathbf{S}} \rangle \equiv \gamma \langle \mathbf{S} \rangle \times \mathcal{B}(t). \quad (5.22)$$

As we know from the discussion in Chapter 4, such a classical description of the spin's evolution does not give a full picture of the quantum reality; in particular, it does not describe the possible large uncertainties of its components – see, e.g., Eqs. (4.135). The situation, however, is different for a collection of $N \gg 1$ similar, non-interacting spins, initially prepared to be in the same state – for example by polarizing all spins with a strong external field \mathcal{B}_0 , at relatively low temperatures T , with $k_B T \ll \gamma \mathcal{B}_0 \hbar$. (A practically important example of such a collection is a set of nuclear spins in macroscopic condensed-matter samples, where the spin interaction with each other and the environment is typically very small.) For such a collection, Eq. (22) is still valid, while the relative uncertainty of the resulting sample's magnetization $\mathbf{M} = n\langle \mathbf{m} \rangle = n\gamma \langle \mathbf{S} \rangle$ (where $n \equiv N/V$ is the spin density) is proportional to $1/N^{1/2} \ll 1$. Thus, the evolution of magnetization may be described, with good precision, by the essentially classical equation (valid for any spin, not necessarily spin- $\frac{1}{2}$):

$$\dot{\mathbf{M}} = \gamma \mathbf{M} \times \mathcal{B}(t). \quad (5.23)$$

This equation, or the equivalent set of three *Bloch equations*¹³ for its Cartesian components, with the right-hand side augmented with small terms describing the effects of dephasing and relaxation (to be discussed in Chapter 7), is used, in particular, to describe the *magnetic resonance*, taking place when the frequency (4.164) of the spin's precession in a strong dc magnetic field approaches the frequency of an additionally applied (and usually weak) ac field.¹⁴⁾

5.2. The Ehrenfest theorem

In Sec. 4.7, we have derived all the basic relations of wave mechanics from the bra-ket formalism, which will also enable us to get some important additional results in that area. One of them is a pair of very interesting relations, together called the *Ehrenfest theorem*. To derive them, for the simplest case of 1D orbital motion, let us calculate the following commutator:

$$[\hat{x}, \hat{p}_x^2] \equiv \hat{x}\hat{p}_x\hat{p}_x - \hat{p}_x\hat{p}_x\hat{x}. \quad (5.24)$$

Let us apply the commutation relation (4.238) in the following form:

$$\hat{x}\hat{p}_x = \hat{p}_x\hat{x} + i\hbar\hat{I}, \quad (5.25)$$

¹² This is also true for the classical angular momentum \mathbf{L} at its torque-induced precession – see, e.g., CM Sec. 4.5.

¹³ They were introduced by F. Bloch in the same 1946 paper as the Bloch-sphere representation.

¹⁴ The quantum theory of this effect will be discussed in the next chapter.

to the first term of the right-hand side of Eq. (24) twice, with the goal to move the coordinate operator to the rightmost position:

$$\hat{x}\hat{p}_x\hat{p}_x = (\hat{p}_x\hat{x} + i\hbar\hat{I})\hat{p}_x \equiv \hat{p}_x\hat{x}\hat{p}_x + i\hbar\hat{p}_x = \hat{p}_x(\hat{p}_x\hat{x} + i\hbar\hat{I}) + i\hbar\hat{p}_x \equiv \hat{p}_x\hat{p}_x\hat{x} + 2i\hbar\hat{p}_x. \quad (5.26)$$

The first term of this result cancels with the last term of Eq. (24), so that the commutator becomes quite simple:

$$[\hat{x}, \hat{p}_x^2] = 2i\hbar\hat{p}_x. \quad (5.27)$$

Let us use this equality to calculate the Heisenberg-picture equation of motion of the operator \hat{x} , by applying the general Heisenberg equation (4.199) to the 1D orbital motion described by the Hamiltonian (4.237), but possibly with a more general, time-dependent potential energy U :

$$\frac{d\hat{x}}{dt} = \frac{1}{i\hbar} [\hat{x}, \hat{H}] = \frac{1}{i\hbar} \left[\hat{x}, \frac{\hat{p}_x^2}{2m} + U(\hat{x}, t) \right]. \quad (5.28)$$

The potential energy operator is a function of the coordinate operator and hence, as we know, commutes with it. Thus, the right-hand side of Eq. (28) is proportional to the commutator (27), and we get

$$\frac{d\hat{x}}{dt} = \frac{\hat{p}_x}{m}.$$

(5.29)

Heisenberg
equation
for
coordinate

In this *operator* equality, we readily recognize the full analog of the classical relation between the particle's momentum and its velocity.

Now let us see what a similar procedure gives for the momentum's derivative:

$$\frac{d\hat{p}_x}{dt} = \frac{1}{i\hbar} [\hat{p}_x, \hat{H}] = \frac{1}{i\hbar} \left[\hat{p}_x, \frac{\hat{p}_x^2}{2m} + U(\hat{x}, t) \right]. \quad (5.30)$$

The kinetic energy operator commutes with the momentum operator and hence drops from the right-hand side of this equation. To calculate the remaining commutator of the momentum and potential energy, let us use the fact that any smooth (infinitely differentiable) function may be represented by its Taylor expansion:

$$U(\hat{x}, t) = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k U}{\partial \hat{x}^k} \hat{x}^k, \quad (5.31)$$

where the derivatives of U may be understood as *c*-numbers (evaluated at $x = 0$, and the given time t), so that we may write

$$[\hat{p}_x, U(\hat{x}, t)] = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k U}{\partial \hat{x}^k} [\hat{p}_x, \hat{x}^k] = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k U}{\partial \hat{x}^k} \left(\hat{p}_x \underbrace{\hat{x}\hat{x}\dots\hat{x}}_{k \text{ times}} - \underbrace{\hat{x}\hat{x}\dots\hat{x}}_{k \text{ times}} \hat{p}_x \right). \quad (5.32a)$$

Applying Eq. (25) k times to the last term in the parentheses, exactly as we did it in Eq. (26), we get

$$[\hat{p}_x, U(\hat{x}, t)] = - \sum_{k=1}^{\infty} \frac{1}{k!} \frac{\partial^k U}{\partial \hat{x}^k} ik\hbar\hat{x}^{k-1} \equiv -i\hbar \sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^k U}{\partial \hat{x}^k} \hat{x}^{k-1}. \quad (5.32b)$$

But the last sum is just the Taylor expansion of the derivative $\partial U / \partial x$. Indeed,

$$\frac{\partial U}{\partial \hat{x}} = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k'}}{\partial \hat{x}^{k'}} \left(\frac{\partial U}{\partial \hat{x}} \right) \hat{x}^{k'} = \sum_{k=0}^{\infty} \frac{1}{k'!} \frac{\partial^{k'+1} U}{\partial \hat{x}^{k'+1}} \hat{x}^{k'} = \sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^k U}{\partial \hat{x}^k} \hat{x}^{k-1}, \quad (5.33)$$

where at the last step the summation index was changed from k' to $k - 1$. As a result, we may rewrite Eq. (5.32b) as

$$[\hat{p}_x, U(\hat{x}, t)] = -i\hbar \frac{\partial}{\partial \hat{x}} U(\hat{x}, t), \quad (5.34)$$

so that Eq. (30) yields:

Heisenberg
equation
for
momentum

$$\frac{d\hat{p}_x}{dt} = -\frac{\partial}{\partial \hat{x}} U(\hat{x}, t). \quad (5.35)$$

This equation also coincides with the classical equation of motion! Moreover, averaging Eqs. (29) and (35) over the initial state (as Eq. (4.191) prescribes), we get similar results for the expectation values:¹⁵

Ehrenfest
theorem

$$\frac{d\langle x \rangle}{dt} = \frac{\langle p_x \rangle}{m}, \quad \frac{d\langle p_x \rangle}{dt} = -\left\langle \frac{\partial U}{\partial x} \right\rangle. \quad (5.36)$$

However, it is important to remember that the equivalence between these quantum-mechanical equations and similar equations of classical mechanics is superficial, and the degree of the similarity between the two mechanics very much depends on the problem. As one extreme, let us consider the case when a particle's state, at any moment between t_0 and t , may be accurately represented by one, relatively p_x -narrow wave packet. Then we may interpret Eqs. (36) as the equations of the essentially classical motion of the wave packet's center, in accordance with the correspondence principle. However, even in this case, it is important to remember the purely quantum mechanical effects of non-zero wave packet width and its spread in time, which were discussed in Sec. 2.2.

As an opposite extreme, let us revisit the “leaky” potential well discussed in Sec. 2.5 – see Fig. 2.15. Since both the potential $U(x)$ and the initial wavefunction of that system are symmetric relative to point $x = 0$ at all times, the right-hand sides of both Eqs. (36) identically equal zero. Of course, the result they predict (that the average values of the coordinate and the momentum stay equal to zero at all times) is correct, but this fact does not tell us much about the rich dynamics of the system: the finite lifetime of the metastable state, the formation of two wave packets, their waveform and propagation speed (see Fig. 2.17), and about the insights the full solution gives for the quantum measurement theory and the system's irreversibility. Another similar example is the energy band theory (Sec. 2.7), with its purely quantum effect of the allowed energy bands and forbidden energy gaps, of which Eqs. (36) give no clue.

To summarize, the Ehrenfest theorem is important as an illustration of the correspondence principle, but its predictive power should not be exaggerated.

5.3. The Feynman path integral

As has been already mentioned, even within the realm of wave mechanics, the bra-ket language may simplify some calculations that would be very bulky using the notation used in Chapters 1-3. Probably the best example is the famous alternative, *path-integral* formulation of quantum mechanics.¹⁶

¹⁵ The equation set (36) constitutes the *Ehrenfest theorem*, named after its author, P. Ehrenfest.

¹⁶ This formulation was developed in 1948 by Richard Phillips Feynman. (According to his memories, this work was motivated by a “mysterious” remark by P. Dirac in his pioneering 1930 textbook on quantum mechanics.)

I will review this important concept, cutting one math corner for the sake of brevity.¹⁷ (This shortcut will be clearly marked below.)

Let us inner-multiply both parts of Eq. (4.157a), which is essentially the definition of the time-evolution operator, by the bra-vector of state x ,

$$\langle x | \alpha(t) \rangle = \langle x | \hat{u}(t, t_0) | \alpha(t_0) \rangle, \quad (5.37)$$

insert the identity operator before the ket-vector on the right-hand side, and then use the closure condition in the form of Eq. (4.252), with x' replaced with x_0 :

$$\langle x | \alpha(t) \rangle = \int dx_0 \langle x | \hat{u}(t, t_0) | x_0 \rangle \langle x_0 | \alpha(t_0) \rangle. \quad (5.38)$$

According to Eq. (4.233), this equality may be represented as

$$\Psi_\alpha(x, t) = \int dx_0 \langle x | \hat{u}(t, t_0) | x_0 \rangle \Psi_\alpha(x_0, t_0). \quad (5.39)$$

Comparing this expression with Eq. (2.44), we see that the long bracket in this relation is nothing other than the 1D propagator, which was discussed in Sec. 2.2, i.e.

$$G(x, t; x_0, t_0) = \langle x | \hat{u}(t, t_0) | x_0 \rangle. \quad (5.40)$$

Let me hope that the reader sees that this equality corresponds to the physical sense of the propagator.

Now let us break the time segment $[t_0, t]$ into N (for the time being, not necessarily equal) parts, by inserting $(N - 1)$ intermediate points (Fig. 4) with

$$t_0 < t_1 < \dots < t_k < \dots < t_{N-1} < t, \quad (5.41)$$

and use the definition (4.157) of the time evolution operator to write

$$\hat{u}(t, t_0) = \hat{u}(t, t_{N-1}) \hat{u}(t_{N-1}, t_{N-2}) \dots \hat{u}(t_2, t_1) \hat{u}(t_1, t_0). \quad (5.42)$$

After plugging Eq. (42) into Eq. (40), let us insert the identity operator, again in the closure form (4.252), but written for x_k rather than x' , between each two partial evolution operators including the time argument t_k . The result is

$$G(x, t; x_0, t_0) = \int dx_{N-1} \int dx_{N-2} \dots \int dx_1 \langle x | \hat{u}(t, t_{N-1}) | x_{N-1} \rangle \langle x_{N-1} | \hat{u}(t_{N-1}, t_{N-2}) | x_{N-2} \rangle \dots \langle x_1 | \hat{u}(t_1, t_0) | x_0 \rangle. \quad (5.43)$$

The physical sense of each integration variable x_k is the wavefunction's argument at time t_k – see Fig. 4.

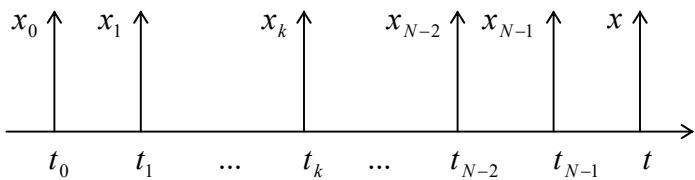

Fig. 5.4. Time partition and coordinate notation at the initial stage of the Feynman path integral's derivation.

¹⁷ A more thorough discussion of the path-integral approach may be found in the famous text by R. Feynman and A. Hibbs, *Quantum Mechanics and Path Integrals*, first published in 1965. (For its latest edition by Dover in 2010, the book was emended by D. Styler.) For a more recent monograph, which reviews more applications, see L. Schulman, *Techniques and Applications of Path Integration*, Wiley, 1981.

The key Feynman's breakthrough was the realization that if all intervals are taken similar and sufficiently small, $t_k - t_{k-1} = d\tau \rightarrow 0$, all the partial brackets participating in Eq. (43) may be expressed via the free-particle's propagator, given by Eq. (2.49), even if the particle is not free, but moves in a stationary potential profile $U(x)$. To show that, let us use either Eq. (4.175) or Eq. (4.181), which, for a small time interval $d\tau$, give the same result:

$$\hat{u}(\tau + d\tau, \tau) = \exp\left\{-\frac{i}{\hbar} \hat{H}d\tau\right\} = \exp\left\{-\frac{i}{\hbar}\left(\frac{\hat{p}^2}{2m}d\tau + U(\hat{x})d\tau\right)\right\}. \quad (5.44)$$

Generally, an exponent of a sum of two operators may be treated as that of *c*-number arguments, and in particular factored into a product of two exponents, only if the operators commute. (In this case, we can use all the standard algebra for the exponents of *c*-number arguments.) In our case, this is not so, because the operator $\hat{p}^2/2m$ does not commute with \hat{x} , and hence with $U(\hat{x})$. However, it may be shown¹⁸ that for an infinitesimal time interval $d\tau$, the non-zero commutator

$$\left[\frac{\hat{p}^2}{2m}d\tau, U(\hat{x})d\tau\right] \neq 0, \quad (5.45)$$

proportional to $(d\tau)^2$, may be ignored in the first, linear approximation in $d\tau$. As a result, we may factorize the right-hand side in Eq. (44) by writing

$$\hat{u}(\tau + d\tau, \tau)_{d\tau \rightarrow 0} \rightarrow \exp\left\{-\frac{i}{\hbar} \frac{\hat{p}^2}{2m}d\tau\right\} \exp\left\{-\frac{i}{\hbar} U(\hat{x})d\tau\right\}. \quad (5.46)$$

(This approximation is very much similar in spirit to the trapezoidal-rule approximation in the usual 1D integration,¹⁹ which is also asymptotically impeccable.)

Since the second exponential function on the right-hand side of Eq. (46) commutes with the coordinate operator, we may move it out of each partial bracket participating in Eq. (43), with $U(x)$ turning into a *c*-number function:

$$\langle x_{\tau+d\tau} | \hat{u}(\tau + d\tau, \tau) | x_\tau \rangle = \langle x_{\tau+d\tau} | \exp\left\{-\frac{i}{\hbar} \frac{\hat{p}^2}{2m}d\tau\right\} | x_\tau \rangle \exp\left\{-\frac{i}{\hbar} U(x)d\tau\right\}. \quad (5.47)$$

But the remaining bracket is just the propagator of a free particle, so that for it we may use Eq. (2.49):

$$\langle x_{\tau+d\tau} | \exp\left\{-\frac{i}{\hbar} \frac{\hat{p}^2}{2m}d\tau\right\} | x_\tau \rangle = \left(\frac{m}{2\pi i \hbar d\tau}\right)^{1/2} \exp\left\{i \frac{m(dx)^2}{2\hbar d\tau}\right\}. \quad (5.48)$$

As the result, the full propagator (43) takes the form

$$G(x, t; x_0, t_0) = \lim_{\substack{d\tau \rightarrow 0 \\ N \rightarrow \infty}} \int dx_{N-1} \int dx_{N-2} \dots \int dx_1 \left(\frac{m}{2\pi i \hbar d\tau}\right)^{N/2} \exp\left\{\sum_{k=1}^N \left[i \frac{m(dx)^2}{2\hbar d\tau} - i \frac{U(x)}{\hbar} d\tau\right]\right\}. \quad (5.49)$$

¹⁸ This is exactly the corner I am going to cut because a strict mathematical proof of this (intuitively evident) statement would take more time/space than I can afford.

¹⁹ See, e.g., MA Eq. (5.2).

At $N \rightarrow \infty$ and hence $d\tau \equiv (t - t_0)/N \rightarrow 0$, the sum under the exponent in this expression may be approximated with the corresponding integral:

$$\sum_{k=1}^N \frac{i}{\hbar} \left[\frac{m}{2} \left(\frac{dx}{d\tau} \right)^2 - U(x) \right]_{\tau=t_k} d\tau \rightarrow \frac{i}{\hbar} \int_{t_0}^t \left[\frac{m}{2} \left(\frac{dx}{d\tau} \right)^2 - U(x) \right] d\tau, \quad (5.50)$$

and the expression in the square brackets is just the particle's Lagrangian function \mathcal{L} .²⁰ The integral of this function over time is the classical action \mathcal{S} calculated along a particular "path" $x(\tau)$.²¹ As a result, defining the (1D) *path integral* as

$$\int (\dots) D[x(\tau)] \equiv \lim_{\substack{d\tau \rightarrow 0 \\ N \rightarrow \infty}} \left(\frac{m}{2\pi i \hbar d\tau} \right)^{N/2} \int dx_{N-1} \int dx_{N-2} \dots \int dx_1 (\dots), \quad (5.51a)$$

1D path integral:
definition

we can bring our result to the following (superficially simple) form:

$$G(x, t; x_0, t_0) = \int \exp \left\{ \frac{i}{\hbar} \mathcal{S}[x(\tau)] \right\} D[x(\tau)]. \quad (5.51b)$$

1D propagator
via path integral

The name "path integral" for the mathematical construct (51a) may be readily explained if we keep the number N of time intervals large but finite, and also approximate each of the enclosed integrals with a sum over $M \gg 1$ discrete points along the coordinate axis – see Fig. 5a.

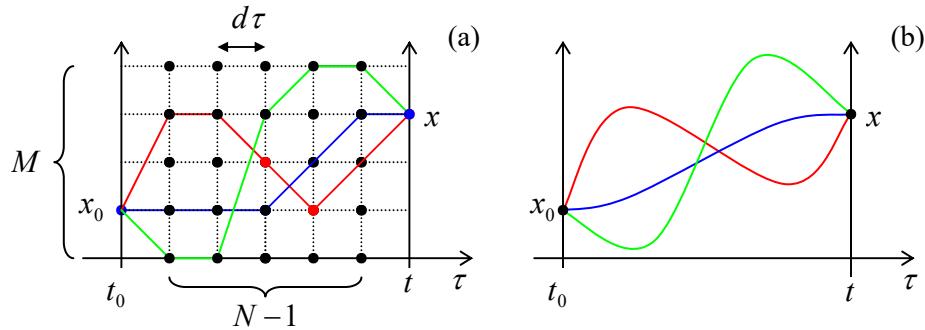

Fig. 5.5. Several 1D classical paths: (a) in the discrete approximation and (b) in the continuous limit.

Then the path integral (51a) is the product of $(N - 1)$ sums corresponding to different values of time τ , each of them with M terms, each of those representing the function under the integral at a particular spatial point. Multiplying those $(N - 1)$ sums, we get a sum of $(N - 1)M$ terms, each evaluating the function at a specific spatial-temporal point $[x, \tau]$. These terms may be now grouped to represent all possible different continuous classical paths $x[\tau]$ from the initial point $[x_0, t_0]$ to the finite point $[x, t]$. It is evident that the last interpretation remains true even in the continuous limit $N, M \rightarrow \infty$ – see Fig. 5b.

Why does such path representation of the sum make sense? This is because in the classical limit the particle follows just a certain path, corresponding to the minimum of the action \mathcal{S} . As a result, for all close trajectories, the difference $(\mathcal{S} - \mathcal{S}_{\text{cl}})$ is proportional to the square of the deviation from the

²⁰ See, e.g., CM Sec. 2.1.

²¹ See, e.g., CM Sec. 10.3.

classical trajectory. Hence, for a quasiclassical motion, with $\mathcal{S}_{\text{cl}} \gg \hbar$, there is a bunch of close trajectories, with $(\mathcal{S} - \mathcal{S}_{\text{cl}}) \ll \hbar$, that give substantial contributions to the path integral. On the other hand, strongly non-classical trajectories, with $(\mathcal{S} - \mathcal{S}_{\text{cl}}) \gg \hbar$, give phases $\mathcal{S}\hbar$ rapidly oscillating from one trajectory to the next one, and their contributions to the path integral are averaged out.²² As a result, for a quasi-classical motion, the propagator's exponent may be evaluated on the classical path only:

$$G_{\text{cl}} \propto \exp\left\{\frac{i}{\hbar} \mathcal{S}_{\text{cl}}\right\} = \exp\left\{\frac{i}{\hbar} \int_{t_0}^t \left[\frac{m}{2} \left(\frac{dx}{d\tau} \right)^2 - U(x) \right] d\tau\right\}. \quad (5.52)$$

The sum of the kinetic and potential energies is the full energy E of the particle, that remains constant for motion in a stationary potential $U(x)$, so that we may rewrite the expression under this integral as²³

$$\left[\frac{m}{2} \left(\frac{dx}{d\tau} \right)^2 - U(x) \right] d\tau = \left[m \left(\frac{dx}{d\tau} \right)^2 - E \right] d\tau = m \frac{dx}{d\tau} dx - Ed\tau. \quad (5.53)$$

With this replacement, Eq. (52) yields

$$G_{\text{cl}} \propto \exp\left\{\frac{i}{\hbar} \int_{x_0}^x m \frac{dx}{d\tau} dx\right\} \exp\left\{-\frac{i}{\hbar} E(t - t_0)\right\} = \exp\left\{\frac{i}{\hbar} \int_{x_0}^x p(x) dx\right\} \exp\left\{-\frac{i}{\hbar} E(t - t_0)\right\}, \quad (5.54)$$

where p is the classical momentum of the particle. But (at least, leaving the pre-exponential factor alone) this is the WKB approximation result that was derived and studied in detail in Chapter 2!

One may question the value of such a complicated calculation, which yields the results that could be readily obtained from Schrödinger's wave mechanics. Feynman's approach is indeed not used too often, but it has its merits. First, it has an important philosophical (and hence heuristic) value. Indeed, Eq. (51) may be interpreted by saying that the essence of quantum mechanics is the exploration, by the system, of all possible paths $x(\tau)$, each of them classical-like, in the sense that the particle's coordinate x and velocity $dx/d\tau$ are exactly defined simultaneously at each point. The resulting contributions to the path integral are added up coherently to form the actual propagator G , and via it, the final probability $W \propto |G|^2$ of the particle's propagation from $[x_0, t_0]$ to $[x, t]$. As the scale of the action \mathcal{S} of the motion decreases and becomes comparable to \hbar , more and more paths produce substantial contributions to this sum, and hence to W , providing a larger and larger difference between the quantum and classical properties of the system.

Second, the path integral provides a justification for some simple explanations of quantum phenomena. A typical example is the quantum interference effects discussed in Sec. 3.1 – see, e.g., Fig. 3.1 and the corresponding text. At that discussion, we used the Huygens principle to argue that at the two-slit interference, the WKB approximation might be restricted to contributions from two paths that pass through different slits, but otherwise consisting of straight-line segments. To have another look at

²² This fact may be proved by expanding the difference $(\mathcal{S} - \mathcal{S}_{\text{cl}})$ in the Taylor series in the path variation (leaving only the leading quadratic terms) and working out the resulting Gaussian integrals. This integration, together with the pre-exponential coefficient in Eq. (51a), gives exactly the pre-exponential factor that we have already found refining the WKB approximation in Sec. 2.4.

²³ The same trick is often used in analytical classical mechanics – say, for proving the Hamilton principle, and for the derivation of the Hamilton – Jacobi equations (see, e.g., CM Secs. 10.3-4).

that assumption, let us generalize the path integral to multi-dimensional geometries. Fortunately, the simple structure of Eq. (51b) makes such generalization virtually evident:

$$G(\mathbf{r}, t; \mathbf{r}_0, t_0) = \int \exp\left\{\frac{i}{\hbar} \mathcal{S}[\mathbf{r}(\tau)]\right\} D[\mathbf{r}(\tau)], \quad \mathcal{S} = \int_{t_0}^t \mathcal{L}\left(\mathbf{r}, \frac{d\mathbf{r}}{d\tau}\right) d\tau = \int_{t_0}^t \left[\frac{m}{2} \left(\frac{d\mathbf{r}}{d\tau} \right)^2 - U(\mathbf{r}) \right] d\tau. \quad (5.55)$$

3D
propagator
as a path
integral

where the definition (51a) of the path integral should be also modified correspondingly. (I will not go into these technical details.) For the Young-type experiment (Fig. 3.1), where a classical particle could reach the detector only after passing through one of the slits, the classical paths are the straight-line segments shown in Fig. 3.1, and if they are much longer than the de Broglie wavelength, the propagator may be well approximated by the sum of two integrals of $\mathcal{L}d\tau = i\mathbf{p}(\mathbf{r}) \cdot d\mathbf{r}/\hbar$ – as it was done in Sec. 3.1.

Last but not least, the path integral allows simple solutions to some problems that would be hard to obtain by other methods. As the simplest example, let us consider the problem of tunneling in multi-dimensional space, sketched in Fig. 6 for the 2D case – just for the graphics' simplicity. Here, the potential profile $U(x, y)$ has a saddle-like shape. (Another helpful image is a mountain path between two summits, in Fig. 6 located on the top and at the bottom of the shown region.) A particle of energy E may move classically in the left and right regions with $U(x, y) < E$, but if E is not sufficiently high, it can pass from one of these regions to another one only via the quantum-mechanical tunneling under the pass. Let us calculate the transparency of this potential barrier in the WKB approximation, ignoring the possible pre-exponential factor.²⁴

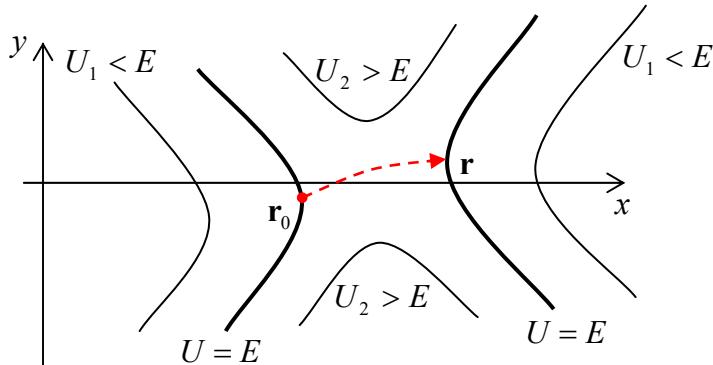

Fig. 5.6. A saddle-type 2D potential profile and the instanton trajectory of a particle of energy E (schematically).

According to the evident multi-dimensional generalization Eq. (54), for the classically forbidden region, where $E < U(x, y)$, and hence $\mathbf{p}(\mathbf{r})/\hbar = i\boldsymbol{\kappa}(\mathbf{r})$, the contributions to the propagator (55) are proportional to

$$e^{-I} \exp\left\{-\frac{i}{\hbar} E(t - t_0)\right\}, \quad \text{where } I \equiv \int_{\mathbf{r}_0}^{\mathbf{r}} \boldsymbol{\kappa}(\mathbf{r}) \cdot d\mathbf{r}, \quad (5.56)$$

where $\boldsymbol{\kappa} \equiv \boldsymbol{\kappa}$ may be calculated just in the 1D case – cf. Eq. (2.97):

$$\frac{\hbar^2 \boldsymbol{\kappa}^2(\mathbf{r})}{2m} = U(\mathbf{r}) - E. \quad (5.57)$$

²⁴ Actually, one can argue that the pre-exponential factor should be close to 1, just like in Eq. (2.117), especially if the potential is smooth, in the sense of Eq. (2.107), in all spatial directions. (Let me remind the reader that for most practical applications of quantum tunneling, the pre-exponential factor is of minor importance.)

Hence the path integral in this region is much simpler than in the classically allowed region, because the spatial exponents are purely real and there is no complex interference between them. Due to the minus sign before I in the exponent (56), the *largest* contribution to G evidently comes from the trajectory (or a narrow bundle of close trajectories) for which the integral I has the *smallest* value, so that the barrier transparency may be calculated as

3D
tunneling
in WKB
limit

$$\mathcal{T} \approx |G|^2 \approx e^{-2I} \equiv \exp \left\{ -2 \int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{k}(\mathbf{r}') \cdot d\mathbf{r}' \right\}, \quad (5.58)$$

where \mathbf{r} and \mathbf{r}_0 are certain points on the opposite classical turning-point surfaces: $U(\mathbf{r}) = U(\mathbf{r}_0) = E$ – see Fig. 6.

Thus the barrier transparency problem is reduced to finding the trajectory (including the points \mathbf{r} and \mathbf{r}_0) that connects the two surfaces and minimizes the functional I . This is of course a well-known problem of the calculus of variations,²⁵ but it is interesting that the path integral provides a simple alternative way of solving it. Let us consider an auxiliary problem of particle's motion in the potential profile $U_{\text{inv}}(\mathbf{r})$ that is *inverted* relative to the particle's energy E , i.e. is defined by the following equality:

$$U_{\text{inv}}(\mathbf{r}) - E \equiv E - U(\mathbf{r}). \quad (5.59)$$

As was discussed above, at fixed energy E , the path integral for the WKB motion in the classically allowed region of potential $U_{\text{inv}}(x, y)$ (that coincides with the classically forbidden region of the original problem) is dominated by the classical trajectory corresponding to the minimum of

$$\mathcal{S}_{\text{inv}} = \int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{p}_{\text{inv}}(\mathbf{r}') \cdot d\mathbf{r}' = \hbar \int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{k}_{\text{inv}}(\mathbf{r}') \cdot d\mathbf{r}, \quad (5.60)$$

where \mathbf{k}_{inv} should be determined from the WKB relation

$$\frac{\hbar^2 k_{\text{inv}}^2(\mathbf{r})}{2m} \equiv E - U_{\text{inv}}(\mathbf{r}). \quad (5.61)$$

But comparing Eqs. (57), (59), and (61), we see that $\mathbf{k}_{\text{inv}} = \mathbf{k}$ at each point! This means that the tunneling path (in the WKB limit) corresponds to the classical (so-called *instanton*²⁶) trajectory of the same particle moving in the inverted potential $U_{\text{inv}}(\mathbf{r})$. If the initial point \mathbf{r}_0 is fixed, this trajectory may be readily found by the means of classical mechanics. (Note that the initial kinetic energy, and hence the initial velocity of the instanton launched from point \mathbf{r}_0 should be zero because by the classical turning point definition, $U_{\text{inv}}(\mathbf{r}_0) = U(\mathbf{r}_0) = E$.) Thus the problem is further reduced to a simpler task of maximizing the transparency (58) by choosing the optimal position of \mathbf{r}_0 on the equipotential surface $U(\mathbf{r}_0) = E$ – see Fig. 6. Moreover, for many symmetric potentials, the position of this point may be readily guessed even without calculations – as it is in Problems 6 and 7, left for the reader's exercise.

Note that besides the calculation of the potential barrier's transparency, the instanton trajectory has one more important implication: the so-called *traversal time* τ_i of the classical motion along it, from

²⁵ For a concise introduction to the field see, e.g., I. Gelfand and S. Fomin, *Calculus of Variations*, Dover, 2000, or L. Elsgolc, *Calculus of Variations*, Dover, 2007.

²⁶ In the quantum field theory, the instanton concept may be formulated somewhat differently, and has more complex applications – see, e.g. R. Rajaraman, *Solitons and Instantons*, North-Holland, 1987.

the point \mathbf{r}_0 to the point \mathbf{r} , in the inverted potential defined by Eq. (59), plays the role of the most important (though not the only one) time scale of the particle's tunneling under the barrier.²⁷

5.4. Revisiting harmonic oscillator

Let us return to the 1D harmonic oscillator, now understood as any system, regardless of its physical nature, described by the Hamiltonian (4.237) with the potential energy (2.111):

$$\hat{H} = \frac{\hat{p}^2}{2m} + \frac{m\omega_0^2 \hat{x}^2}{2}. \quad (5.62)$$

Harmonic oscillator:
Hamiltonian

In Sec. 2.9 we have used a “brute-force” (wave-mechanics) approach to analyze the eigenfunctions $\psi_n(x)$ and eigenvalues E_n of this Hamiltonian, and found that, unfortunately, this approach required relatively complex mathematics, which does not enable an easy calculation of its key characteristics. Fortunately, the bra-ket formalism helps to make such calculations.

First, introducing normalized (dimensionless) operators of coordinates and momentum:²⁸

$$\hat{\xi} \equiv \frac{\hat{x}}{x_0}, \quad \hat{\zeta} \equiv \frac{\hat{p}}{m\omega_0 x_0}, \quad (5.63)$$

where $x_0 \equiv (\hbar/m\omega_0)^{1/2}$ is the natural coordinate scale discussed in detail in Sec. 2.9, we can represent the Hamiltonian (62) in a very simple and $x \leftrightarrow p$ symmetric form:

$$\hat{H} = \frac{\hbar\omega_0}{2} \left(\hat{\xi}^2 + \hat{\zeta}^2 \right). \quad (5.64)$$

This symmetry, as well as our discussion of the very similar coordinate and momentum representations in Sec. 4.7, hints that much may be gained by treating the operators $\hat{\xi}$ and $\hat{\zeta}$ on equal footing. Inspired by this clue, let us introduce a new operator

$$\hat{a} \equiv \frac{\hat{\xi} + i\hat{\zeta}}{\sqrt{2}} \equiv \left(\frac{m\omega_0}{2\hbar} \right)^{1/2} \left(\hat{x} + i\frac{\hat{p}}{m\omega_0} \right). \quad (5.65a)$$

Annihilation operator:
definition

Since both operators $\hat{\xi}$ and $\hat{\zeta}$ correspond to real observables, i.e. have real eigenvalues and hence are Hermitian (self-adjoint), the Hermitian conjugate of the operator \hat{a} is simply its complex conjugate:

$$\hat{a}^\dagger \equiv \frac{\hat{\xi} - i\hat{\zeta}}{\sqrt{2}} \equiv \left(\frac{m\omega_0}{2\hbar} \right)^{1/2} \left(\hat{x} - i\frac{\hat{p}}{m\omega_0} \right). \quad (5.65b)$$

Creation operator:
definition

Because of the reason that will be clear very soon, \hat{a}^\dagger and \hat{a} (in this order!) are called the *creation and annihilation operators*.

²⁷ For more on this interesting issue see, e.g., M. Buttiker and R. Landauer, *Phys. Rev. Lett.* **49**, 1739 (1982), and references therein.

²⁸ This normalization is not really necessary, it just makes the following calculations less bulky – and thus more aesthetically appealing.

Now solving the simple system of two linear equations (65) for $\hat{\xi}$ and $\hat{\zeta}$, we get the following reciprocal relations:

$$\hat{\xi} = \frac{\hat{a} + \hat{a}^\dagger}{\sqrt{2}}, \quad \hat{\zeta} = \frac{\hat{a} - \hat{a}^\dagger}{\sqrt{2} i}, \quad \text{i.e. } \hat{x} = \left(\frac{\hbar}{m\omega_0} \right)^{1/2} \frac{\hat{a} + \hat{a}^\dagger}{\sqrt{2}}, \quad \hat{p} = (\hbar m \omega_0)^{1/2} \frac{\hat{a} - \hat{a}^\dagger}{\sqrt{2} i}. \quad (5.66)$$

Our Hamiltonian (64) includes squares of these operators. Calculating them, we have to be careful to avoid swapping the new operators, because they do not commute. Indeed, for the normalized operators (63), Eq. (2.14) gives

$$[\hat{\xi}, \hat{\zeta}] \equiv \frac{1}{x_0^2 m \omega_0} [\hat{x}, \hat{p}] = i\hat{I}, \quad (5.67)$$

so that Eqs. (65) yield

$$[\hat{a}, \hat{a}^\dagger] = \frac{1}{2} [(\hat{\xi} + i\hat{\zeta}), (\hat{\xi} - i\hat{\zeta})] = -\frac{i}{2} ([\hat{\xi}, \hat{\zeta}] - [\hat{\zeta}, \hat{\xi}]) = \hat{I}. \quad (5.68)$$

With such due caution, Eq. (66) gives

$$\hat{\xi}^2 = \frac{1}{2} \left(\hat{a}^2 + \hat{a}^{\dagger 2} + \hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a} \right), \quad \hat{\zeta}^2 = -\frac{1}{2} \left(\hat{a}^2 + \hat{a}^{\dagger 2} - \hat{a}\hat{a}^\dagger - \hat{a}^\dagger\hat{a} \right). \quad (5.69)$$

Plugging these expressions back into Eq. (64), we get

$$\hat{H} = \frac{\hbar\omega_0}{2} (\hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a}). \quad (5.70)$$

This expression is elegant enough, but may be recast into an even more convenient form. For that, let us rewrite the commutation relation (68) as

$$\hat{a}\hat{a}^\dagger = \hat{a}^\dagger\hat{a} + \hat{I}, \quad (5.71)$$

and plug it into Eq. (70). The result is

$$\hat{H} = \frac{\hbar\omega_0}{2} (2\hat{a}^\dagger\hat{a} + \hat{I}) \equiv \hbar\omega_0 \left(\hat{N} + \frac{1}{2} \hat{I} \right), \quad (5.72)$$

where, in the last form, one more (evidently, Hermitian) operator,

$$\hat{N} \equiv \hat{a}^\dagger\hat{a}, \quad (5.73)$$

has been introduced. Since, according to Eq. (72), the operators \hat{H} and \hat{N} differ only by the addition of the identity operator and multiplication by a c -number, these operators commute. Hence, according to the general arguments of Sec. 4.5, they share a set of stationary eigenstates n (they are frequently called the *Fock states*), and we can write the standard eigenproblem (4.68) for the new operator as

$$\hat{N}|n\rangle = N_n|n\rangle, \quad (5.74)$$

where N_n are some eigenvalues that, according to Eq. (72), determine also the energy spectrum of the oscillator:

$$E_n = \hbar\omega_0 \left(N_n + \frac{1}{2} \right). \quad (5.75)$$

So far, we know only that all eigenvalues N_n are real; to calculate them, let us carry out the following calculation – splendid in its simplicity and efficiency. Consider the result of the action of the operator \hat{N} on the ket-vector $\hat{a}^\dagger|n\rangle$. Using the definition (73) and then the associative rule of the bra-ket formalism, we may write

$$\hat{N}(\hat{a}^\dagger|n\rangle) = (\hat{a}^\dagger \hat{a})(\hat{a}^\dagger|n\rangle) = \hat{a}^\dagger(\hat{a}\hat{a}^\dagger)|n\rangle. \quad (5.76)$$

Now using the commutation relation (71), and then Eq. (74), we may continue as

$$\hat{a}^\dagger(\hat{a}\hat{a}^\dagger)|n\rangle = \hat{a}^\dagger(\hat{a}^\dagger \hat{a} + \hat{I})|n\rangle = \hat{a}^\dagger(\hat{N} + \hat{I})|n\rangle = \hat{a}^\dagger(N_n + 1)|n\rangle = (N_n + 1)(\hat{a}^\dagger|n\rangle). \quad (5.77)$$

For clarity, let us summarize the result of this calculation:

$$\hat{N}(\hat{a}^\dagger|n\rangle) = (N_n + 1)(\hat{a}^\dagger|n\rangle). \quad (5.78)$$

Performing a similar calculation for the operator \hat{a} , we get a similar formula:

$$\hat{N}(\hat{a}|n\rangle) = (N_n - 1)(\hat{a}|n\rangle). \quad (5.79)$$

It is time to stop calculations for a minute, and translate these results into plain English: if $|n\rangle$ is an eigenket of the operator \hat{N} with the eigenvalue N_n , then $\hat{a}^\dagger|n\rangle$ and $\hat{a}|n\rangle$ are also eigenkets of that operator, with the eigenvalues $(N_n + 1)$, and $(N_n - 1)$, respectively. This statement may be vividly represented on the so-called *ladder diagram* shown in Fig. 7.

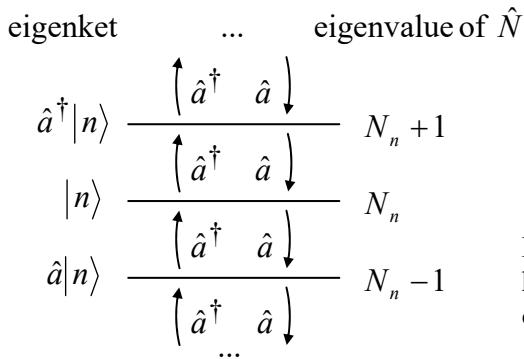

Fig. 5.7. The “ladder diagram” of eigenstates of a 1D harmonic oscillator. Arrows show the actions of the creation and annihilation operators on the eigenstates.

The operator \hat{a}^\dagger moves the system one step up this ladder, while the operator \hat{a} brings it one step down. In other words, the former operator creates a new *excitation* of the system,²⁹ while the latter operator kills (“annihilates”) such excitation.³⁰ On the other hand, according to Eq. (74) inner-multiplied by the bra-vector $\langle n|$, the operator \hat{N} does not change the state of the system, but “counts” its position on the ladder:

²⁹ For electromagnetic field oscillators, such excitations are called *photons*; for mechanical wave oscillators, *phonons*, etc.

³⁰ This is exactly why \hat{a}^\dagger is called the *creation* operator, and \hat{a} , the *annihilation* operator.

$$\langle n | \hat{N} | n \rangle = \langle n | N_n | n \rangle = N_n. \quad (5.80)$$

This is why \hat{N} is called the *number operator*, in our current context meaning the number of the elementary excitations of the oscillator.

This calculation still needs completion. Indeed, we still do not know whether the ladder shown in Fig. 7 shows *all* eigenstates of the oscillator, and what exactly the numbers N_n are. Fascinating enough, both questions may be answered by exploring just one paradox. Let us start with some state n (read a step of the ladder), and keep going down the ladder, applying the operator \hat{a} again and again. According to Eq. (79), at each step the eigenvalue N_n is decreased by one, so that eventually it should become negative. However, this cannot happen, because any actual eigenstate, including the states represented by kets $|d\rangle \equiv \hat{a}|n\rangle$ and $|n\rangle$, should have a positive norm – see Eq. (4.16). Comparing the norms,

$$\|n\|^2 = \langle n | n \rangle, \quad \|d\|^2 = \langle n | \hat{a}^\dagger a | n \rangle = \langle n | \hat{N} | n \rangle = N_n \langle n | n \rangle, \quad (5.81)$$

we see that both of them cannot be positive simultaneously if N_n is negative.

To resolve this paradox let us notice that the action of the creation and annihilation operators on the stationary states n may consist of not only their promotion to an adjacent step of the ladder diagram but also by their multiplication by some c -numbers:

$$\hat{a}|n\rangle = A_n |n-1\rangle, \quad \hat{a}^\dagger |n\rangle = A'_n |n+1\rangle. \quad (5.82)$$

(The linear relations (78)-(79) clearly allow that.) Let us calculate the coefficients A_n assuming, for convenience, that all eigenstates, including the states n and $(n-1)$, are normalized:

$$\langle n | n \rangle = 1, \quad \langle n-1 | n-1 \rangle = \langle n | \frac{\hat{a}^\dagger}{A_n^*} \frac{\hat{a}}{A_n} | n \rangle = \frac{1}{A_n^* A_n} \langle n | \hat{N} | n \rangle = \frac{N_n}{A_n^* A_n} \langle n | n \rangle = 1. \quad (5.83)$$

From here, we get $|A_n| = (N_n)^{1/2}$, i.e.

$$\hat{a}|n\rangle = N_n^{1/2} e^{i\varphi_n} |n-1\rangle, \quad (5.84)$$

where φ_n is an arbitrary real phase. Now let us consider what happens if all numbers N_n are integers. (Because of the definition of N_n , given by Eq. (74), it is convenient to call these integers n , i.e. to use the same letter as for the corresponding eigenstate.) Then when we have come down to the state with $n = 0$, an attempt to make one more step down gives

$$\hat{a}|0\rangle = | -1 \rangle. \quad (5.85)$$

But according to Eq. (4.9), the state on the right-hand side of this equation is the “null-state”, i.e. does not exist.³¹ This gives the (only known :-) resolution of the state ladder paradox: the ladder has the lowest step with $N_n = n = 0$.

As a by-product of our discussion, we have obtained a very important relation $N_n = n$, which means, in particular, that the state ladder shown in Fig. 7 includes *all* eigenstates of the oscillator.

³¹ Please note again the radical difference between the null-state on the right-hand side of Eq. (85) and the state described by the ket-vector $|0\rangle$ on the left-hand side of that relation. The latter state *does* exist and, moreover, represents the most important, ground state of the system, with $n = 0$ – see Eqs. (2.274)-(2.275).

Plugging this relation into Eq. (75), we see that the *full* spectrum of eigenenergies of the harmonic oscillator is described by the simple formula

$$E_n = \hbar\omega_0 \left(n + \frac{1}{2} \right), \quad n = 0, 1, 2, \dots, \quad (5.86)$$

which was already discussed in Sec. 2.9. It is rather remarkable that the bra-ket formalism has allowed us to derive it without calculating the corresponding (rather cumbersome) wavefunctions $\psi_n(x)$ – see Eqs. (2.284).

Moreover, this formalism may be also used to calculate virtually any matrix element of the oscillator, without using $\psi_n(x)$. However, to do that, we should first calculate the coefficient A'_n participating in the second of Eqs. (82). This may be done similarly to the above calculation of A_n ; alternatively, since we already know that $|A_n| = (N_n)^{1/2} = n^{1/2}$, we may notice that according to Eqs. (73) and (82), the eigenproblem (74), which in our new notation for N_n becomes

$$\hat{N}|n\rangle = n|n\rangle, \quad (5.87)$$

may be rewritten as

$$n|n\rangle = \hat{a}^\dagger \hat{a}|n\rangle = \hat{a}^\dagger A_n |n-1\rangle = A_n A'_{n-1} |n\rangle. \quad (5.88)$$

Comparing the first and the last form of this equality, we see that $|A'_{n-1}| = n/|A_n| = n^{1/2}$, so that $A'_n = (n+1)^{1/2} \exp(i\varphi_n')$. Taking all phases φ_n and φ_n' equal to zero for simplicity, we may spell out Eqs. (82) as³²

$$\hat{a}^\dagger |n\rangle = (n+1)^{1/2} |n+1\rangle, \quad \hat{a}|n\rangle = n^{1/2} |n-1\rangle. \quad (5.89)$$

Fock state ladder

Now we can use these formulas to calculate, for example, the matrix elements of the operator \hat{x} in the Fock state basis:

$$\begin{aligned} \langle n'|\hat{x}|n\rangle &\equiv x_0 \langle n'|\hat{\xi}|n\rangle = \frac{x_0}{\sqrt{2}} \langle n'|\left(\hat{a} + \hat{a}^\dagger\right)|n\rangle = \frac{x_0}{\sqrt{2}} \left(\langle n'|\hat{a}|n\rangle + \langle n'|\hat{a}^\dagger|n\rangle \right) \\ &= \frac{x_0}{\sqrt{2}} \left[n^{1/2} \langle n'|n-1\rangle + (n+1)^{1/2} \langle n'|n-1\rangle \right]. \end{aligned} \quad (5.90)$$

Taking into account the Fock state orthonormality:

$$\langle n'|n\rangle = \delta_{n'n}, \quad (5.91)$$

this result becomes

$$\langle n'|\hat{x}|n\rangle = \frac{x_0}{\sqrt{2}} \left[n^{1/2} \delta_{n',n-1} + (n+1)^{1/2} \delta_{n',n+1} \right] \equiv \left(\frac{\hbar}{2m\omega_0} \right)^{1/2} \left[n^{1/2} \delta_{n',n-1} + (n+1)^{1/2} \delta_{n',n+1} \right]. \quad (5.92)$$

Coordinate's matrix elements

Acting absolutely similarly, for the momentum's matrix elements we get a similar expression:

$$\langle n'|\hat{p}|n\rangle = i \left(\frac{\hbar m \omega_0}{2} \right)^{1/2} \left[-n^{1/2} \delta_{n',n-1} + (n+1)^{1/2} \delta_{n',n+1} \right] \quad (5.93)$$

³² A useful mnemonic rule for these key relations is that the *c*-number coefficient in any of them is equal to the square root of the *largest* number of the two states it relates.

Hence the matrices of both operators in the Fock-state basis have only two diagonals, adjacent to the main diagonal; all other elements (including the main-diagonal ones) are zeros.

The matrix elements of higher powers of these operators, as well as their products, may be handled similarly, though the higher the power, the bulkier the result. For example,

$$\begin{aligned}\langle n' | \hat{x}^2 | n \rangle &= \langle n' | \hat{x} \hat{x} | n \rangle = \sum_{n''=0}^{\infty} \langle n' | \hat{x} | n'' \rangle \langle n'' | \hat{x} | n \rangle \\ &= \frac{x_0^2}{2} \sum_{n''=0}^{\infty} [(n'')^{1/2} \delta_{n',n''-1} + (n''+1)^{1/2} \delta_{n',n''+1}] [n^{1/2} \delta_{n'',n-1} + (n+1)^{1/2} \delta_{n'',n+1}] \\ &= \frac{x_0^2}{2} \left\{ [n(n-1)]^{1/2} \delta_{n',n-2} + [(n+1)(n+2)]^{1/2} \delta_{n',n+2} + (2n+1) \delta_{n',n} \right\}.\end{aligned}\quad (5.94)$$

For applications, the most important of these matrix elements are those on its main diagonal:

$$\langle x^2 \rangle \equiv \langle n | \hat{x}^2 | n \rangle = \frac{x_0^2}{2} (2n+1). \quad (5.95)$$

This expression shows, in particular, that the expectation value of the oscillator's potential energy in the n^{th} Fock state is

$$\langle U \rangle \equiv \frac{m\omega_0^2}{2} \langle x^2 \rangle = \frac{m\omega_0^2 x_0^2}{2} \left(n + \frac{1}{2} \right) \equiv \frac{\hbar\omega_0}{2} \left(n + \frac{1}{2} \right). \quad (5.96)$$

This is exactly one-half of the total energy (86) of the oscillator. As a sanity check, an absolutely similar calculation for the momentum squared, and hence for the kinetic energy $p^2/2m$, yields

$$\langle p^2 \rangle = \langle n | \hat{p}^2 | n \rangle = (m\omega_0 x_0)^2 \left(n + \frac{1}{2} \right) \equiv \hbar m \omega_0 \left(n + \frac{1}{2} \right), \quad \text{so that } \langle \frac{p^2}{2m} \rangle = \frac{\hbar\omega_0}{2} \left(n + \frac{1}{2} \right), \quad (5.97)$$

i.e. both partial energies are equal to $E_n/2$, just as in a classical oscillator.³³

Note that according to Eqs. (92) and (93), the expectation values of both x and p in any Fock state are equal to zero:

$$\langle x \rangle \equiv \langle n | \hat{x} | n \rangle = 0, \quad \langle p \rangle \equiv \langle n | \hat{p} | n \rangle = 0, \quad (5.98)$$

This is why, according to the general Eqs. (1.33)-(1.34), the results (95) and (97) also give the variances of the coordinate and the momentum, i.e. the squares of their uncertainties, $(\delta x)^2$ and $(\delta p)^2$. In particular, for the ground state ($n = 0$), these uncertainties are

$$\delta x = \frac{x_0}{\sqrt{2}} \equiv \left(\frac{\hbar}{2m\omega_0} \right)^{1/2}, \quad \delta p = \frac{m\omega_0 x_0}{\sqrt{2}} \equiv \left(\frac{\hbar m \omega_0}{2} \right)^{1/2}. \quad (5.99)$$

In the theory of precise measurements (to be reviewed in brief in Chapter 10), these expressions are often called the *standard quantum limit*.

³³ Still note that operators of the partial (potential and kinetic) energies do *not* commute with either each other or with the full-energy (Hamiltonian) operator, so that the Fock states n are *not* their eigenstates. This fact maps on the well-known oscillations of these partial energies (with the frequency $2\omega_0$) in a classical oscillator, at the full energy staying constant.

5.5. Glauber states and squeezed states

There is a huge difference between a quantum stationary (Fock) state of the oscillator and its classical state. Indeed, let us write the well known classical equations of motion of the oscillator (using capital letters to distinguish classical variables from the arguments of quantum wavefunctions):³⁴

$$\dot{X} = \frac{P}{m}, \quad \dot{P} = -\frac{\partial U}{\partial x} = -m\omega_0^2 X. \quad (5.100)$$

On the so-called *phase plane*, with the Cartesian coordinates x and p , these equations describe a clockwise rotation of the representation point $\{X(t), P(t)\}$ along an elliptic trajectory starting from the initial point $\{X(0), P(0)\}$. (The normalization of the momentum by $m\omega_0$, similar to the one performed by the second of Eqs. (63), makes this trajectory pleasingly circular, with a constant radius equal to the oscillations amplitude A , corresponding to the constant full energy

$$E = \frac{m\omega_0^2}{2} A^2, \quad \text{with } A^2 = [X(t)]^2 + \left[\frac{P(t)}{m\omega_0} \right]^2 = \text{const} = [X(0)]^2 + \left[\frac{P(0)}{m\omega_0} \right]^2, \quad (5.101)$$

determined by the initial conditions – see Fig. 8.)

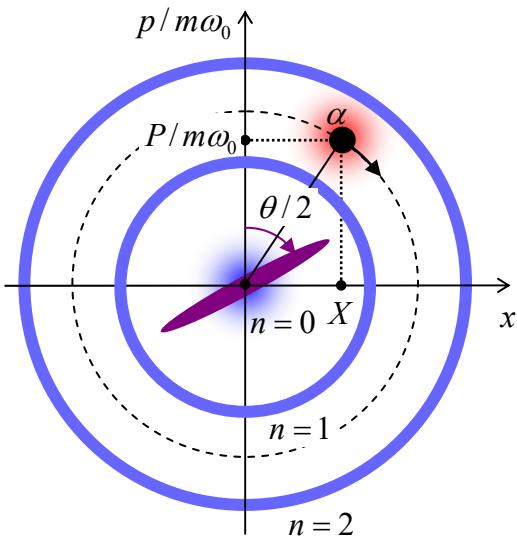

Fig. 5.8. Representations of various states of a harmonic oscillator on the phase plane. The bold black point represents a classical state with the complex amplitude α , with the dashed line showing its trajectory. The (very imperfect) classical images of the Fock states with $n = 0, 1$, and 2 are shown in blue. The blurred red spot is the (equally schematic) image of the Glauber state α . Finally, the magenta elliptical spot is a classical image of a *squeezed* ground state – see below. Arrows show the direction of the states' evolution in time.

For the forthcoming comparison with quantum states, it is convenient to describe this classical motion by the following dimensionless complex variable

$$\alpha(t) = \frac{1}{\sqrt{2}x_0} \left[X(t) + i \frac{P(t)}{m\omega_0} \right], \quad (5.102)$$

which is essentially the standard complex-number representation of the representing point's position on the 2D phase plane, with $|\alpha| \equiv A/\sqrt{2}x_0$. With this definition, Eqs. (100) are conveniently merged into one equation,

$$\dot{\alpha} = -i\omega_0\alpha, \quad (5.103)$$

³⁴ If Eqs. (100) are not evident, please consult a classical mechanics course – e.g., CM Sec. 3.2 and/or Sec. 10.1.

with an evident, very simple solution

$$\alpha(t) = \alpha(0) \exp\{-i\omega_0 t\}, \quad (5.104)$$

where the constant $\alpha(0)$ may be complex, and is just the (normalized) classical complex amplitude of oscillations.³⁵ This equation describes sinusoidal oscillations of both $X(t) \propto \text{Re}[\alpha(t)]$ and $P \propto \text{Im}[\alpha(t)]$, with a phase shift of $\pi/2$ between them.

On the other hand, according to the basic Eq. (4.161), the time dependence of a Fock state, as of a stationary state of the oscillator, is limited to the phase factor $\exp\{-iE_n t/\hbar\}$. This factor drops out at the averaging (4.125) for any observable. As a result, in this state the expectation values of x , p , or of any function thereof are time-independent. (Moreover, as Eqs. (98) show, $\langle x \rangle = \langle p \rangle = 0$.) Taking into account Eqs. (96)-(97), the closest (though very imperfect) geometric image³⁶ of such a state on the phase plane is a static circle of the radius $A_n = x_0(2n + 1)^{1/2}$, along which the wavefunction is uniformly spread – see the blue rings in Fig. 8. For the ground state ($n = 0$), with the wavefunction (2.275), a better image may be a blurred round spot, of a radius $\sim x_0$, at the origin. (It is easy to criticize such blurring, intended to represent the non-vanishing spreads (99), because it fails to reflect the fact that the total energy of the oscillator in the state, $E_0 = \hbar\omega_0/2$ is defined exactly, without any uncertainty.)

So, the difference between a classical state of the oscillator and its Fock state n is very profound. However, the Fock states are not the only possible quantum states of the oscillator: according to the basic Eq. (4.6), any state described by the ket-vector

$$|\alpha\rangle = \sum_{n=0}^{\infty} \alpha_n |n\rangle \quad (5.105)$$

with an arbitrary set of (complex) c -numbers α_n , is also its legitimate state, subject only to the normalization condition $\langle \alpha | \alpha \rangle = 1$, giving

$$\sum_{n=0}^{\infty} |\alpha_n|^2 = 1. \quad (5.106)$$

It is natural to ask: could we select the coefficients α_n in such a special way that the state properties would be closer to the classical one; in particular the expectation values $\langle x \rangle$ and $\langle p \rangle$ of the coordinate and momentum would evolve in time as the classical values $X(t)$ and $P(t)$, while the uncertainties of these observables would be, just as in the ground state, given by Eqs. (99), and hence have the smallest possible uncertainty product, $\delta x \delta p = \hbar/2$. Let me show that such a *Glauber state*,³⁷ which is

³⁵ See, e.g., CM Chapter 5, especially Eqs. (5.4).

³⁶ I have to confess that such geometric mapping of a quantum state on the phase plane $[x, p]$ is not exactly defined; you may think about colored areas in Fig. 8 as the regions of the observable pairs $\{x, p\}$ most probably obtained in measurements. A quantitative definition of such a mapping will be given in Sec. 7.3 using the Wigner function, though, as we will see, even such imaging has certain internal contradictions. Still, such cartoons as Fig. 8 have a substantial heuristic value, provided that their limitations are kept in mind.

³⁷ Named after Roy Jay Glauber who studied these states in detail in the mid-1960s, though they had been discussed in brief by Ervin Schrödinger as early as in 1926. Another popular adjective, “coherent”, for the Glauber states is very misleading, because *all* quantum states of *all* systems we have studied so far (including the Fock states of the harmonic oscillator) may be represented as coherent (pure) superpositions of the basis states. This is why I will not use this term for the Glauber states.

schematically represented in Fig. 8 by a blurred red spot around the classical point $\{X(t), P(t)\}$, is indeed possible.

Conceptually the simplest way to find the corresponding coefficients α_n would be to calculate $\langle x \rangle$, $\langle p \rangle$, δx , and δp for an arbitrary set of α_n , and then try to optimize these coefficients to reach our goal. However, this problem may be solved much easier using wave mechanics. Indeed, let us consider the following wavefunction:

$$\Psi_\alpha(x, t) = \left(\frac{m\omega_0}{\pi\hbar} \right)^{1/2} \exp \left\{ -\frac{m\omega_0}{2\hbar} [x - X(t)]^2 + i \frac{P(t)x}{\hbar} \right\}, \quad (5.107)$$

Glauber state:
coordinate representation

Its comparison with Eqs. (2.275) shows that this is just the ground-state wavefunction, but with the center shifted from the origin into the classical point $\{X(t), P(t)\}$. A straightforward (though a bit bulky) differentiation over x and t shows that it satisfies the oscillator's Schrödinger equation, provided that the c -number functions $X(t)$ and $P(t)$ obey the classical equations (100). Moreover, a similar calculation shows that the wavefunction (107) also satisfies the Schrödinger equation of an oscillator under the effect of a pulse of a classical force $F(t)$, provided that the oscillator initially was in its ground state, and that the classical evolution law $\{X(t), P(t)\}$ in Eq. (107) takes this force into account.³⁸ Since for many experimental implementations of the harmonic oscillator, the ground state may be readily formed (for example, by providing a weak coupling of the oscillator to a low-temperature environment), the Glauber state is usually easier to form than any Fock state with $n > 0$. This is why the Glauber states are so important and deserve much discussion.

In such a discussion, there is a substantial place for the bra-ket formalism. For example, to calculate the corresponding coefficients in the expansion (105) by wave-mechanical means,

$$\alpha_n(t) \equiv \langle n | \alpha(t) \rangle = \int dx \langle n | x \rangle \langle x | \alpha(t) \rangle = \int \psi_n^*(x) \Psi_\alpha(x, t) dx, \quad (5.108)$$

we would need to use not only the simple Eq. (107), but also the Fock state wavefunctions $\psi_n(x)$, which are not very appealing – see Eq. (2.284) again. Instead, this calculation may be readily done in the bra-ket formalism, giving us one important byproduct result as well.

Let us start by expressing the double shift of the ground state (by X and P), which has led us to Eq. (107), in the operator language. Forgetting about the P for a minute, let us find the *translation operator* $\hat{\mathcal{T}}_X$ that would produce the desired shift of an arbitrary wavefunction $\psi(x)$ by a c -number distance X along the coordinate argument x . This means

$$\hat{\mathcal{T}}_X \psi(x) \equiv \psi(x - X). \quad (5.109)$$

Representing the wavefunction ψ as the standard wave packet (4.264), we see that

$$\hat{\mathcal{T}}_X \psi(x) = \frac{1}{(2\pi\hbar)^{1/2}} \int \phi(p) \exp \left\{ i \frac{p(x - X)}{\hbar} \right\} dp \equiv \frac{1}{(2\pi\hbar)^{1/2}} \int \left[\phi(p) \exp \left\{ -i \frac{pX}{\hbar} \right\} \right] \exp \left\{ i \frac{px}{\hbar} \right\} dp. \quad (5.110)$$

³⁸ For its description, it is sufficient to solve Eqs. (100), with $F(t)$ added to the right-hand side of the second of these equations.

Hence, the shift may be achieved by the multiplication of each Fourier component of the packet, with the momentum p , by $\exp\{-ipX/\hbar\}$. This gives us a hint that the general form of the translation operator, valid in *any* representation, should be

$$\hat{\mathcal{T}}_x = \exp\left\{-i\frac{\hat{p}X}{\hbar}\right\}. \quad (5.111)$$

The proof of this formula is provided merely by the fact that, as we know from Chapter 4, any operator is uniquely determined by the set of its matrix elements in any full and orthogonal basis, in particular the basis of momentum states p . According to Eq. (110), the analog of Eq. (4.235) for the p -representation, applied to the translation operator (which is evidently local), is

$$\int dp \langle p | \hat{\mathcal{T}}_x | p' \rangle \phi(p') = \exp\left\{-i\frac{pX}{\hbar}\right\} \phi(p), \quad (5.112)$$

so that the operator (111) does exactly the job we need it to.

The operator that provides the shift of momentum by a *c*-number P is absolutely similar – with the opposite sign under the exponent, due to the opposite sign of the exponent in the reciprocal Fourier transform, so that the simultaneous shift by both X and P may be achieved by the following translation operator:

$$\hat{\mathcal{T}}_\alpha = \exp\left\{i\frac{P\hat{x} - \hat{p}X}{\hbar}\right\}. \quad (5.113)$$

Translation operator

As we already know, for a harmonic oscillator the creation-annihilation operators are more natural, so that we may use Eqs. (66) to recast Eq. (113) as

$$\hat{\mathcal{T}}_\alpha = \exp\left\{\alpha\hat{a}^\dagger - \alpha^*\hat{a}\right\}, \quad \text{so that } \hat{\mathcal{T}}_\alpha^\dagger = \exp\left\{\alpha^*\hat{a} - \alpha\hat{a}^\dagger\right\}, \quad (5.114)$$

where α (which, generally, may be a function of time) is the *c*-number defined by Eq. (102). Now, according to Eq. (107), we may form the Glauber state's ket-vector just as

$$|\alpha\rangle = \hat{\mathcal{T}}_\alpha |0\rangle. \quad (5.115)$$

This formula, valid in any representation, is very elegant, but using it for practical calculations (say, of the expectation values of observables) is not too easy because of the exponent-of-operators form of the translation operator. Fortunately, it turns out that a much simpler representation for the Glauber state is possible. To show this, let us start with the following general (and very useful) property of exponential functions of an operator argument: if

$$[\hat{A}, \hat{B}] = \mu\hat{l}, \quad (5.116)$$

(where \hat{A} and \hat{B} are arbitrary linear operators, and μ is a *c*-number), then³⁹

$$\exp\{+\hat{A}\}\hat{B}\exp\{-\hat{A}\} = \hat{B} + \mu\hat{l}. \quad (5.117)$$

³⁹ A proof of Eq. (117) may be readily achieved by expanding the operator $\hat{f}(\lambda) \equiv \exp\{+\lambda\hat{A}\}\hat{B}\exp\{-\lambda\hat{A}\}$ in the Taylor series with respect to the *c*-number parameter λ , and then evaluating the result for $\lambda = 1$. This simple exercise is left for the reader.

Let us apply Eqs. (116)-(117) to two cases, both with

$$\hat{A} = \alpha^* \hat{a} - \alpha \hat{a}^\dagger, \quad \text{so that } \exp\{\hat{A}\} = \hat{\mathcal{T}}_\alpha^\dagger, \quad \exp\{-\hat{A}\} = \hat{\mathcal{T}}_\alpha. \quad (5.118)$$

First, let us take $\hat{B} = \hat{I}$; then Eq. (116) is valid with $\mu = 0$, and Eq. (117) yields

$$\hat{\mathcal{T}}_\alpha^\dagger \hat{\mathcal{T}}_\alpha = \hat{I}, \quad (5.119)$$

This equality means that the translation operator is unitary – not a big surprise, because if we shift a classical point on the phase plane by a complex number ($+\alpha$) and then by ($-\alpha$), we certainly must come back to the initial position. Eq. (119) means merely that this fact is true for any quantum state as well.

Second, let us take $\hat{B} = \hat{a}$; in order to find the corresponding parameter μ , we must calculate the commutator on the left-hand side of Eq. (116) for this case. Using, at the due stage of the calculation, Eq. (68), we get

$$[\hat{A}, \hat{B}] = [\alpha^* \hat{a} - \alpha \hat{a}^\dagger, \hat{a}] = -\alpha [\hat{a}^\dagger, \hat{a}] = \alpha \hat{I}, \quad (5.120)$$

so that in this case $\mu = \alpha$, and Eq. (117) yields

$$\hat{\mathcal{T}}_\alpha^\dagger \hat{a} \hat{\mathcal{T}}_\alpha = \hat{a} + \alpha \hat{I}. \quad (5.121)$$

We have approached the summit of this beautiful calculation. Let us consider the following operator:

$$\hat{\mathcal{T}}_\alpha \hat{\mathcal{T}}_\alpha^\dagger \hat{a} \hat{\mathcal{T}}_\alpha. \quad (5.122)$$

Using Eq. (119), we may reduce this product to $\hat{a} \hat{\mathcal{T}}_\alpha$, while the application of Eq. (121) to the same expression (122) yields $\hat{\mathcal{T}}_\alpha \hat{a} + \alpha \hat{\mathcal{T}}_\alpha$. Hence, we get the following operator equality:

$$\hat{a} \hat{\mathcal{T}}_\alpha = \hat{\mathcal{T}}_\alpha \hat{a} + \alpha \hat{\mathcal{T}}_\alpha, \quad (5.123)$$

which may be applied to any state. Now acting by both sides of this equality on the ground state's ket $|0\rangle$, and using the fact that $\hat{a}|0\rangle$ is the null-state, while according to Eq. (115), $\hat{\mathcal{T}}_\alpha|0\rangle \equiv |\alpha\rangle$, we finally get a very simple and elegant result:⁴⁰

$\hat{a}|\alpha\rangle = \alpha|\alpha\rangle. \quad (5.124)$

Glauber
state as
eigenstate

Thus any Glauber state α is one of the eigenstates of the annihilation operator, namely the one with the eigenvalue equal to the *c*-number parameter α of the state, i.e. to the complex representation (102) of the classical point which is the center of the Glauber state's wavefunction.⁴¹ This fact makes the

⁴⁰ This result is also rather counter-intuitive. Indeed, according to Eq. (89), the annihilation operator \hat{a} , acting upon a Fock state n , “beats it down” to the lower-energy state $(n - 1)$. However, according to Eq. (124), the action of the same operator on a Glauber state α does *not* lead to the state change and hence to any energy change! The resolution of this paradox is given by the representation of the Glauber state as a series of Fock states – see Eq. (134) below. The operator \hat{a} indeed transfers each Fock component of this series to a lower-energy state, but it also re-weights each term, so that the complete energy of the Glauber state remains constant.

⁴¹ This fact means that the spectrum of eigenvalues α in Eq. (124), viewed as an eigenproblem, is continuous – it may be *any* complex number.

calculations of all Glauber state properties much simpler. As an example, let us calculate $\langle x \rangle$ in the Glauber state with some c -number α :

$$\langle x \rangle = \langle \alpha | \hat{x} | \alpha \rangle = \frac{x_0}{\sqrt{2}} \langle \alpha | \left(\hat{a} + \hat{a}^\dagger \right) | \alpha \rangle \equiv \frac{x_0}{\sqrt{2}} \left(\langle \alpha | \hat{a} | \alpha \rangle + \langle \alpha | \hat{a}^\dagger | \alpha \rangle \right). \quad (5.125)$$

In the first term in the parentheses, we can apply Eq. (124) directly, while in the second term, we can use the bra-counterpart of that relation, $\langle \alpha | \hat{a}^\dagger = \langle \alpha | \alpha^*$. Now assuming that the Glauber state is normalized, $\langle \alpha | \alpha \rangle = 1$, and using Eq. (102), we get

$$\langle x \rangle = \frac{x_0}{\sqrt{2}} \left(\langle \alpha | \alpha | \alpha \rangle + \langle \alpha | \dots \alpha^* | \alpha \rangle \right) = \frac{x_0}{\sqrt{2}} (\alpha + \alpha^*) = X, \quad (5.126)$$

Acting absolutely similarly, we may verify that $\langle p \rangle = P$, and that δx and δp do indeed obey Eqs. (99).

As the last sanity check, let us use Eq. (124) to re-calculate the Glauber state's wavefunction (107). Inner-multiplying both sides of that relation by the bra-vector $\langle x |$, and using the definition (65a) of the annihilation operator, we get

$$\frac{1}{\sqrt{2}x_0} \langle x | \left(\hat{x} + i \frac{\hat{p}}{m\omega_0} \right) | \alpha \rangle = \alpha \langle x | \alpha \rangle. \quad (5.127)$$

Since $\langle x |$ is the bra-vector of the eigenstate of the Hermitian operator \hat{x} , they may be swapped, with the operator giving its eigenvalue x ; acting on that bra-vector by the (local!) operator of momentum, we have to use it in the coordinate representation – see Eq. (4.245). As a result, we get

$$\frac{1}{\sqrt{2}x_0} \left(x \langle x | \alpha \rangle + \frac{\hbar}{m\omega_0} \frac{\partial}{\partial x} \langle x | \alpha \rangle \right) = \alpha \langle x | \alpha \rangle. \quad (5.128)$$

But $\langle x | \alpha \rangle$ is nothing else than the Glauber state's wavefunction Ψ_α so that Eq. (128) gives for it a first-order differential equation

$$\frac{1}{\sqrt{2}x_0} \left(x \Psi_\alpha + \frac{\hbar}{m\omega_0} \frac{\partial}{\partial x} \Psi_\alpha \right) = \alpha \Psi_\alpha. \quad (5.129)$$

Chasing Ψ_α and x to the opposite sides of the equation, and using the definition (102) of the parameter α , we can bring this equation to the form (valid at fixed t , and hence fixed X and P):

$$\frac{d\Psi_\alpha}{\Psi_\alpha} = \frac{m\omega_0}{\hbar} \left[-x + \left(X + i \frac{P}{m\omega_0} \right) \right] dx. \quad (5.130)$$

Integrating both parts, we return to Eq. (107).

Now we can use Eq. (124) for finding the coefficients α_n in the expansion (105) of the Glauber state α in the series over the Fock states n . Plugging Eq. (105) into both sides of Eq. (124), using the second of Eqs. (89) on the left-hand side, and requiring the coefficients at each ket-vector $|n\rangle$ in both parts of the resulting relation to be equal, we get the following recurrence relation:

$$\alpha_{n+1} = \frac{\alpha}{(n+1)^{1/2}} \alpha_n. \quad (5.131)$$

Applying this relation sequentially for $n = 0, 1, 2, \dots$, we get

$$\alpha_n = \frac{\alpha^n}{(n!)^{1/2}} \alpha_0. \quad (5.132)$$

Now we can find α_0 from the normalization requirement (106), getting

$$|\alpha_0|^2 \sum_{n=0}^{\infty} \frac{|\alpha|^{2n}}{n!} = 1. \quad (5.133)$$

In this sum, we may readily recognize the Taylor expansion of the function $\exp\{|\alpha|^2\}$, so that the final result (besides an arbitrary common phase multiplier) is

$$|\alpha\rangle = \exp\left\{-\frac{|\alpha|^2}{2}\right\} \sum_{n=0}^{\infty} \frac{\alpha^n}{(n!)^{1/2}} |n\rangle. \quad (5.134)$$

Glauber state vs Fock states

Hence, if the oscillator is in the Glauber state α , the probabilities $W_n \equiv \alpha_n \alpha_n^*$ of finding the system on the n^{th} energy level (86) obey the well-known *Poisson distribution* (Fig. 9):

$$W_n = \frac{\langle n \rangle^n}{n!} e^{-\langle n \rangle}, \quad (5.135)$$

Poisson distribution

where $\langle n \rangle$ is the statistical average of n – see Eq. (1.37):

$$\langle n \rangle = \sum_{n=0}^{\infty} n W_n. \quad (5.136)$$

The result of such summation is not necessarily integer! In our particular case, Eqs. (134)-(136) yield

$$\langle n \rangle = |\alpha|^2. \quad (5.137)$$

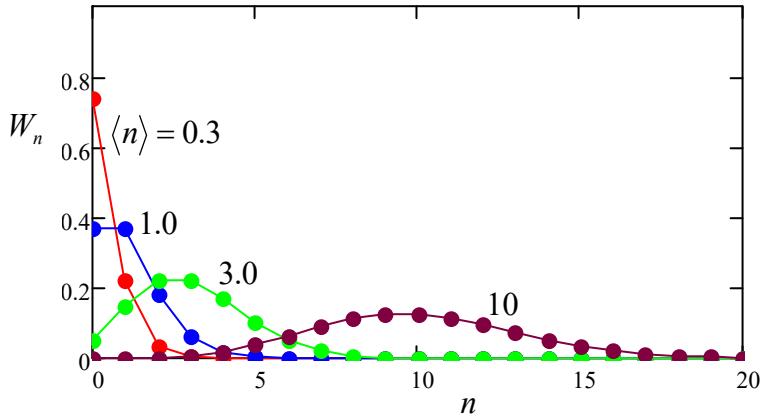

Fig. 5.9. The Poisson distribution (135) for several values of $\langle n \rangle$. Note that W_n are defined only for integer values of n ; the lines are only guides for the eye.

For applications, perhaps the most important mathematical property of this distribution is

$$\langle \tilde{n}^2 \rangle \equiv \langle (n - \langle n \rangle)^2 \rangle = \langle n \rangle, \quad \text{so that } \delta n \equiv \langle \tilde{n}^2 \rangle^{1/2} = \langle n \rangle^{1/2}. \quad (5.138)$$

Glauber state: r.m.s. uncertainty

Another important property is that at $\langle n \rangle \gg 1$, the Poisson distribution approaches the Gaussian (“normal”) one, with a small relative r.m.s. uncertainty: $\delta n / \langle n \rangle \ll 1$ – the trend clearly visible in Fig. 9.

Now let us discuss the Glauber state's evolution in time. In the wave-mechanics language, it is completely described by the dynamics (100) of the *c*-number shifts $X(t)$ and $P(t)$ participating in the wavefunction (107). Note again that, in contrast to the spread of the wave packet of a free particle, discussed in Sec. 2.2, in the harmonic oscillator the Gaussian packet of the special width (99) does not spread at all!

An alternative and equivalent way of dynamics description is to use the Heisenberg equation of motion. As Eqs. (29) and (35) tell us, such equations for the Heisenberg operators of coordinate and momentum have to be similar to the classical equations (100):

$$\dot{\hat{x}}_H = \frac{\hat{p}_H}{m}, \quad \dot{\hat{p}}_H = -m\omega_0^2 \hat{x}_H. \quad (5.139)$$

Now using Eqs. (66), for the Heisenberg-picture creation and annihilation operators we get the equations

$$\dot{\hat{a}}_H = -i\omega_0 \hat{a}_H, \quad \dot{\hat{a}}_H^\dagger = +i\omega_0 \hat{a}_H^\dagger, \quad (5.140)$$

which are completely similar to the classical equation (103) for the *c*-number parameter α and its complex conjugate, and hence have the solutions identical to Eq. (104):

$$\hat{a}_H(t) = \hat{a}_H(0)e^{-i\omega_0 t}, \quad \hat{a}_H^\dagger(t) = \hat{a}_H^\dagger(0)e^{i\omega_0 t}. \quad (5.141)$$

As was discussed in Sec. 4.6, such equations are very convenient, because they enable simple calculation of time evolution of observables for any initial state of the oscillator (Fock, Glauber, or any other) using Eq. (4.191). In particular, Eq. (141) shows that regardless of the initial state, the oscillator always returns to it *exactly* with the period $2\pi/\omega_0$.⁴² Applied to the Glauber state with $\alpha = 0$, i.e. the ground state of the oscillator, such calculation confirms that the Gaussian wave packet of the special width (99) does not spread in time at all – even temporarily.

Now let me briefly mention the states whose initial wave packets are still Gaussian, but have different widths, say $\delta x < x_0/\sqrt{2}$. As we already know from Sec. 2.2, the momentum spread δp will be correspondingly larger, still with the smallest possible uncertainty product: $\delta x \delta p = \hbar/2$. Such *squeezed ground state* ζ , with zero expectation values of x and p , may be generated from the Fock/Glauber ground state:

$$|\zeta\rangle = \hat{\mathcal{S}}_\zeta |0\rangle, \quad (5.142a)$$

using the so-called *squeezing operator*,

$$\hat{\mathcal{S}}_\zeta \equiv \exp\left\{\frac{1}{2}\left(\zeta^* \hat{a} \hat{a} - \zeta \hat{a}^\dagger \hat{a}^\dagger\right)\right\}, \quad (5.142b)$$

which depends on a complex *c*-number parameter $\zeta = re^{i\theta}$, where r and θ are real. The parameter's modulus r determines the squeezing degree; if ζ is real (i.e. $\theta = 0$), then

⁴² Actually, this fact is also evident from the Schrödinger picture of the oscillator's time evolution: due to the exactly equal distances $\hbar\omega_0$ between the eigenenergies (86), the time functions $a_n(t)$ in the fundamental expansion (1.69) of its wavefunction oscillate with frequencies $n\omega_0$, and hence they all share the same time period $2\pi/\omega_0$.

Squeezed
ground
state

Squeezing
operator

$$\delta x = \frac{x_0}{\sqrt{2}} e^{-r}, \quad \delta p = \frac{m\omega_0 x_0}{\sqrt{2}} e^r, \quad \text{so that } \delta x \delta p = \frac{m\omega_0 x_0^2}{2} = \frac{\hbar}{2}. \quad (5.143)$$

On the phase plane (Fig. 8), this state, with $r > 0$, may be represented by an oval spot squeezed along one of two mutually perpendicular axes (hence the state's name), and stretched by the same factor e^r along the counterpart axis; the same formulas but with $r < 0$ describe squeezing along the other axis. On the other hand, the phase θ of the squeezing parameter ζ determines the angle $\theta/2$ of the squeezing/stretching axes about the phase plane origin – see the magenta ellipse in Fig. 8. If $\theta \neq 0$, Eqs. (143) are valid for the variables $\{x', p'\}$ obtained from $\{x, p\}$ via clockwise rotation by that angle. For any of such origin-centered squeezed ground states, the time evolution is reduced to an increase of the angle with the rate ω_0 , i.e. to the clockwise rotation of the ellipse, without its deformation, with the angular velocity ω_0 – see the magenta arrows in Fig. 8. As a result, the uncertainties δx and δp oscillate in time with the double frequency $2\omega_0$. Such squeezed ground states may be formed, for example, by a parametric excitation of the oscillator,⁴³ with a parameter modulation depth close to, but still below the threshold of the excitation of degenerate parametric oscillations.

By action of an additional external force, the center of a squeezed state may be displaced from the origin to an arbitrary point $\{X, P\}$. Such displaced squeezed state may be described by the action of the translation operator (113) upon the ground squeezed state, i.e. by the action of the operator product $\hat{T}_\alpha \hat{\zeta}_\zeta$ on the usual (Fock / Glauber, i.e. non-squeezed) ground state. Calculations similar to those that led us from Eq. (114) to Eq. (124), show that such displaced squeezed state is an eigenstate of the following mixed operator:

$$\hat{b} \equiv \hat{a} \cosh r + \hat{a}^\dagger e^{i\theta} \sinh r, \quad (5.144)$$

with the same parameters r and θ , with the eigenvalue

$$\beta = \alpha \cosh r + \alpha^* e^{i\theta} \sinh r, \quad (5.145)$$

thus generalizing Eq. (124), which corresponds to $r = 0$. For the particular case $\alpha = 0$, Eq. (145) yields $\beta = 0$, i.e. the action of the operator (144) on the squeezed ground state ζ yields the null-state. Just as Eq. (124) in the case of the Glauber states, Eqs. (144)-(145) make the calculation of the basic properties of the squeezed states (for example, the proof of Eqs. (143) for the case $\alpha = \theta = 0$) very straightforward.

Unfortunately, I do not have more time/space for a further discussion of the squeezed states in this section, but their importance for precise quantum measurements will be discussed in Sec. 10.2 below.⁴⁴

⁴³ For a discussion and classical theory of this effect, see, e.g., CM Sec. 5.5.

⁴⁴ For more on the squeezed states see, e.g., Chapter 7 in the monograph by C. Gerry and P. Knight, *Introductory Quantum Optics*, Cambridge U. Press, 2005. Also, note the spectacular measurements of the Glauber and squeezed states of electromagnetic (optical) oscillators by G. Breitenbach *et al.*, *Nature* **387**, 471 (1997), a large (ten-fold) squeezing achieved in such oscillators by H. Vahlbruch *et al.*, *Phys. Rev. Lett.* **100**, 033602 (2008), and the first results on the ground state squeezing in micromechanical oscillators, with resonance frequencies $\omega_0/2\pi$ as low as a few MHz, using their parametric coupling to microwave electromagnetic oscillators – see, e.g., E. Wollman *et al.*, *Science* **349**, 952 (2015) and/or J.-M. Pirkkalainen *et al.*, *Phys. Rev. Lett.* **115**, 243601 (2015).

5.6. Revisiting spherically-symmetric systems

One more blank spot to fill has been left by our study, in Sec. 3.6, of wave mechanics of particle motion in spherically-symmetric 3D potentials. Indeed, while the azimuthal components of the eigenfunctions (the spherical harmonics) of such systems are very simple,

$$\psi_m = (2\pi)^{-1/2} e^{im\varphi}, \quad \text{with } m = 0, \pm 1, \pm 2, \dots, \quad (5.146)$$

their polar components include the associated Legendre functions $P_l^m(\cos\theta)$, which may be expressed via elementary functions only indirectly – see Eqs. (3.165) and (3.168). This makes all the calculations less than transparent and, in particular, does not allow a clear insight into the origin of the very simple energy spectrum of such systems – see, e.g., Eq. (3.163). The bra-ket formalism, applied to the angular momentum operator, not only enables such insight and produces a very convenient tool for many calculations involving spherically-symmetric potentials, but also opens a clear way toward the unification of the orbital momentum with the particle's spin – the latter task to be addressed in the next section.

Let us start by using the correspondence principle to spell out the quantum-mechanical vector operator of the orbital angular momentum $\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}$ of a point particle:

Angular momentum operator

$$\hat{\mathbf{L}} \equiv \hat{\mathbf{r}} \times \hat{\mathbf{p}} = \begin{vmatrix} \mathbf{n}_x & \mathbf{n}_y & \mathbf{n}_z \\ \hat{r}_1 & \hat{r}_2 & \hat{r}_3 \\ \hat{p}_1 & \hat{p}_2 & \hat{p}_3 \end{vmatrix}, \quad \text{i.e. } \hat{L}_j \equiv \sum_{j'=1}^3 \hat{r}_{j'} \hat{p}_{j''} \varepsilon_{jj''},$$

(5.147)

where each of the indices j , j' , and j'' may take values 1, 2, and 3 (with $j'' \neq j, j'$), and $\varepsilon_{jj''}$ is the Levi-Civita permutation symbol, which we have already used in Sec. 4.5, and also in Sec. 1 of this chapter, in similar expressions (17)-(18). From this definition, we can readily calculate the commutation relations for all Cartesian components of operators $\hat{\mathbf{L}}$, $\hat{\mathbf{r}}$, and $\hat{\mathbf{p}}$; for example,

$$[\hat{L}_j, \hat{r}_{j''}] = \left[\sum_{k=1}^3 \hat{r}_k \hat{p}_{j''} \varepsilon_{jk''}, \hat{r}_{j''} \right] \equiv - \sum_{k=1}^3 \hat{r}_k [\hat{r}_{j'}, \hat{p}_{j''}] \varepsilon_{jk''} = -i\hbar \sum_{k=1}^3 \hat{r}_k \delta_{j'j''} \varepsilon_{jk''} \equiv i\hbar \sum_{k=1}^3 \hat{r}_k \varepsilon_{jj'k} \equiv i\hbar \hat{r}_{j''} \varepsilon_{jj''}, \quad (5.148)$$

The summary of all these calculations may be represented in similar compact forms:

Key commutation relations

$$[\hat{L}_j, \hat{r}_{j''}] = i\hbar \hat{r}_{j''} \varepsilon_{jj''}, \quad [\hat{L}_j, \hat{p}_{j''}] = i\hbar \hat{p}_{j''} \varepsilon_{jj''}, \quad [\hat{L}_j, \hat{L}_{j''}] = i\hbar \hat{L}_{j''} \varepsilon_{jj''};$$

(5.149)

the last of them shows that the commutator of two different Cartesian components of the vector-operator $\hat{\mathbf{L}}$ is proportional to its complementary component.

Also introducing, in a natural way, the (scalar!) operator of the observable $L^2 \equiv |\mathbf{L}|^2$,

Operator of L^2

$$\hat{L}^2 \equiv \hat{L}_x^2 + \hat{L}_y^2 + \hat{L}_z^2 \equiv \sum_{j=1}^3 \hat{L}_j^2,$$

(5.150)

it is straightforward to check that this operator commutes with each of the Cartesian components:

$$[\hat{L}^2, \hat{L}_j] = 0. \quad (5.151)$$

This result, at the first sight, may seem to contradict the last of Eqs. (149). Indeed, haven't we learned in Sec. 4.5 that commuting operators (e.g., \hat{L}^2 and any of \hat{L}_j) share their eigenstate sets? If yes, shouldn't this set has to be common for all four angular momentum operators? The resolution in this paradox may be found in the condition that was mentioned just after Eq. (4.138), but (sorry!) was not sufficiently emphasized there. According to that relation, if an operator has *degenerate* eigenstates (i.e. if some $A_j = A_{j'}$ even for $j \neq j'$), they should not be necessarily all shared by another compatible operator.

This is exactly the situation with the orbital angular momentum operators, which may be schematically shown on a *Venn diagram* (Fig. 10):⁴⁵ the eigenstates of the operator \hat{L}^2 are highly degenerate,⁴⁶ and their set is broader than those of any component operator \hat{L}_j (that, as will be shown below, are non-degenerate – until we consider particle's spin).

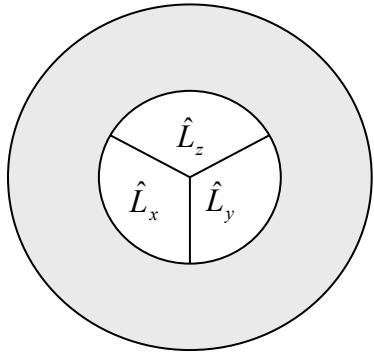

Fig. 5.10. The Venn diagram showing the partitioning of the set of eigenstates of the operator \hat{L}^2 . Each inner sector corresponds to the states shared with one of the Cartesian component operators \hat{L}_j , while the outer (shaded) ring represents the eigenstates of \hat{L}^2 that are not shared with either of \hat{L}_j – for example, all linear combinations of the eigenstates of different component operators.

Let us focus on just one of these three joint sets of eigenstates – by tradition, of the operators \hat{L}_z and \hat{L}_x . (This tradition stems from the canonical form of the spherical coordinates, in which the polar angle is measured from the z -axis. Indeed, in the coordinate representation we may write

$$\hat{L}_z \equiv \hat{x}p_y - \hat{y}p_x = x\left(-i\hbar \frac{\partial}{\partial y}\right) - y\left(-i\hbar \frac{\partial}{\partial x}\right) = -i\hbar \frac{\partial}{\partial \varphi}. \quad (5.152)$$

Writing the standard eigenproblem for the operator in this representation, $\hat{L}_z \psi_m = L_z \psi_m$, we see that it is satisfied by the eigenfunctions (146), with eigenvalues $L_z = \hbar m$ – which was already conjectured in Sec. 3.5.) More specifically, let us consider a set of eigenstates $\{l, m\}$ corresponding to a certain degenerate eigenvalue of the operator \hat{L}^2 , and all possible eigenvalues of the operator \hat{L}_z , i.e. all possible quantum numbers m . (At this point, l is just some label of the eigenvalue of the operator \hat{L}^2 ; it will be defined more explicitly in a minute.) To analyze this set, it is instrumental to introduce the so-called *ladder* (also called, respectively, “raising” and “lowering”) *operators*⁴⁷

⁴⁵ This is just a particular example of the Venn diagrams (introduced in the 1880s by John Venn) that show possible relations (such as intersections, unions, complements, etc.) between various sets of objects, and are very useful tool in the general set theory.

⁴⁶ Note that this particular result is consistent with the classical picture of the angular momentum vector: even when its length is fixed, the vector may be oriented in various directions, corresponding to different values of its Cartesian components. However, in the classical picture, all these components may be fixed simultaneously, while in the quantum picture this is not true.

⁴⁷ Note a substantial similarity between this definition and Eqs. (65) for the creation/annihilation operators.

Ladder
operators

$$\hat{L}_{\pm} \equiv \hat{L}_x \pm i\hat{L}_y. \quad (5.153)$$

It is simple (and hence left for the reader's exercise) to use this definition and the last of Eqs. (149) to calculate the following commutators:

Important
commutation
relations

$$[\hat{L}_+, \hat{L}_-] = 2\hbar\hat{L}_z, \quad \text{and} \quad [\hat{L}_z, \hat{L}_{\pm}] = \pm\hbar\hat{L}_{\pm}, \quad (5.154)$$

and also to use Eqs. (149)-(150) to prove two other important operator relations:

$$\hat{L}^2 = \hat{L}_z^2 + \hat{L}_+ \hat{L}_- - \hbar \hat{L}_z, \quad \hat{L}^2 = \hat{L}_z^2 + \hat{L}_- \hat{L}_+ + \hbar \hat{L}_z. \quad (5.155)$$

Now let us rewrite the last of Eqs. (154) as

$$\hat{L}_z \hat{L}_{\pm} = \hat{L}_{\pm} \hat{L}_z \pm \hbar \hat{L}_{\pm}, \quad (5.156)$$

and act by its both sides upon the ket-vector $|l, m\rangle$ of an arbitrary common eigenstate:

$$\hat{L}_z \hat{L}_{\pm} |l, m\rangle = \hat{L}_{\pm} \hat{L}_z |l, m\rangle \pm \hbar \hat{L}_{\pm} |l, m\rangle. \quad (5.157)$$

Since the eigenvalues of the operator \hat{L}_z are equal to $\hbar m$, in the first term of the right-hand side of Eq. (157) we may write

$$\hat{L}_z |l, m\rangle = \hbar m |l, m\rangle. \quad (5.158)$$

With that, Eq. (157) may be recast as

$$\hat{L}_z (\hat{L}_{\pm} |l, m\rangle) = \hbar(m \pm 1) (\hat{L}_{\pm} |l, m\rangle). \quad (5.159)$$

In a spectacular similarity with Eqs. (78)-(79) for the harmonic oscillator, Eq. (159) means that the states $\hat{L}_{\pm} |l, m\rangle$ are also eigenstates of the operator \hat{L}_z , corresponding to eigenvalues $\hbar(m \pm 1)$. Thus the ladder operators act exactly as the creation and annihilation operators of a harmonic oscillator, moving the system up or down a ladder of eigenstates – see Fig. 11.

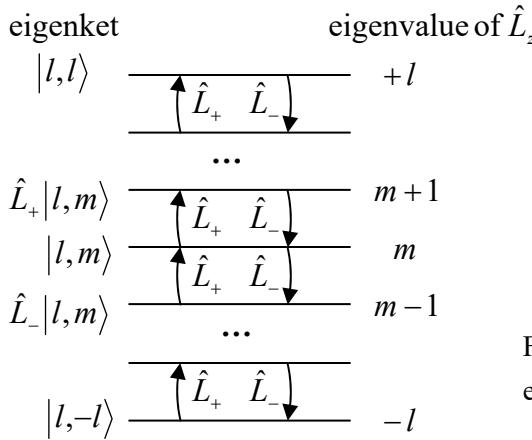

Fig. 5.11. The ladder diagram of the common eigenstates of the operators \hat{L}^2 and \hat{L}_z .

The most significant difference is that now the state ladder must end in both directions, because an infinite increase of $|m|$, with whichever sign of m , would cause the expectation values of the operator

$$\hat{L}_x^2 + \hat{L}_y^2 \equiv \hat{L}^2 - \hat{L}_z^2, \quad (5.160)$$

which corresponds to a non-negative observable, to become negative. Hence there have to be two states at both ends of the ladder, with such ket-vectors $|l, m_{\max}\rangle$ and $|l, m_{\min}\rangle$ that

$$\hat{L}_+|l, m_{\max}\rangle = 0, \quad \hat{L}_-|l, m_{\min}\rangle = 0. \quad (5.161)$$

Due to the symmetry of the whole problem with respect to the replacement $m \rightarrow -m$, we should have $m_{\min} = -m_{\max}$. This m_{\max} is exactly the quantum number traditionally called l , so that

$$-l \leq m \leq +l. \quad (5.162)$$

Relation between m and l

Evidently, this relation of quantum numbers m and l is semi-quantitatively compatible with the classical image of the angular momentum vector \mathbf{L} , of the same length L , pointing in various directions, thus affecting the value of its component L_z . In this classical picture, however, L^2 would be equal to the square of $(L_z)_{\max}$, i.e. to $(\hbar l)^2$; however, in quantum mechanics, this is not so. Indeed, applying both parts of the second of the operator equalities (155) to the top state's vector $|l, m_{\max}\rangle \equiv |l, l\rangle$, we get

$$\begin{aligned} \hat{L}^2|l, l\rangle &= \hbar \hat{L}_z|l, l\rangle + \hat{L}_z^2|l, l\rangle + \hat{L}_- \hat{L}_+|l, l\rangle = \hbar^2 l |l, l\rangle + \hbar^2 l^2 |l, l\rangle + 0 \\ &= \hbar^2 l(l+1)|l, l\rangle. \end{aligned} \quad (5.163)$$

Eigenvalues of L^2

Since by our initial assumption, all eigenvectors $|l, m\rangle$ correspond to the same eigenvalue of \hat{L}^2 , this result means that all these eigenvalues are equal to $\hbar^2 l(l+1)$. Just as in the case of the spin- $\frac{1}{2}$ vector operators discussed in Sec. 4.5, the deviation of this result from $\hbar^2 l^2$ may be interpreted as the result of unavoidable uncertainties (“fluctuations”) of the x - and y -components of the angular momentum, which give non-zero positive contributions to $\langle L_x^2 \rangle$ and $\langle L_y^2 \rangle$, and hence to $\langle L^2 \rangle$, even if the angular momentum vector is aligned with the z -axis in the best possible way.

(For various applications of the ladder operators (153), one more relation is convenient:

$$\hat{L}_{\pm}|l, m\rangle = \hbar [l(l+1) - m(m \pm 1)]^{1/2} |l, m \pm 1\rangle. \quad (5.164)$$

This equality, valid to the multiplier $e^{i\varphi}$ with an arbitrary real phase φ , may be readily proved from the above relations in the same way as the parallel Eqs. (89) for the harmonic-oscillator operators (65) were proved in Sec. 4; due to this similarity, the proof is also left for the reader's exercise.⁴⁸⁾

Now let us compare our results with those of Sec. 3.6. Using the expression of Cartesian coordinates via the spherical ones exactly as this was done in Eq. (152), we get the following expressions for the ladder operators (153) in the coordinate representation:

⁴⁸ The reader is also challenged to use the commutation relations discussed above to prove one more important property of the common eigenstates of \hat{L}_z and \hat{L}^2 :

$$\langle l, m | \hat{r}_j | l', m' \rangle = 0, \quad \text{unless } l' = l \pm 1 \text{ and } m' = \text{either } m \pm 1 \text{ or } m.$$

This property gives the *selection rule* for the orbital electric-dipole quantum transitions, to be discussed later in the course, especially in Sec. 9.3. (The final selection rules at these transitions may be affected by the particle's spin – see the next section.)

$$\hat{L}_\pm = \hbar e^{\pm i\varphi} \left(\pm \frac{\partial}{\partial \theta} + i \cotan \theta \frac{\partial}{\partial \varphi} \right). \quad (5.165)$$

Now plugging this relation, together with Eq. (152), into any of Eqs. (155), we get

$$\hat{L}^2 = -\hbar^2 \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \varphi^2} \right]. \quad (5.166)$$

But this is exactly the operator (besides its division by the constant parameter $2mR^2$) that stands on the left-hand side of Eq. (3.156). Hence that equation, which was explored by the “brute-force” (wave-mechanical) approach in Sec. 3.6, may be understood as the eigenproblem for the operator \hat{L}^2 in the coordinate representation, with the eigenfunctions $Y_l^m(\theta, \varphi)$ corresponding to the eigenkets $|l, m\rangle$, and the eigenvalues $\hat{L}^2 = 2mR^2E$. As a reminder, the main result of that, rather involved analysis was expressed by Eq. (3.163), which now may be rewritten as

$$L_l^2 \equiv 2mR^2 E_l = \hbar^2 l(l+1), \quad (5.167)$$

in full agreement with Eq. (163), which was obtained by much more efficient means based on the bracket formalism. In particular, it is fascinating to see how easy it is to operate with the eigenvectors $|l, m\rangle$, while the coordinate representations of these ket-vectors, the spherical harmonics $Y_l^m(\theta, \varphi)$, may be only expressed by rather complicated functions – please have one more look at Eq. (3.171) and Fig. 3.20.

Note that all relations discussed in this section are not conditioned by any particular Hamiltonian of the system under analysis, though they (as well as those discussed in the next section) are especially important for particles moving in spherically-symmetric potentials.

5.7. Spin and its addition to orbital angular momentum

The theory described in the last section is useful for much more than orbital motion analysis. In particular, it helps to generalize the spin-½ results discussed in Chapter 4 to other values of spin s – the parameter still to be quantitatively defined. For that, let us notice that the commutation relations (4.155) for spin-½, which were derived from the Pauli matrix properties, may be rewritten in exactly the same form as Eqs. (149) and (151) for the orbital momentum:

$$[\hat{S}_j, \hat{S}_{j'}] = i\hbar \hat{S}_{j''} \epsilon_{jj''}, \quad [\hat{S}^2, \hat{S}_j] = 0. \quad (5.168)$$

It had been postulated (and then confirmed by numerous experiments) that these relations hold for quantum particles with any spin. Now notice that all the calculations of the last section have been based *almost* exclusively on such relations – the only exception will be discussed imminently. Hence, we may repeat them for the spin operators, and get the relations similar to Eqs. (158) and (163):

$$\hat{S}_z |s, m_s\rangle = \hbar m_s |s, m_s\rangle, \quad \hat{S}^2 |s, m_s\rangle = \hbar^2 s(s+1) |s, m_s\rangle, \quad 0 \leq s, \quad -s \leq m_s \leq +s, \quad (5.169)$$

where m_s is a quantum number parallel to the orbital magnetic number m , and the non-negative constant s is defined as the maximum value of $|m_s|$. The *c*-number s is exactly what is called the *particle’s spin*.

Now let us return to the only part of our orbital moment calculations that has *not* been derived from the commutation relations. This was the fact, based on the solution (146) of the orbital motion problems, that the quantum number m (the analog of m_s) may be only an integer. For spin, we do not have such a solution, so that the spectrum of numbers m_s (and hence its limits $\pm s$) should be found from the more loose requirement that the eigenstate ladder, extending from $-s$ to $+s$, has an integer number of steps. Hence, $2s$ has to be an integer, i.e. the spin s of a quantum particle may be either *integer* (as it is, for example, for photons, gluons, and massive bosons W^\pm and Z^0), or *half-integer* (e.g., for all quarks and leptons, notably including electrons).⁴⁹ For $s = \frac{1}{2}$, this picture yields all the properties of the spin- $\frac{1}{2}$ that were derived in Chapter 4 from Eqs. (4.115)-(4.117). In particular, the operators \hat{S}^2 and \hat{S}_z have two common eigenstates (\uparrow and \downarrow), with $S_z = \hbar m_s = \pm \hbar/2$, both with $S^2 = s(s+1)\hbar^2 = (3/4)\hbar^2$.

Note that this analogy with the angular momentum sheds new light on the symmetry properties of spin- $\frac{1}{2}$. Indeed, the fact that m in Eq. (146) is integer was derived in Sec. 3.5 from the requirement that making a full circle around axis z , we should find a similar value of wavefunction ψ_m , which differs from the initial one by an inconsequential factor $\exp\{2\pi im\} = +1$. With the replacement $m \rightarrow m_s = \pm \frac{1}{2}$, such operation would multiply the wavefunction by $\exp\{\pm\pi i\} = -1$, i.e. reverse its sign. Of course, spin properties cannot be described by a usual wavefunction, but this *odd parity* of electrons, shared by all other spin- $\frac{1}{2}$ particles, is clearly revealed in properties of multiparticle systems (see Chapter 8 below), and as a result, in their statistics (see, e.g., SM Chapter 2).

Now we are sufficiently equipped to analyze the situations in which a particle has both the orbital momentum and the spin – as an electron in an atom. In classical mechanics, such an object, with the spin \mathbf{S} interpreted as the angular moment of its internal rotation, would be characterized by the *total angular momentum* vector $\mathbf{J} = \mathbf{L} + \mathbf{S}$. Following the correspondence principle, we may assume that quantum-mechanical properties of this observable may be described by the similarly defined vector operator:

$$\hat{\mathbf{J}} \equiv \hat{\mathbf{L}} + \hat{\mathbf{S}}, \quad (5.170)$$

Total
angular
momentum

with Cartesian components

$$\hat{J}_z \equiv \hat{L}_z + \hat{S}_z, \text{ etc.}, \quad (5.171)$$

and the magnitude squared equal to

$$\hat{J}^2 \equiv \hat{J}_x^2 + \hat{J}_y^2 + \hat{J}_z^2. \quad (5.172)$$

Let us examine the properties of this vector operator. Since its two components (170) describe different degrees of freedom of the particle, i.e. belong to different Hilbert spaces, they have to be completely commuting:

$$[\hat{L}_j, \hat{S}_{j'}] = 0, \quad [\hat{L}^2, \hat{S}^2] = 0, \quad [\hat{L}_j, \hat{S}^2] = 0, \quad [\hat{L}^2, \hat{S}_j] = 0. \quad (5.173)$$

The above equalities are sufficient to derive the commutation relations for the operator $\hat{\mathbf{J}}$, and unsurprisingly, they turn out to be absolutely similar to those of its components:

⁴⁹ As a reminder, in the Standard Model of particle physics, such hadrons as mesons and baryons (notably including protons and neutrons) are essentially composite particles. However, at non-relativistic energies, protons and neutrons may be considered fundamental particles with $s = \frac{1}{2}$.

Total
momentum:
commutation
relations

Total
momentum:
eigenstates,
and
eigenvalues

$$[\hat{J}_j, \hat{J}_{j'}] = i\hbar \hat{J}_{j''} \epsilon_{jj''}, \quad [\hat{J}^2, \hat{J}_j] = 0. \quad (5.174)$$

Now repeating all the arguments of the last section, we may derive the following expressions for the common eigenstates of the operators \hat{J}^2 and \hat{J}_z :

$$J_z |j, m_j\rangle = \hbar m_j |j, m_j\rangle, \quad \hat{J}^2 |j, m_j\rangle = \hbar^2 j(j+1) |j, m_j\rangle, \quad 0 \leq j, \quad -j \leq m_j \leq +j, \quad (5.175)$$

where j and m_j are new quantum numbers.⁵⁰ Repeating the arguments just made for s and m_s , we may conclude that j and m_j may be either integer or half-integer.

Before we proceed, one remark on notation: it is very convenient to use the same letter m for numbering eigenstates of all momentum components participating in Eq. (171), with corresponding indices (j , l , and s), in particular, to replace what we called m with m_l . With this replacement, the main results of the last section may be summarized in a form similar to Eqs. (168), (169), (174), and (175):

$$[\hat{L}_j, \hat{L}_{j'}] = i\hbar \hat{L}_{j''} \epsilon_{jj''}, \quad [\hat{L}^2, \hat{L}_j] = 0, \quad (5.176)$$

$$\hat{L}_z |l, m_l\rangle = \hbar m_l |l, m_l\rangle, \quad \hat{L}^2 |l, m_l\rangle = \hbar^2 l(l+1) |l, m_l\rangle, \quad 0 \leq l, \quad -l \leq m_l \leq +l. \quad (5.177)$$

In order to understand which eigenstates participating in Eqs. (169), (175), and (177) are compatible with each other, it is straightforward to use Eq. (172), together with Eqs. (168), (173), (174), and (176) to get the following relations:

$$[\hat{J}^2, \hat{L}^2] = 0, \quad [\hat{J}^2, \hat{S}^2] = 0, \quad (5.178)$$

$$[\hat{J}^2, \hat{L}_z] \neq 0, \quad [\hat{J}^2, \hat{S}_z] \neq 0. \quad (5.179)$$

This result is represented schematically on the Venn diagram shown in Fig. 12, in which the crossed arrows indicate the only *non-commuting* pairs of operators.

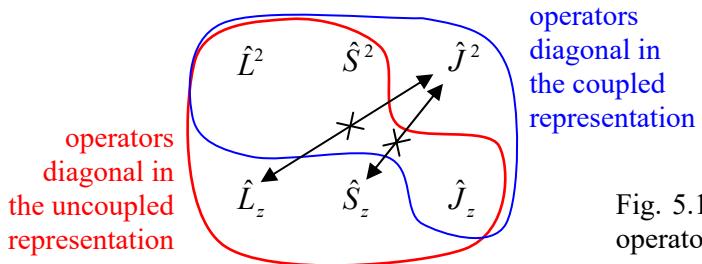

Fig. 5.12. The Venn diagram of angular momentum operators, and their mutually-commuting groups.

This means that there are eigenstates shared by two operator groups encircled with colored lines in Fig. 12. The first group (encircled red), consists of all these operators but \hat{J}^2 . Hence there are eigenstates shared by the five remaining operators, and these states correspond to definite values of the corresponding quantum numbers: l , m_l , s , m_s , and m_j . Actually, only four of these numbers are

⁵⁰ Let me hope that the difference between the quantum number j , and the indices j, j', j'' numbering the Cartesian components in the relations like Eqs. (168) or (174), is absolutely clear from the context.

independent, because due to Eq. (171) for these compatible operators, for each eigenstate of this group, their “magnetic” quantum numbers m have to satisfy the following relation:

$$m_j = m_l + m_s. \quad (5.180)$$

Hence the common eigenstates of the operators of this group are fully defined by just four quantum numbers, for example, l , m_l , s , and m_s . For some calculations, especially those for the systems whose Hamiltonians include only the operators of this group, it is convenient⁵¹ to use this set of eigenstates as the basis; frequently this approach is called the *uncoupled representation*.

However, in some situations we cannot ignore interactions between the orbital and spin degrees of freedom (in the common jargon, the *spin-orbit coupling*), which leads in particular to splitting (called the *fine structure*) of the atomic energy levels even in the absence of external magnetic field. I will discuss these effects in detail in the next chapter, and now will only note that they may be described by a term proportional to the product $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$, in the system’s Hamiltonian. If this term is substantial, the uncoupled representation becomes inconvenient. Indeed, writing

$$\hat{J}^2 = (\hat{\mathbf{L}} + \hat{\mathbf{S}})^2 = \hat{L}^2 + \hat{S}^2 + 2\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}, \quad \text{so that } 2\hat{\mathbf{L}} \cdot \hat{\mathbf{S}} = \hat{J}^2 - \hat{L}^2 - \hat{S}^2, \quad (5.181)$$

and looking at Fig. 12 again, we see that operator $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$, describing the spin-orbit coupling, does not commute with operators \hat{L}_z and \hat{S}_z . This means that stationary states of the system with such term in the Hamiltonian do not belong to the uncoupled representation’s basis. On the other hand, Eq. (181) shows that the operator $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$ does commute with all four operators of another group, encircled blue in Fig. 12. According to Eqs. (178), (179), and (181), all operators of that group also commute with each other, so that they have common eigenstates, described by the quantum numbers, l , s , j , and m_j . This group is the basis for the so-called *coupled representation* of particle states.

Excluding, for the notation brevity, the quantum numbers l and s , common for both groups, it is convenient to denote the common ket-vectors of each group as, respectively,

$ m_l, m_s\rangle$, for the uncoupled representation's basis, $ j, m_j\rangle$, for the coupled representation's basis.	Coupled and uncoupled bases
------------------------------------------------------------------------------------------------------------------------------	---------------------------------------------------------------

(5.182)

As we will see in the next chapter, for the solution of some important problems (e.g., the fine structure of atomic spectra and the Zeeman effect), we will need the relation between the kets $|j, m_j\rangle$ and the kets $|m_l, m_s\rangle$. This relation may be represented as the usual linear superposition,

$ j, m_j\rangle = \sum_{m_l, m_s} m_l, m_s\rangle \langle m_l, m_s j, m_j \rangle.$	Clebsch-Jordan coefficients: definition
----------------------------------------------------------------------------------------	---------------------------------------------------------------------------

(5.183)

The short brackets in this relation, essentially the elements of the unitary matrix of the transformation between two eigenstate bases (182), are called the *Clebsch-Gordan coefficients*.

The best (though imperfect) classical interpretation of Eq. (183) I can offer is as follows. If the lengths of the vectors \mathbf{L} and \mathbf{S} (in quantum mechanics associated with the numbers l and s , respectively),

⁵¹ This is especially true for motion in spherically-symmetric potentials, whose stationary states correspond to definite l and m_l ; however, the relations discussed in this section are important for some other problems as well.

and also their scalar product $\mathbf{L} \cdot \mathbf{S}$, are all fixed, then so is the length of the vector $\mathbf{J} = \mathbf{L} + \mathbf{S}$ – whose length in quantum mechanics is described by the number j . Hence, the classical image of a specific eigenket $|j, m_j\rangle$, in which l , s , j , and m_j are all fixed, is a state in which L^2 , S^2 , J^2 , and J_z are fixed. However, this fixation still allows for arbitrary rotation of the pair of vectors \mathbf{L} and \mathbf{S} (with a fixed angle between them, and hence fixed $\mathbf{L} \cdot \mathbf{S}$ and J^2) about the direction of the vector \mathbf{J} – see Fig. 13.

Hence the components L_z and S_z in these conditions are *not* fixed, and in classical mechanics may take a continuum of values, two of which (with the largest and the smallest possible values of S_z) are shown in Fig. 13. In quantum mechanics, these components are quantized, with their states represented by eigenkets $|m_l, m_s\rangle$, so that a linear combination of such kets is necessary to represent a ket $|j, m_j\rangle$. This is exactly what Eq. (183) does.

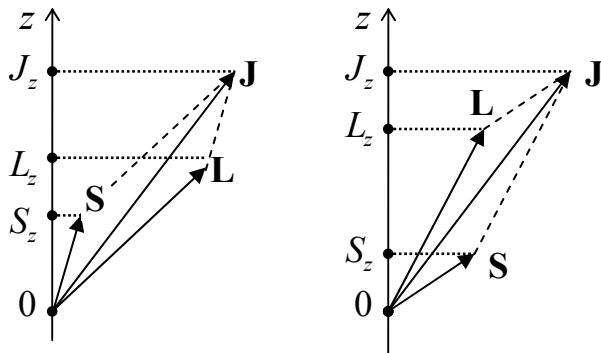

Fig. 5.13. A classical image of two different quantum states with the same quantum numbers l , s , j , and m_j , but different m_l and m_s .

Some properties of the Clebsch-Gordan coefficients $\langle m_l, m_s | j, m_j \rangle$ may be readily established. For example, the coefficients do not vanish only if the involved magnetic quantum numbers satisfy Eq. (180). In our current case, this relation is not an elementary corollary of Eq. (171), because in the Clebsch-Gordan coefficients, with the quantum numbers m_l , m_s in one state vector, and m_j in the other state vector, characterize the relation between different groups of the basis states, so we need to prove this fact. All matrix elements of the null-operator

$$\hat{J}_z - (\hat{L}_z + \hat{S}_z) = \hat{0} \quad (5.184)$$

should equal zero in any basis; in particular

$$\langle j, m_j | \hat{J}_z - (\hat{L}_z + \hat{S}_z) | m_l, m_s \rangle = 0. \quad (5.185)$$

Acting by the operator \hat{J}_z upon the bra-vector, and by the sum $(\hat{L}_z + \hat{S}_z)$ upon the ket-vector, we get

$$[m_j - (m_l + m_s)] \langle j, m_j | m_l, m_s \rangle = 0, \quad (5.186)$$

thus proving that

$$\langle m_l, m_s | j, m_j \rangle \equiv \langle j, m_j | m_l, m_s \rangle^* = 0, \quad \text{if } m_j \neq m_l + m_s. \quad (5.187)$$

For the most important case of spin- $\frac{1}{2}$ particles (with $s = \frac{1}{2}$, and hence $m_s = \pm\frac{1}{2}$), whose uncoupled representation basis includes $2(2l+1)$ states, the restriction (187) enables the representation of all non-zero Clebsch-Gordan coefficients on the simple “rectangular” diagram shown in Fig. 14. Indeed, each coupled-representation eigenket $|j, m_j\rangle$, with $m_j = m_l + m_s = m_l \pm \frac{1}{2}$, may be related by non-zero Clebsch-Gordan coefficients to at most two uncoupled-representation eigenstates $|m_l, m_s\rangle$. Since m_l

may only take integer values from $-l$ to $+l$, m_j may only take semi-integer values on the interval $[-l - \frac{1}{2}, l + \frac{1}{2}]$. Hence, by the definition of j as $(m_j)_{\max}$, its maximum value has to be $l + \frac{1}{2}$, and for $m_j = l + \frac{1}{2}$, this is the only possible value with this j . This means that the uncoupled state with $m_l = l$ and $m_s = \frac{1}{2}$ should be identical to the coupled-representation state with $j = l + \frac{1}{2}$ and $m_j = l + \frac{1}{2}$:

$$|j = l + \frac{1}{2}, m_j = l + \frac{1}{2}\rangle = |m_l = m_j - \frac{1}{2}, m_s = +\frac{1}{2}\rangle. \quad (5.188)$$

In Fig. 14, these two identical states are represented with the top-rightmost point (the uncoupled representation) and the sloped line passing through it (the coupled representation).

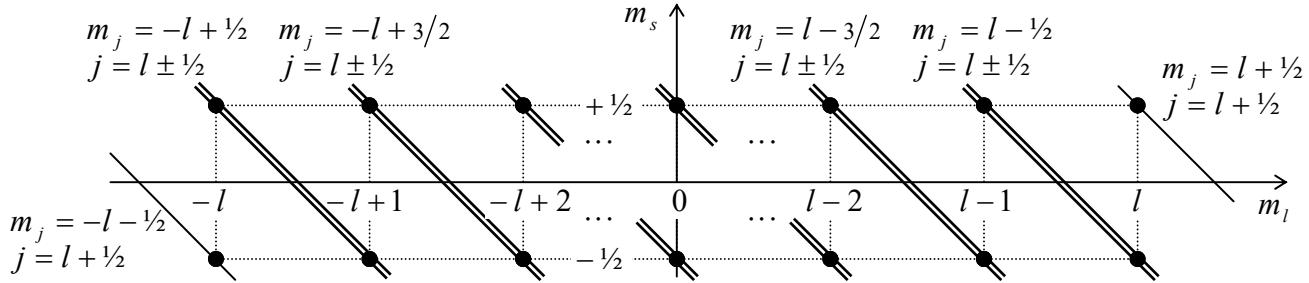

Fig. 5.14. A graphical representation of possible basis states of a spin- $\frac{1}{2}$ particle with a fixed l . Each dot corresponds to an uncoupled-representation ket-vector $|m_l, m_s\rangle$, while each sloped line corresponds to one coupled-representation ket-vector $|j, m_j\rangle$, related by Eq. (183) to the kets $|m_l, m_s\rangle$ whose dots it connects.

However, already the next value of this quantum number, $m_j = l - \frac{1}{2}$, is compatible with two values of j , so that each $|m_l, m_s\rangle$ ket has to be related to two $|j, m_j\rangle$ kets by two Clebsch-Gordan coefficients. Since j changes in unit steps, these values of j have to be $l \pm \frac{1}{2}$. This choice,

$$j = l \pm \frac{1}{2}, \quad (5.189)$$

evidently satisfies all lower values of m_j as well – see Fig. 14.⁵² (Again, only one value, $j = l + \frac{1}{2}$, is necessary to represent the state with the lowest $m_j = -l - \frac{1}{2}$ – see the bottom-leftmost point of that diagram.) Note that the total number of the coupled-representation states is $1 + 2 \times 2l + 1 \equiv 2(2l + 1)$, i.e. is the same as those in the uncoupled representation. So, for spin- $\frac{1}{2}$ systems, each sum (183), for fixed j and m_j (plus the fixed common parameter l , plus the common $s = \frac{1}{2}$), has at most two terms, i.e. involves at most two Clebsch-Gordan coefficients.

These coefficients may be calculated in a few steps, all but the last one rather simple even for an arbitrary spin s . First, the similarity of the vector operators $\hat{\mathbf{J}}$ and $\hat{\mathbf{S}}$ to the operator $\hat{\mathbf{L}}$, expressed by Eqs. (169), (175), and (177), may be used to argue that the matrix elements of the operators \hat{S}_\pm and \hat{J}_\pm , defined similarly to \hat{L}_\pm , have the matrix elements similar to those given by Eq. (164). Next, acting by the operator $\hat{J}_\pm = \hat{L}_\pm + \hat{S}_\pm$ upon both parts of Eq. (183), and then inner-multiplying the result by the bra

⁵² Eq. (5.189) allows a semi-qualitative classical interpretation in terms of the vector diagrams shown in Fig. 13: since, according to Eq. (169), $\hbar s$ gives the scale of the length of the vector \mathbf{S} , if it is small ($s = \frac{1}{2}$), the length of vector \mathbf{J} (similarly scaled by $\hbar j$) cannot deviate much from the length of the vector \mathbf{L} (scaled by $\hbar l$) for any spatial orientation of these vectors, so that j cannot differ from l too much. Note also that for a fixed m_j , the alternating sign in Eq. (189) is independent of the sign of m_s – see also Eqs. (190).

vector $\langle m_l, m_s |$ and using the above matrix elements, we may get recurrence relations for the Clebsch-Gordan coefficients with adjacent values of m_l , m_s , and m_j . Finally, these relations may be sequentially applied to the adjacent states in both representations, starting from any of the two states common for them – for example, from the state with the ket-vector (188), corresponding to the top right point in Fig. 14.

Let me leave these straightforward but a bit tedious calculations for the reader's exercise, and just cite the final result of this procedure for $s = \frac{1}{2}$:⁵³

Clebsch –
Gordan
coefficients
for $s = \frac{1}{2}$

$$\langle m_l = m_j - \frac{1}{2}, m_s = +\frac{1}{2} | j = l \pm \frac{1}{2}, m_j \rangle = \pm \left(\frac{l \pm m_j + \frac{1}{2}}{2l+1} \right)^{1/2},$$

$$\langle m_l = m_j + \frac{1}{2}, m_s = -\frac{1}{2} | j = l \pm \frac{1}{2}, m_j \rangle = + \left(\frac{l \mp m_j + \frac{1}{2}}{2l+1} \right)^{1/2}.$$

(5.190)

In this course, these relations will be used mostly in Sec. 6.4 for an analysis of the anomalous Zeeman effect. Moreover, the angular momentum addition theory described above is also valid for the addition of angular momenta of multiparticle system components, so we will revisit it in Chapter 8.

To conclude this section, I have to note that the Clebsch-Gordan coefficients (for arbitrary s) participate also in the so-called *Wigner-Eckart theorem* that expresses the matrix elements of *spherical tensor operators*, in the coupled-representation basis $|j, m_j\rangle$, via a reduced set of matrix elements. This theorem may be useful, for example, for the calculation of the rate of quantum transitions to/from high- n states in spherically-symmetric potentials. Unfortunately, a discussion of this theorem and its applications would require a higher mathematical background than I can expect from my readers, and more time/space than I can afford.⁵⁴

5.8. Exercise problems

5.1. Use the discussion in Sec. 1 to find an alternative solution of Problem 4.18.

5.2. A spin- $\frac{1}{2}$ is placed into an external magnetic field, with a time-independent orientation, its magnitude $\mathcal{B}(t)$ being an arbitrary function of time. Find explicit expressions for the Heisenberg operators and the expectation values of all three Cartesian components of the spin, as functions of time, in a coordinate system of your choice.

5.3. A two-level system is in the quantum state α described by the ket-vector $|\alpha\rangle = \alpha|\uparrow\rangle + \alpha|\downarrow\rangle$, with given (generally, complex) c -number coefficients $\alpha_{\uparrow\downarrow}$. Prove that we can always select such a geometric c -number vector $\mathbf{c} = \{c_x, c_y, c_z\}$, that α is an eigenstate of $\mathbf{c} \cdot \hat{\mathbf{\sigma}}$, where $\hat{\mathbf{\sigma}}$ is the Pauli vector operator. Find all possible values of \mathbf{c} satisfying this condition, and the second eigenstate (orthogonal to α) of the operator $\mathbf{c} \cdot \hat{\mathbf{\sigma}}$. Give a Bloch-sphere interpretation of your result.

⁵³ For arbitrary spin s , the calculations and even the final expressions for the Clebsch-Gordan coefficients are rather bulky. They may be found, typically in a table form, mostly in special monographs – see, e.g., A. Edmonds, *Angular Momentum in Quantum Mechanics*, Princeton U. Press, 1957.

⁵⁴ For the interested reader, I can recommend either Sec. 17.7 in E. Merzbacher, *Quantum Mechanics*, 3rd ed., Wiley, 1998, or Sec. 3.10 in J. Sakurai, *Modern Quantum Mechanics*, Addison-Wesley, 1994.

5.4.* Analyze statistics of the spacing $S \equiv E_+ - E_-$ between energy levels of a two-level system, assuming that all elements $H_{jj'}$ of its Hamiltonian matrix (2) are independent random numbers, with equal and constant probability densities within the energy interval of interest. Compare the result with that for a purely diagonal Hamiltonian matrix, with the similar probability distribution of its random diagonal elements.

5.5. For a periodic motion of a single particle in a confining potential $U(\mathbf{r})$, the *virial theorem* of non-relativistic classical mechanics⁵⁵ is reduced to the following equality:

$$\bar{T} = \frac{1}{2} \overline{\mathbf{r} \cdot \nabla U},$$

where T is the particle's kinetic energy, and the top bar means averaging over the time period of motion. Prove the following quantum-mechanical version of the theorem for an arbitrary stationary quantum state, in the absence of spin effects:

$$\langle T \rangle = \frac{1}{2} \langle \mathbf{r} \cdot \nabla U \rangle,$$

where the angular brackets mean the expectation values of the observables.

Hint: Mimicking the proof of the classical virial theorem, consider the time evolution of the following operator:

$$\hat{G} \equiv \hat{\mathbf{r}} \cdot \hat{\mathbf{p}}.$$

5.6. Calculate, in the WKB approximation, the transparency \mathcal{T} of the following saddle-shaped potential barrier:

$$U(x, y) = U_0 \left(1 + \frac{xy}{a^2} \right),$$

where $U_0 > 0$ and a are real constants, for tunneling of a 2D particle with energy $E < U_0$.

5.7. Calculate the so-called *Gamow factor*⁵⁶ for the alpha decay of atomic nuclei, i.e. the exponential factor in the transparency of the potential barrier resulting from the following simple model for the alpha-particle's potential energy as a function of its distance from the nuclear center:

$$U(r) = \begin{cases} U_0 < 0, & \text{for } r < R, \\ \frac{ZZ'e^2}{4\pi\epsilon_0 r}, & \text{for } R < r, \end{cases}$$

(where $Ze = 2e > 0$ is the charge of the particle, $Z'e > 0$ is that of the nucleus after the decay, and R is the nucleus' radius), in the WKB approximation.

5.8. Use the WKB approximation to calculate the average time of ionization of a hydrogen atom, initially in its ground state, made metastable by application of an additional weak, uniform, time-independent electric field \mathcal{E} . Formulate the conditions of validity of your result.

⁵⁵ See, e.g., CM Problem 1.12.

⁵⁶ Named after G. Gamow, who made this calculation as early as in 1928.

5.9. For a 1D harmonic oscillator with mass m and frequency ω_0 , calculate:

- (i) all matrix elements $\langle n | \hat{x}^3 | n' \rangle$, and
- (ii) the diagonal matrix elements $\langle n | \hat{x}^4 | n \rangle$,

where n and n' are arbitrary Fock states.

5.10. Calculate the sum (over all $n > 0$) of the so-called *oscillator strengths*,

$$f_n \equiv \frac{2m}{\hbar^2} (E_n - E_0) |\langle n | \hat{x} | 0 \rangle|^2,$$

- (i) for a 1D harmonic oscillator, and
- (ii) for a 1D particle confined in an arbitrary stationary potential.

5.11. Prove the so-called *Bethe sum rule*,

$$\sum_{n'} (E_{n'} - E_n) \left| \langle n | e^{ik\hat{x}} | n' \rangle \right|^2 = \frac{\hbar^2 k^2}{2m},$$

valid for a 1D particle moving in an arbitrary time-independent potential $U(x)$, and discuss its relation with the *Thomas-Reiche-Kuhn sum rule* whose derivation was the subject of the previous problem.

Hint: Calculate the expectation value, in a stationary state n , of the following double commutator,

$$\hat{D} = [\hat{H}, e^{ik\hat{x}}], e^{-ik\hat{x}},$$

in two ways: first, just spelling out both commutators, and, second, using the commutation relations between operators \hat{p}_x and $e^{ik\hat{x}}$, and compare the results.

5.12. Given Eq. (116), prove Eq. (117), using the hint given in the accompanying footnote.

5.13. Use Eqs. (116)-(117) to simplify the following operators:

- (i) $\exp\{+ia\hat{x}\} \hat{p}_x \exp\{-ia\hat{x}\}$, and
- (ii) $\exp\{+ia\hat{p}_x\} \hat{x} \exp\{-ia\hat{p}_x\}$,

where a is a *c*-number.

5.14. For a 1D harmonic oscillator, calculate:

- (i) the expectation value of energy, and
- (ii) the time evolution of the expectation values of the coordinate and momentum,

provided that in the initial moment ($t = 0$) it was in the state described by the following ket-vector:

$$|\alpha\rangle = \frac{1}{\sqrt{2}} (|31\rangle + |32\rangle),$$

where $|n\rangle$ are the ket-vectors of the stationary (Fock) states of the oscillator.

5.15.* Re-derive the London dispersion force's potential of the interaction of two isotropic 3D harmonic oscillators (already calculated in Problem 3.16), using the language of mutually-induced polarization.

5.16. An external force pulse $F(t)$, of a finite time duration \mathcal{T} , has been exerted on a 1D harmonic oscillator, initially in its ground state. Use the Heisenberg-picture equations of motion to calculate the expectation value of the oscillator's energy at the end of the pulse.

5.17. Use Eqs. (144)-(145) to calculate the uncertainties δx and δp for a harmonic oscillator in its squeezed ground state, and in particular, to prove Eqs. (143) for the case $\theta = 0$.

5.18. Calculate the energy of a harmonic oscillator in the squeezed ground state ζ .

5.19.* Prove that the squeezed ground state, described by Eqs. (142) and (144)-(145), may be sustained by a sinusoidal modulation of a harmonic oscillator's parameter, and calculate the squeezing factor r as a function of the parameter modulation depth, assuming that the depth is small, and the oscillator's damping is negligible.

5.20. Use Eqs. (148) to prove that the operators \hat{L}_j and \hat{L}^2 commute with the Hamiltonian of a spinless particle placed in any central potential field.

5.21. Use Eqs. (149)-(150) and (153) to prove Eqs. (155).

5.22. Derive Eq. (164), using any of the prior formulas.

5.23. In the basis of common eigenstates of the operators \hat{L}_z and \hat{L}^2 , described by kets $|l, m\rangle$:

(i) calculate the matrix elements $\langle l, m_1 | \hat{L}_x | l, m_2 \rangle$ and $\langle l, m_1 | \hat{L}_x^2 | l, m_2 \rangle$;

(ii) spell out your results for diagonal matrix elements (with $m_1 = m_2$) and their y -axis counterparts; and

(iii) calculate the diagonal matrix elements $\langle l, m | \hat{L}_x \hat{L}_y | l, m \rangle$ and $\langle l, m | \hat{L}_y \hat{L}_x | l, m \rangle$.

5.24. For the state described by the common eigenket $|l, m\rangle$ of the operators \hat{L}_z and \hat{L}^2 in a reference frame $\{x, y, z\}$, calculate the expectation values $\langle L_z \rangle$ and $\langle L_z^2 \rangle$ in the reference frame whose z' -axis forms angle θ with the z -axis.

5.25. Write down the matrices of the following angular momentum operators: $\hat{L}_x, \hat{L}_y, \hat{L}_z$, and \hat{L}_\pm , in the z -basis of the $\{l, m\}$ states with $l = 1$.

5.26. Calculate the angular factor of the orbital wavefunction of a particle with a definite value of L^2 , equal to $6\hbar^2$, and the largest possible value of L_x . What is this value?

5.27. For the state with the wavefunction $\psi = Cxye^{-\lambda r}$, with a real, positive λ , calculate:

- (i) the expectation values of the observables L_x , L_y , L_z , and L^2 , and
- (ii) the normalization constant C .

5.28. An angular state of a spinless particle is described by the following ket-vector:

$$|\alpha\rangle = \frac{1}{\sqrt{2}}(|l=3, m=0\rangle + |l=3, m=1\rangle).$$

Calculate the expectation values of the x - and y -components of its angular momentum. Is the result sensitive to a possible phase shift between the component eigenkets?

5.29. A particle is in a quantum state α with the orbital wavefunction proportional to the spherical harmonic $Y_1^1(\theta, \phi)$. Find the angular dependence of the wavefunctions corresponding to the following ket-vectors:

- (i) $\hat{L}_x|\alpha\rangle$, (ii) $\hat{L}_y|\alpha\rangle$, (iii) $\hat{L}_z|\alpha\rangle$, (iv) $\hat{L}_+ \hat{L}_- |\alpha\rangle$, and (v) $\hat{L}^2|\alpha\rangle$.

5.30. A charged, spinless 2D particle of mass m is trapped in a soft potential well $U(x, y) = m\omega_0^2(x^2 + y^2)/2$. Calculate its energy spectrum in the presence of a uniform magnetic field \mathcal{B} , normal to the $[x, y]$ -plane of particle's motion.

5.31. Solve the previous problem for a spinless 3D particle, placed (in addition to a uniform magnetic field \mathcal{B}) into a spherically-symmetric potential well $U(\mathbf{r}) = m\omega_0^2 r^2/2$.

5.32. Calculate the spectrum of rotational energies of an axially-symmetric, rigid body.

5.33. Simplify the following double commutator:

$$[\hat{r}_j, [\hat{L}^2, \hat{r}_{j'}]].$$

5.34. Prove the following commutation relation:

$$[\hat{L}^2, [\hat{L}^2, \hat{r}_j]] = 2\hbar^2 (\hat{r}_j \hat{L}^2 + \hat{L}^2 \hat{r}_j).$$

5.35. Use the commutation relation proved in the previous problem, and Eq. (148), to prove the orbital electric-dipole selection rules mentioned in Sec. 5.6 of the lecture notes.

5.36. Express the commutators listed in Eq. (179), $[\hat{J}^2, \hat{L}_z]$ and $[\hat{J}^2, \hat{S}_z]$, via \hat{L}_j and \hat{S}_j .

5.37. Find the operator $\hat{\mathcal{T}}_\phi$ describing a quantum state's rotation by angle ϕ about a certain axis, using the similarity of this operation with the shift of a Cartesian coordinate, discussed in Sec. 5. Then use this operator to calculate the probabilities of measurements of spin- $1/2$ components of a beam of

particles with z -polarized spin, by a Stern-Gerlach instrument turned by angle θ within the $[z, x]$ plane, where y is the axis of particle propagation – see Fig. 4.1.⁵⁷

5.38. The rotation (“angular translation”) operator $\hat{\mathcal{T}}_\phi$ analyzed in the previous problem, and the linear translation operator $\hat{\mathcal{T}}_x$ discussed in Sec. 5, have a similar structure:

$$\hat{\mathcal{T}}_\lambda = \exp\left\{-i\hat{C}\lambda/\hbar\right\},$$

where λ is a real c -number, characterizing the shift, and \hat{C} is a Hermitian operator, which does not explicitly depend on time.

(i) Prove that such operators $\hat{\mathcal{T}}_\lambda$ are unitary.

(ii) Prove that if the shift by λ , induced by the operator $\hat{\mathcal{T}}_\lambda$, leaves the Hamiltonian of some system unchanged for any λ , then $\langle C \rangle$ is a constant of motion for any initial state of the system.

(iii) Discuss what the last conclusion means for the particular operators $\hat{\mathcal{T}}_x$ and $\hat{\mathcal{T}}_\phi$.

5.39. A particle with spin s is in a state with definite quantum numbers l and j . Prove that the observable $\mathbf{L} \cdot \mathbf{S}$ also has a definite value, and calculate it.

5.40. For a spin- $\frac{1}{2}$ particle in a state with definite quantum numbers l , m_l , and m_s , calculate the expectation value of the observable J^2 , and the probabilities of all its possible values. Interpret your results in the terms of the Clebsh-Gordan coefficients (190).

5.41. Derive general recurrence relations for the Clebsh-Gordan coefficients.

Hint: Using the similarity of the commutation relations discussed in Sec. 7, write the relations similar to Eqs. (164) for other components of the angular momentum, and apply them to Eq. (170).

5.42. Use the recurrence relations derived in the previous problem to prove Eqs. (190) for the spin- $\frac{1}{2}$ Clebsh-Gordan coefficients.

5.43. A spin- $\frac{1}{2}$ particle is in a state with definite values of L^2 , J^2 , and J_z . Find all possible values of the observables S^2 , S_z , and L_z , the probability of each listed value, and the expectation value for each of these observables.

5.44. Re-solve the Landau-level problem discussed in Sec. 3.2, for a spin- $\frac{1}{2}$ particle. Discuss the result for the particular case of an electron, with the g -factor equal to 2.

5.45. In the Heisenberg picture of quantum dynamics, find an explicit relation between the operators of velocity $\hat{\mathbf{v}} \equiv d\hat{\mathbf{r}}/dt$ and acceleration $\hat{\mathbf{a}} \equiv d\hat{\mathbf{v}}/dt$ of a spin- $\frac{1}{2}$ particle with electric charge q , moving in an arbitrary external electromagnetic field. Compare the result with the corresponding classical expression.

Hint: For the orbital motion’s description, you may use Eq. (3.26).

⁵⁷ Note that the last task is just a particular case of Problem 4.18 (see also Problem 1).

5.46. A byproduct of the solution of Problem 41 is the following relation for the spin operators (valid for any spin s):

$$\langle m_s \pm 1 | \hat{S}_\pm | m_s \rangle = \hbar [(s \pm m_s + 1)(s \mp m_s)]^{1/2}.$$

Use this result to spell out the matrices S_x , S_y , S_z , and S^2 of a particle with $s = 1$, in the z -basis – defined as the basis in which the matrix S_z is diagonal.

5.47.* For a particle with an arbitrary spin s , moving in a spherically-symmetric field, find the ranges of the quantum numbers m_j and j that are necessary to describe, in the coupled-representation basis:

- (i) all states with a definite quantum number l , and
- (ii) a state with definite values of not only l , but also m_l and m_s .

Give an interpretation of your results in terms of the classical geometric vector diagram (Fig. 13).

5.48. A particle of mass m , with electric charge q and spin s , free to move along a plane ring of a radius R , is placed into a constant, uniform magnetic field \mathcal{B} , directed normally to the ring's plane. Calculate the energy spectrum of the system. Explore and interpret the particular form the result takes when the particle is an electron with the g-factor $g_e = 2$.

Chapter 6. Perturbative Approaches

This chapter discusses several perturbative approaches to problems of quantum mechanics, and their simplest but important applications including the fine structure of atomic energy levels, and the effects of external dc and ac electric and magnetic fields on these levels. It continues with a discussion of the perturbation theory of transitions to continuous spectrum and the Golden Rule of quantum mechanics, which naturally brings us to the issue of open quantum systems – to be discussed in the next chapter.

6.1. Time-independent perturbations

Unfortunately, only a few problems of quantum mechanics may be solved exactly in an analytical form. Actually, in the previous chapters we have solved a substantial part of such problems for a single particle, while for multiparticle systems, the exactly solvable cases are even more rare. However, most practical problems of physics feature a certain small parameter, and this smallness may be exploited by various approximate analytical methods giving *asymptotically correct* results – i.e. the results whose error tends to zero at the reduction of the small parameter(s). Earlier in the course, we have explored one of them, the WKB approximation, which is adequate for a particle moving through a soft potential profile. In this chapter, we will discuss other techniques that are more suitable for other cases. The historic name for these techniques is *the perturbation theory*, though it is more fair to speak about several *perturbative approaches*, because they are substantially different for different situations.

The simplest version of the perturbation theory addresses the problem of stationary states and energy levels of systems described by time-independent Hamiltonians of the type

$$\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)}, \quad (6.1)$$

where the operator $\hat{H}^{(1)}$, describing the system's “perturbation”, is relatively small – in the sense that its addition to the unperturbed operator $\hat{H}^{(0)}$ results in a relatively small change of the eigenenergies E_n of the system, and the corresponding eigenstates. A typical problem of this type is the 1D *weakly anharmonic oscillator* (Fig. 1), described by the Hamiltonian (1) with

$$\hat{H}^{(0)} = \frac{\hat{p}^2}{2m} + \frac{m\omega_0^2 \hat{x}^2}{2}, \quad \hat{H}^{(1)} = \alpha \hat{x}^3 + \beta \hat{x}^4 + \dots \quad (6.2)$$

Weakly
anharmonic
oscillator

with sufficiently small coefficients α, β, \dots

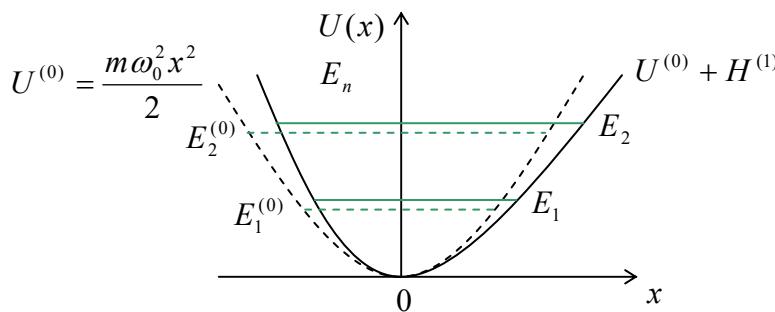

Fig. 6.1. The simplest application of the perturbation theory: a weakly anharmonic 1D oscillator. (Dashed lines characterize the unperturbed, harmonic oscillator.)

I will use this system as our first example, but let me start by describing the perturbative approach to the general time-independent Hamiltonian (1). In the bra-ket formalism, the eigenproblem (4.68) for the perturbed Hamiltonian, i.e. the stationary Schrödinger equation of the system, is

$$(\hat{H}^{(0)} + \hat{H}^{(1)})|n\rangle = E_n |n\rangle. \quad (6.3)$$

Let the eigenstates and eigenvalues of the unperturbed Hamiltonian, which satisfy the equation

$$\hat{H}^{(0)}|n^{(0)}\rangle = E_n^{(0)}|n^{(0)}\rangle, \quad (6.4)$$

be considered as known. In this case, the solution of problem (3) means finding, first, its perturbed eigenvalues E_n and, second, the coefficients $\langle n',^{(0)}|n\rangle$ of the expansion of the perturbed state's vectors $|n\rangle$ in the following series over the unperturbed ones, $|n',^{(0)}\rangle$:

$$|n\rangle = \sum_{n'} |n',^{(0)}\rangle \langle n',^{(0)}|n\rangle. \quad (6.5)$$

Let us plug Eq. (5), with the summation index n' replaced with n'' (just to have a more compact notation in our forthcoming result), into both sides of Eq. (3):

$$\sum_{n''} \langle n'',^{(0)}|n\rangle \hat{H}^{(0)}|n'',^{(0)}\rangle + \sum_{n''} \langle n'',^{(0)}|n\rangle \hat{H}^{(1)}|n'',^{(0)}\rangle = \sum_{n''} \langle n'',^{(0)}|n\rangle E_n |n'',^{(0)}\rangle. \quad (6.6)$$

and then inner-multiply all terms by an arbitrary unperturbed bra-vector $\langle n',^{(0)}|$ of the system. Assuming that the unperturbed eigenstates are orthonormal, $\langle n',^{(0)}|n'',^{(0)}\rangle = \delta_{n'n''}$, and using Eq. (4) in the first term on the left-hand side, we get the following system of linear equations

$$\sum_{n''} \langle n'',^{(0)}|n\rangle H_{n'n''}^{(1)} = \langle n',^{(0)}|n\rangle (E_n - E_{n'}^{(0)}), \quad (6.7)$$

where the matrix elements of the perturbation are calculated, by definition, in the *unperturbed* brackets:

$H_{n'n''}^{(1)} \equiv \langle n',^{(0)}|\hat{H}^{(1)}|n'',^{(0)}\rangle.$

(6.8)

Perturbation's
matrix
elements

The linear equation system (7) is still exact,¹ and is frequently used for numerical calculations. (Since the matrix coefficients (8) typically decrease when n' and/or n'' become sufficiently large, the sum on the left-hand side of Eq. (7) may usually be truncated, still giving an acceptable accuracy of the solution.) To get analytical results, we need to make approximations. In the simple perturbation theory we are discussing now, this is achieved by the expansion of both the eigenenergies and the expansion coefficients into the Taylor series in a certain small parameter μ of the problem:

$$E_n = E_n^{(0)} + E_n^{(1)} + E_n^{(2)} \dots, \quad (6.9)$$

$$\langle n',^{(0)}|n\rangle = \langle n',^{(0)}|n\rangle^{(0)} + \langle n',^{(0)}|n\rangle^{(1)} + \langle n',^{(0)}|n\rangle^{(2)} \dots, \quad (6.10)$$

where

¹ Please note the similarity of Eq. (7) with Eq. (2.215) of the 1D band theory. Indeed, the latter equation is not much more than a particular form of Eq. (7) for the 1D wave mechanics, and a specific (periodic) potential $U(x)$ considered as the perturbation Hamiltonian. Moreover, the whole approximate treatment of the weak-potential limit in Sec. 2.7 is essentially a particular case of the perturbation theory we are discussing now (in its 1st order).

$$E_n^{(k)} \propto \langle n'^{(0)} | n \rangle^{(k)} \propto \mu^k. \quad (6.11)$$

In order to explore the 1st-order approximation, which ignores all terms $O(\mu^2)$ and higher, let us plug only the two first terms of the expansions (9) and (10) into the basic equation (7):

$$\sum_{n''} H_{n'n''}^{(1)} \left(\delta_{n''n} + \langle n''^{(0)} | n \rangle^{(1)} \right) = \left(\delta_{n'n} + \langle n'^{(0)} | n \rangle^{(1)} \right) (E_n^{(0)} + E_n^{(1)} - E_{n'}^{(0)}). \quad (6.12)$$

Now let us open the parentheses, and disregard all the remaining terms $O(\mu^2)$. The result is

$$H_{n'n}^{(1)} = \delta_{n'n} E_n^{(1)} + \langle n'^{(0)} | n \rangle^{(1)} (E_n^{(0)} - E_{n'}^{(0)}), \quad (6.13)$$

This relation is valid for any set of indices n and n' ; let us start from the case $n = n'$, immediately getting a very simple (and practically, the most important!) result:

Energy:
1st-order
correction

$$E_n^{(1)} = H_{nn}^{(1)} \equiv \langle n^{(0)} | \hat{H}^{(1)} | n^{(0)} \rangle. \quad (6.14)$$

For example, let us see what this result gives for two first perturbation terms in the weakly anharmonic oscillator (2):

$$E_n^{(1)} = \alpha \langle n^{(0)} | \hat{x}^3 | n^{(0)} \rangle + \beta \langle n^{(0)} | \hat{x}^4 | n^{(0)} \rangle. \quad (6.15)$$

As the reader knows (or should know :-) from the solution of Problem 5.9, the first bracket equals zero, while the second one yields²

$$E_n^{(1)} = \frac{3}{4} \beta x_0^4 (2n^2 + 2n + 1). \quad (6.16)$$

Naturally, there should be some non-vanishing contribution to the energies from the (typically, larger) perturbation proportional to α , so that for its calculation we need to explore the 2nd order of the theory. However, before doing that, let us complete our discussion of its 1st order.

For $n' \neq n$, Eq. (13) may be used to calculate the eigenstates rather than the eigenvalues:

$$\langle n'^{(0)} | n \rangle^{(1)} = \frac{H_{n'n}^{(1)}}{E_n^{(0)} - E_{n'}^{(0)}}, \quad \text{for } n' \neq n. \quad (6.17)$$

This means that the eigenket's expansion (5), in the 1st order, may be represented as

States:
1st-order
result

$$| n^{(1)} \rangle = C | n^{(0)} \rangle + \sum_{n' \neq n} \frac{H_{n'n}^{(1)}}{E_n^{(0)} - E_{n'}^{(0)}} | n'^{(0)} \rangle. \quad (6.18)$$

The coefficient $C \equiv \langle n^{(0)} | n^{(1)} \rangle$ cannot be found from Eq. (17); however, requiring the final state n to be normalized, we see that other terms may provide only corrections $O(\mu^2)$, so that in the 1st order we should take $C = 1$. The most important feature of Eq. (18) is its denominators: the closer are the unperturbed eigenenergies of two states, the larger is their mutual “interaction” due to the perturbation.

² A useful exercise for the reader: analyze the relation between Eq. (16) and the result of the classical theory of such weakly anharmonic (“nonlinear”) oscillator – see, e.g., CM Sec. 5.2, in particular, Eq. (5.49).

This feature also affects the 1st-order's validity condition, which may be quantified using Eq. (17): the magnitudes of the brackets it describes have to be much less than the unperturbed bracket $\langle n|n \rangle^{(0)} = 1$, so that all elements of the perturbation matrix have to be much less than the difference between the corresponding unperturbed energies. For the anharmonic oscillator's energy corrections (16), this requirement is reduced to $E_n^{(1)} \ll \hbar\omega_0$.

Now we are ready for going after the 2nd-order approximation to Eq. (7). Let us focus on the case $n' = n$, because as we already know, only this term will give us a correction to the eigenenergies. Moreover, since the left-hand side of Eq. (7) already has a small factor $H_{n'n}^{(1)} \propto \mu$, the bracket coefficients in that part may be taken from the 1st-order result (17). As a result, we get

$$E_n^{(2)} = \sum_{n''} \langle n''^{(0)} | n \rangle^{(1)} H_{nn''}^{(1)} = \sum_{n'' \neq n} \frac{H_{n''n}^{(1)} H_{nn''}^{(1)}}{E_n^{(0)} - E_{n''}^{(0)}}. \quad (6.19)$$

Since $\hat{H}^{(1)}$ has to be Hermitian, we may rewrite this expression as

$$E_n^{(2)} = \sum_{n' \neq n} \frac{|H_{n'n}^{(1)}|^2}{E_n^{(0)} - E_{n'}^{(0)}} \equiv \sum_{n' \neq n} \frac{|\langle n'^{(0)} | \hat{H}^{(1)} | n^{(0)} \rangle|^2}{E_n^{(0)} - E_{n'}^{(0)}}. \quad (6.20)$$

Energy:
2nd-order
correction

This is the much-celebrated 2nd-order perturbation result, which frequently (in sufficiently symmetric problems) is the first non-vanishing correction to the state energy – for example, from the cubic term (proportional to α) in our weakly anharmonic oscillator problem (2). To calculate the corresponding correction, we may use another result of the solution of Problem 5.9:

$$\begin{aligned} \langle n' | \hat{x}^3 | n \rangle &= \left(\frac{x_0}{\sqrt{2}} \right)^3 \\ &\times \left\{ [n(n-1)(n-2)]^{1/2} \delta_{n',n-3} + 3n^{3/2} \delta_{n',n-1} + 3(n+1)^{3/2} \delta_{n',n+1} + [(n+1)(n+2)(n+3)]^{1/2} \delta_{n',n+3} \right\}. \end{aligned} \quad (6.21)$$

So, according to Eq. (20), we need to calculate

$$\begin{aligned} E_n^{(2)} &= \alpha^2 \left(\frac{x_0}{\sqrt{2}} \right)^6 \\ &\times \sum_{n' \neq n} \frac{\left\{ [n(n-1)(n-2)]^{1/2} \delta_{n',n-3} + 3n^{3/2} \delta_{n',n-1} + 3(n+1)^{3/2} \delta_{n',n+1} + [(n+1)(n+2)(n+3)]^{1/2} \delta_{n',n+3} \right\}^2}{\hbar\omega_0(n-n')}. \end{aligned} \quad (6.22)$$

The summation is not as cumbersome as may look, because at the curly brackets' squaring, all mixed products are proportional to the products of different Kronecker deltas and hence vanish, so that we need to sum up only the squares of each term, finally getting

$$E_n^{(2)} = -\frac{15}{4} \frac{\alpha^2 x_0^6}{\hbar\omega_0} \left(n^2 + n + \frac{11}{30} \right). \quad (6.23)$$

This formula shows that all energy level corrections are negative, regardless of the sign of α .³ On the contrary, the 1st order correction $E_n^{(1)}$, given by Eq. (16), does depend on the sign of β , so that the net correction, $E_n^{(1)} + E_n^{(2)}$, may be of any sign.

³ Note that this is correct for the ground-state energy correction $E_g^{(2)}$ of *any* system, because for this state, the denominators of all terms of the sum (20) are negative, while their numerators are always non-negative.

The results (18) and (20) are clearly inapplicable to the degenerate case where, in the absence of perturbation, several states correspond to the same energy level, because of the divergence of their denominators.⁴ This divergence hints that in this case, the largest effect of the perturbation is the *degeneracy lifting*, e.g., some splitting of the initially degenerate energy level $E^{(0)}$ (Fig. 2), and that for the analysis of this case we can, in the first approximation, ignore the effect of all other energy levels. (A careful analysis shows that this is indeed the case until the level splitting becomes comparable with the distance to other energy levels.)

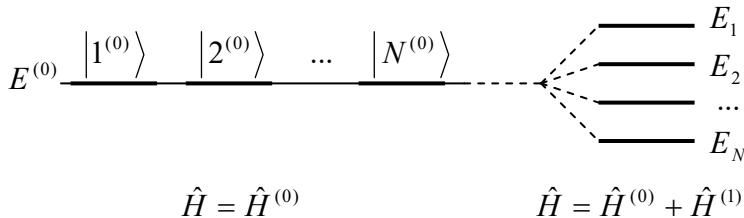

Fig. 5.2. Lifting the energy level degeneracy by a perturbation (schematically).

Limiting the summation in Eq. (7) to the group of N degenerate states with equal $E_{n'}^{(0)} \equiv E^{(0)}$, we reduce it to

$$\sum_{n''=1}^N \langle n''^{(0)} | n \rangle H_{n'n''}^{(1)} = \langle n'^{(0)} | n \rangle (E_n - E^{(0)}), \quad (6.24)$$

where now n' and n'' number the N states of the degenerate group.⁵ For $n = n'$, Eq. (24) may be rewritten as

$$\sum_{n''=1}^N (H_{n'n''}^{(1)} - E_{n''}^{(1)} \delta_{n'n''}) \langle n''^{(0)} | n' \rangle = 0, \quad \text{where } E_n^{(1)} \equiv E_n - E^{(0)}. \quad (6.25)$$

For each $n' = 1, 2, \dots, N$, this is a system of N linear, homogenous equations (with N terms each) for N unknown coefficients $\langle n''^{(0)} | n' \rangle$. In this problem, we may readily recognize the problem of diagonalization of the perturbation matrix $H^{(1)}$ – cf. Sec. 4.4 and in particular Eq. (4.101). As in the general case, the condition of self-consistency of the system is:

Initially
degenerate
system:
energy levels

$$\begin{vmatrix} H_{11}^{(1)} - E_n^{(1)} & H_{12}^{(1)} & \dots \\ H_{21}^{(1)} & H_{22}^{(1)} - E_n^{(1)} & \dots \\ \dots & \dots & \dots \end{vmatrix} = 0, \quad (6.26)$$

where now the index n numbers the N roots of this equation, in an arbitrary order. According to the definition (25) of $E_n^{(1)}$, the resulting N energy levels E_n may be found as $E^{(0)} + E_n^{(1)}$. If the perturbation matrix is diagonal in the chosen basis $n''^{(0)}$, the result is extremely simple,

$$E_n - E^{(0)} \equiv E_n^{(1)} = H_{nn}^{(1)}, \quad (6.27)$$

⁴ This is exactly the reason why such simple perturbation approach runs into serious problems for systems with a continuous spectrum, and other techniques (such as the WKB approximation) are often necessary.

⁵ Note that here the choice of the basis is to some extent arbitrary, because due to the linearity of equations of quantum mechanics, any linear combination of the states $n''^{(0)}$ is also an eigenstate of the unperturbed Hamiltonian. However, for using Eq. (25), these combinations have to be orthonormal, as was supposed at the derivation of Eq. (7).

and formally coincides with Eq. (14) for the non-degenerate case, but now it may give a different result for each of N previously degenerate states n .

Now let us see what this general theory gives for several important examples. First of all, let us consider a system with just two degenerate states with energy sufficiently far from all other levels. Then, in the basis of these two degenerate states, the most general perturbation matrix is

$$\mathbf{H}^{(1)} = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix} \quad (6.28)$$

This matrix coincides with the general matrix (5.2) of a two-level system. Hence, we come to the very important conclusion: for a weak perturbation, all properties of any double-degenerate system are identical to those of the genuine two-level systems, which were the subject of numerous discussions in Chapter 4 and again in Sec. 5.1. In particular, its eigenenergies are given by Eq. (5.6), and may be described by the level-anticrossing diagram shown in Fig. 5.1.

6.2. The linear Stark effect

As a more involved example of the level degeneracy lifting by a perturbation, let us discuss the *Stark effect*⁶ – the atomic level splitting by an external electric field. Let us study this effect, in the linear approximation, for a hydrogen-like atom/ion. Taking the direction of the external electric field \mathcal{E} (which is practically always uniform on the atomic scale) for the z -axis, the perturbation may be represented by the following Hamiltonian:

$$\hat{H}^{(1)} = -F\hat{z} = -q\mathcal{E}\hat{z} = -q\mathcal{E}r \cos\theta. \quad (6.29)$$

(In the last form, the operator sign is dropped, because we will work in the coordinate representation.)

As you (should :-) remember, energy levels of a hydrogen-like atom/ion depend only on the principal quantum number n – see Eq. (3.201); hence all the states, besides the ground $1s$ state in which $n = 1$ and $l = m = 0$, have some orbital degeneracy, which grows rapidly with n . Let us consider the lowest degenerate level with $n = 2$. Since, according to Eq. (3.203), $0 \leq l \leq n-1$, at this level the orbital quantum number l may equal either 0 (one $2s$ state, with $m = 0$) or 1 (three $2p$ states, with $m = 0, \pm 1$). Due to this 4-fold degeneracy, $\mathbf{H}^{(1)}$ is a 4×4 matrix with 16 elements:

$$\mathbf{H}^{(1)} = \underbrace{\begin{matrix} l=0 \\ m=0 & m=0 & m=+1 & m=-1 \end{matrix}}_{\text{m=0}} \left\{ \begin{array}{ll} \left(\begin{matrix} H_{11} & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{matrix} \right) & \begin{array}{l} m=0, \\ m=0, \\ m=+1, \\ m=-1, \end{array} \\ \left. \begin{array}{l} l=0, \\ l=0, \\ l=1, \\ l=1. \end{array} \right\} & \end{array} \right. \quad (6.30)$$

⁶ This effect was discovered experimentally in 1913 by Johannes Stark and independently by Antonio Lo Surdo, so it is sometimes (and more fairly) called the “Stark – Lo Surdo effect”. Sometimes this name is used with the qualifier “dc” to distinguish it from the *ac* Stark effect – the energy level shift under the effect of an ac field – see Sec. 5 below.

However, there is no need to be scared. First, due to the Hermitian nature of the operator, only ten of these matrix elements (four diagonal and six off-diagonal ones) may be substantially different from each other. Moreover, due to a high symmetry of the problem, there are a lot of zeros even among these elements. Indeed, let us have a look at the angular components Y_l^m of the corresponding wavefunctions, with $l = 0$ and $l = 1$, described by Eqs. (3.174)-(3.175). For the states with $m = \pm 1$, the azimuthal parts of wavefunctions are proportional to $\exp\{\pm i\varphi\}$; hence the off-diagonal elements H_{34} and H_{43} of the matrix (30), relating these functions, are proportional to

$$\oint d\Omega Y_1^\pm * \hat{H}^{(1)} Y_1^\mp \propto \int_0^{2\pi} d\varphi \left(e^{\pm i\varphi} \right)^* \left(e^{\mp i\varphi} \right) = 0. \quad (6.31)$$

The azimuthal-angle symmetry also kills the off-diagonal elements $H_{13}, H_{14}, H_{23}, H_{24}$ (and hence their complex conjugates H_{31}, H_{41}, H_{32} , and H_{42}), because they relate states with $m = 0$ and $m = \pm 1$, and hence are proportional to

$$\oint d\Omega Y_1^0 * \hat{H}^{(1)} Y_1^{\pm 1} \propto \int_0^{2\pi} d\varphi e^{\pm i\varphi} = 0. \quad (6.32)$$

For the diagonal matrix elements H_{33} and H_{44} , corresponding to $l = 1$ and $m = \pm 1$, the azimuthal-angle integrals do not vanish, but since the corresponding spherical harmonics depend on the polar angle as $\sin\theta$, these elements are proportional to

$$\oint d\Omega Y_1^{\pm 1} * \hat{H}^{(1)} Y_1^{\pm 1} \propto \int_0^\pi \sin\theta d\theta \sin\theta \cos\theta \sin\theta = \int_{-1}^{+1} \cos\theta (1 - \cos^2\theta) d(\cos\theta), \quad (6.33)$$

and hence are equal to zero – as any limit-symmetric integral of an odd function. Finally, for the states $2s$ and $2p$ with $m = 0$, the diagonal elements H_{11} and H_{22} are also killed by the polar-angle integration:

$$\oint d\Omega Y_0^0 * \hat{H}^{(1)} Y_0^0 \propto \int_0^\pi \sin\theta d\theta \cos\theta = \int_{-1}^1 \cos\theta d(\cos\theta) = 0, \quad (6.34)$$

$$\oint d\Omega Y_0^1 * \hat{H}^{(1)} Y_0^1 \propto \int_0^\pi \sin\theta d\theta \cos^3\theta = \int_{-1}^{+1} \cos^3\theta d(\cos\theta) = 0. \quad (6.35)$$

Hence, the only non-zero elements of the matrix (30) are two off-diagonal elements H_{12} and H_{21} , which relate two states with the same $m = 0$, but different $l = \{0, 1\}$, because they are proportional to

$$\oint d\Omega Y_0^0 * \cos\theta Y_1^0 = \frac{\sqrt{3}}{4\pi} \int_0^{2\pi} d\varphi \int_0^\pi \sin\theta d\theta \cos^2\theta = \frac{1}{\sqrt{3}} \neq 0. \quad (6.36)$$

What remains is to use Eqs. (3.209) for the radial parts of these functions to complete the calculation of those two matrix elements:

$$H_{12} = H_{21} = -\frac{q\mathcal{E}}{\sqrt{3}} \int_0^\infty r^2 dr \mathcal{R}_{2,0}(r) r \mathcal{R}_{2,1}(r). \quad (6.37)$$

Due to the additive structure of the function $\mathcal{R}_{2,0}(r)$, the integral falls into a sum of two table integrals, both of the type MA Eq. (6.7d), finally giving

$$H_{12} = H_{21} = 3q\mathcal{E}r_0, \quad (6.38)$$

where r_0 is the spatial scale (3.192); for the hydrogen atom, it is just the Bohr radius r_B – see Eq. (1.10).

Thus, the perturbation matrix (30) is reduced to

$$H^{(1)} = \begin{pmatrix} 0 & 3q\epsilon r_0 & 0 & 0 \\ 3q\epsilon r_0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad (6.39)$$

so that the condition (26) of self-consistency of the system (25),

$$\begin{vmatrix} -E_2^{(1)} & 3q\epsilon r_0 & 0 & 0 \\ 3q\epsilon r_0 & -E_2^{(1)} & 0 & 0 \\ 0 & 0 & -E_2^{(1)} & 0 \\ 0 & 0 & 0 & -E_2^{(1)} \end{vmatrix} = 0, \quad (6.40)$$

gives a very simple characteristic equation

$$(E_2^{(1)})^2 [(E_2^{(1)})^2 - (3q\epsilon r_0)^2] = 0. \quad (6.41)$$

with four roots:

$$(E_2^{(1)})_{1,2} = 0, \quad (E_2^{(1)})_{3,4} = \pm 3q\epsilon r_0. \quad (6.42)$$

Linear Stark effect for $n = 2$

so that the degeneracy is only partly lifted – see the levels in Fig. 3.⁷

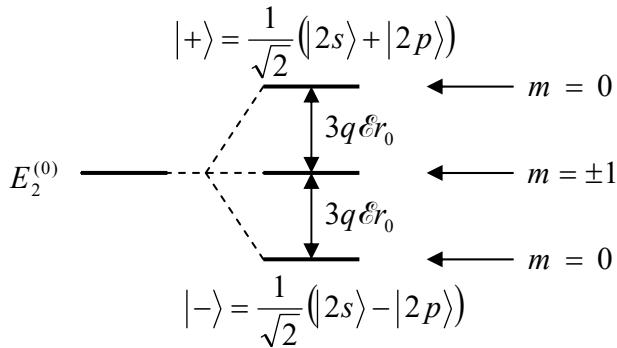

Fig. 6.3. The linear Stark effect for the level $n = 2$ of a hydrogen-like atom.

Generally, in order to understand the nature of states corresponding to these levels, we should return to Eq. (25) with each calculated value of $E_2^{(1)}$, and find the corresponding expansion coefficients $\langle n''|n' \rangle$ that describe the perturbed states. However, in our simple case, the outcome of this procedure is clear in advance. Indeed, since the states with $\{l = 1, m = \pm 1\}$ are not affected by the perturbation at all (in the linear approximation in the electric field), their degeneracy is not lifted, and energy is not affected – see the middle line in Fig. 3. On the other hand, the partial perturbation matrix connecting the states $2s$ and $2p$, i.e. the top left 2×2 part of the full matrix (39), is proportional to the Pauli matrix σ_x , and we already know the result of its diagonalization – see Eqs. (4.113)-(4.114). This means that the

⁷ The proportionality of this splitting to the small field is responsible for the qualifier “linear” in the name of this effect. If observable effects grow only as ϵ^2 (see, e.g., Problem 9), the term *quadratic Stark effect* is used instead.

upper and lower split levels correspond to very simple linear combinations of the previously degenerate states with $m = 0$,

$$|\pm\rangle = \frac{1}{\sqrt{2}}(|2s\rangle \pm |2p\rangle). \quad (6.43)$$

Finally, let us estimate the magnitude of the linear Stark effect for a hydrogen atom. For a very high electric field of $\mathcal{E} = 3 \times 10^6 \text{ V/m}$,⁸ $|q| = e \approx 1.6 \times 10^{-19} \text{ C}$, and $r_0 = r_B \approx 0.5 \times 10^{-10} \text{ m}$, we get a level splitting of $3q\mathcal{E}r_0 \approx 0.8 \times 10^{-22} \text{ J} \approx 0.5 \text{ meV}$. This number is much lower than the unperturbed energy of the level, $E_2 = -E_H/(2 \times 2^2) \approx -3.4 \text{ eV}$, so that the perturbative result is quite applicable. On the other hand, the calculated splitting is much larger than the resolution limit imposed by the line's natural width ($\sim 10^{-7} E_2$, see Chapter 9), so that the effect is quite observable even in substantially lower electric fields. Note, however, that our simple results are quantitatively correct only when the Stark splitting (42) is much larger than the fine-structure splitting of the same level in the absence of the field— see the next section.

6.3. Fine structure of atomic levels

Now let us use the same perturbation theory to analyze, also for the simplest case of a hydrogen-like atom/ion, the so-called *fine structure* of atomic levels – their degeneracy lifting even in the absence of external fields. Since the effective speed v of the electron motion in atoms is much smaller than the speed of light c , the fine structure may be analyzed as a sum of two independent relativistic effects. To analyze the first of them, let us expand the well-known classical relativistic expression⁹ for the kinetic energy $T = E - mc^2$ of a free particle with the rest mass m ,¹⁰

$$T = (m^2 c^4 + p^2 c^2)^{1/2} - mc^2 \equiv mc^2 \left[\left(1 + \frac{p^2}{m^2 c^2} \right)^{1/2} - 1 \right], \quad (6.44)$$

into the Taylor series with respect to the small ratio $(p/mc)^2 \approx (v/c)^2$:

$$T = mc^2 \left[1 + \frac{1}{2} \left(\frac{p}{mc} \right)^2 - \frac{1}{8} \left(\frac{p}{mc} \right)^4 + \dots - 1 \right] \equiv \frac{p^2}{2m} - \frac{p^4}{8m^3 c^2} + \dots, \quad (6.45)$$

and drop all the terms besides the two spelled-out terms. Of them, the first term is non-relativistic, while the second one represents the first relativistic correction to T .

Following the correspondence principle, the quantum-mechanical problem in this approximation may be described by the perturbative Hamiltonian (1), whose unperturbed part (whose eigenstates and eigenenergies were discussed in Sec. 3.5) is

$$\hat{H}^{(0)} = \frac{\hat{p}^2}{2m} + \hat{U}(r), \quad \hat{U}(r) = -\frac{C}{r}, \quad (6.46)$$

while the kinetic-relativistic perturbation

⁸ This value approximately corresponds to the threshold of electric breakdown in air at ambient conditions, due to the impact ionization. As a result, experiments with higher dc fields are rather difficult.

⁹ See, e.g., EM Eq. (9.78) – or any undergraduate text on special relativity.

¹⁰ This fancy font is used, as in Secs. 3.5-3.8, to distinguish the mass m from the magnetic quantum number m .

$$\hat{H}^{(1)} = -\frac{\hat{p}^4}{8m^3c^2} \equiv -\frac{1}{2mc^2} \left(\frac{\hat{p}^2}{2m} \right)^2. \quad (6.47)$$

Kinetic-relativistic perturbation

Using Eq. (46), we may rewrite the last formula as

$$\hat{H}^{(1)} = -\frac{1}{2mc^2} (\hat{H}^{(0)} - \hat{U}(r))^2, \quad (6.48)$$

so that its matrix elements participating in the characteristic equation (25) for a given degenerate energy level (3.201), i.e. a given principal quantum number n , are

$$\langle nlm | \hat{H}^{(1)} | nl'm' \rangle = -\frac{1}{2mc^2} \langle nlm | (\hat{H}^{(0)} - \hat{U}(r)) (\hat{H}^{(0)} - \hat{U}(r)) | nl'm' \rangle, \quad (6.49)$$

where the bra- and ket-vectors describe the unperturbed eigenstates, whose eigenfunctions (in the coordinate representation) are given by Eq. (3.200): $\psi_{n,l,m} = \mathcal{R}_{n,l}(r)Y_l^m(\theta, \phi)$.

It is straightforward (and hence left for the reader :-) to prove that all off-diagonal elements of the set (49) are equal to 0. Thus we may use Eq. (27) for each set of the quantum numbers $\{n, l, m\}$:

$$\begin{aligned} E_{n,l,m}^{(1)} &\equiv E_{n,l,m} - E_n^{(0)} = \langle nlm | \hat{H}^{(1)} | nlm \rangle = -\frac{1}{2mc^2} \left\langle (\hat{H}^{(0)} - \hat{U}(r))^2 \right\rangle_{n,l,m} \\ &= -\frac{1}{2mc^2} \left(E_n^2 - 2E_n \langle \hat{U} \rangle_{n,l} + \langle \hat{U}^2 \rangle_{n,l} \right) = -\frac{1}{2mc^2} \left(\frac{E_0^2}{4n^4} - \frac{E_0}{n^2} C \left\langle \frac{1}{r} \right\rangle_{n,l} + C^2 \left\langle \frac{1}{r^2} \right\rangle_{n,l} \right), \end{aligned} \quad (6.50)$$

where the index m has been dropped, because the radial wavefunctions $\mathcal{R}_{n,l}(r)$, which affect these expectation values, do not depend on that quantum number. Now using Eqs. (3.191), (3.201) and the first two of Eqs. (3.211), we finally get

$$E_{n,l}^{(1)} = -\frac{mc^2}{2\hbar^2 c^2 n^4} \left(\frac{n}{l + \frac{1}{2}} - \frac{3}{4} \right) \equiv -\frac{2E_n^2}{mc^2} \left(\frac{n}{l + \frac{1}{2}} - \frac{3}{4} \right). \quad (6.51)$$

Kinetic-relativistic energy correction

Let us discuss this result. First of all, its last form confirms that the correction (51) is indeed much smaller than the unperturbed energy E_n (and hence the perturbation theory is valid) if the latter is much smaller than the relativistic rest energy mc^2 of the particle – as it is for the hydrogen atom. Next, since in the Bohr problem’s solution $n \geq l + 1$, the first fraction in the parentheses of Eq. (51) is always larger than 1, and hence than 3/4, so that the kinetic relativistic correction to energy is negative for all n and l . (Actually, this fact could be predicted already from Eq. (47), which shows that the perturbation’s Hamiltonian is a negatively defined form.) Finally, for a fixed principal number n , the negative correction’s magnitude decreases with the growth of l . This fact may be interpreted using the second of Eqs. (3.211): the larger is l (at fixed n), the larger is the particle’s effective distance from the center, and hence the smaller is its effective velocity, i.e. the smaller is the magnitude of the quantum-mechanical average of the negative relativistic correction (47) to the kinetic energy.

The result (51) is valid for the Coulomb interaction $U(r) = -C/r$ of any physical nature. However, if we speak specifically about hydrogen-like atoms/ions, there is also another relativistic correction to energy, due to the so-called *spin-orbit interaction* (alternatively called the “spin-orbit coupling”). Its physics may be understood from the following semi-quantitative classical reasoning: from the “the point of view” of an electron rotating about the nucleus at distance r with velocity v , it is the nucleus, of the

electric charge Ze , that rotates about the electron with the velocity $(-\mathbf{v})$ and hence the time period $\mathcal{T} = 2\pi r/v$. From the point of view of magnetostatics, such circular motion of the electric charge $Q = Ze$, is equivalent to a circular dc electric current $I = Q/\mathcal{T} = (Ze)(v/2\pi r)$, which creates, at the electron's location, i.e. in the center of the current loop, the magnetic field with the following magnitude:¹¹

$$\mathcal{B}_a = \frac{\mu_0}{2r} I = \frac{\mu_0}{2r} \frac{Zev}{2\pi r} \equiv \frac{\mu_0 Zev}{4\pi r^2}. \quad (6.52)$$

The field's direction \mathbf{n} is perpendicular to the apparent plane of the nucleus' rotation (i.e. that of the real rotation of the electron), and hence its vector may be readily expressed via the similarly directed vector $\mathbf{L} = m_e v r n$ of the electron's angular (orbital) momentum:

$$\mathcal{B}_a = \frac{\mu_0 Zev}{4\pi r^2} \mathbf{n} \equiv \frac{\mu_0 Ze}{4\pi r^3 m_e} m_e v r n \equiv \frac{\mu_0 Ze}{4\pi r^3 m_e} \mathbf{L} \equiv \frac{Ze}{4\pi \epsilon_0 r^3 m_e c^2} \mathbf{L}, \quad (6.53)$$

where the last step used the basic relation between the SI-unit constants: $\mu_0 \equiv 1/c^2 \epsilon_0$.

A more careful (but still classical) analysis of the problem¹² brings both good and bad news. The bad news is that the result (53) is wrong by the so-called *Thomas factor* of two even for the circular motion, because the electron moves with acceleration, and the reference frame bound to it cannot be inertial (as was implied in the above reasoning), so that the effective magnetic field felt by the electron is actually

$$\mathcal{B} = \frac{Ze}{8\pi \epsilon_0 r^3 m_e c^2} \mathbf{L}. \quad (6.54)$$

The good news is that this result is valid not only for circular but an arbitrary orbital motion in the Coulomb field $U(r)$. Hence from the discussion in Sec. 4.1 and Sec. 4.4 we may expect that the quantum-mechanical description of the interaction between this effective magnetic field and the electron's spin moment (4.115) is given by the following perturbation Hamiltonian¹³

$$\hat{H}^{(1)} = -\hat{\mathbf{m}} \cdot \hat{\mathcal{B}} = -\gamma_e \hat{\mathbf{S}} \cdot \left(\frac{Ze}{8\pi \epsilon_0 r^3 m_e c^2} \hat{\mathbf{L}} \right) \equiv \frac{1}{2m_e^2 c^2} \frac{Ze^2}{4\pi \epsilon_0} \frac{1}{r^3} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}}, \quad (6.55)$$

where at spelling out the electron's gyromagnetic ratio $\gamma_e \equiv -g_e e/2m_e$, the small correction to the value $g_e = 2$ of the electron's *g*-factor (see Sec. 4.4) is ignored, because Eq. (55) is already a small correction. This expectation is confirmed by the fully-relativistic Dirac theory, to be discussed in Sec. 9.7 below: it yields, for an arbitrary central potential $U(r)$, the following spin-orbit coupling Hamiltonian:

$$\hat{H}^{(1)} = \frac{1}{2m_e^2 c^2} \frac{1}{r} \frac{dU(r)}{dr} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}}. \quad (6.56)$$

For the Coulomb potential $U(r) = -Ze^2/4\pi \epsilon_0 r$, this formula is reduced to Eq. (55).

¹¹ See, e.g., EM Sec. 5.1, in particular, Eq. (5.24). Note that such effective magnetic field is induced by any motion of electrons, in particular that in solids, leading to a variety of spin-orbit effects there – see, e.g., a concise review by R. Winkler *et al.*, in B. Kramer (ed.), *Advances in Solid State Physics* **41**, 211 (2001).

¹² It was carried out first by Llewellyn Thomas in 1926; for a simple review see, e.g., R. Harr and L. Curtis, *Am. J. Phys.* **55**, 1044 (1987).

¹³ In the Gaussian units, Eq. (55) is valid without the factor $4\pi \epsilon_0$ in the denominator; while Eq. (56), “as is”.

As we already know from the discussion in Sec. 5.7, the angular factor of this Hamiltonian commutes with all the operators of the coupled-representation group (inside the blue line in Fig. 5.12): \hat{L}^2 , \hat{S}^2 , \hat{J}^2 , and \hat{J}_z , and hence is diagonal in the coupled-representation basis with definite quantum numbers l , j , and m_j (and of course $s = \frac{1}{2}$). Hence, using Eq. (5.181) to rewrite Eq. (56) as

$$\hat{H}^{(1)} = \frac{1}{2m_e^2 c^2} \frac{Ze^2}{4\pi\epsilon_0} \frac{1}{r^3} \frac{1}{2} (\hat{J}^2 - \hat{L}^2 - \hat{S}^2), \quad (6.57)$$

we may again use Eq. (27) for each set $\{s, l, j, m_j\}$, with common n :

$$E_{n,j,l}^{(1)} = \frac{1}{2m_e^2 c^2} \frac{Ze^2}{4\pi\epsilon_0} \left\langle \frac{1}{r^3} \right\rangle_{n,l} \frac{1}{2} \langle \hat{J}^2 - \hat{L}^2 - \hat{S}^2 \rangle_{j,s}, \quad (6.58)$$

where the indices irrelevant for each particular factor have been dropped. Now using the last of Eqs. (3.211), and similar expressions (5.169), (5.175), and (5.177) for eigenvalues of the involved operators, we get an explicit expression for the spin-orbit corrections¹⁴

$$E_{n,j,l}^{(1)} = \frac{1}{2m_e^2 c^2} \frac{Ze^2}{4\pi\epsilon_0} \frac{\hbar^2}{2r_0^3} \frac{j(j+1) - l(l+1) - \frac{3}{4}}{n^3 l(l+\frac{1}{2})(l+1)} \equiv \frac{E_n^2}{m_e c^2} n \frac{j(j+1) - l(l+1) - \frac{3}{4}}{l(l+\frac{1}{2})(l+1)}, \quad (6.59)$$

Spin-orbit energy correction

with l and j related by Eq. (5.189): $j = l \pm \frac{1}{2}$.

The last form of its result shows clearly that this correction has the same scale as the kinetic correction (51).¹⁵ In the 1st order of the perturbation theory, they may be just added (with $m = m_e$), giving a surprisingly simple formula for the net fine structure of the n^{th} energy level:

$$E_{\text{fine}}^{(1)} = \frac{E_n^2}{2m_e c^2} \left(3 - \frac{4n}{j + \frac{1}{2}} \right). \quad (6.60)$$

Fine structure of atomic levels

This simplicity, as well as the independence of the result of the orbital quantum number l , will become less surprising when (in Sec. 9.7) we see that this formula follows in one shot from the Dirac theory, in which the Bohr atom's energy spectrum is numbered only with n and j , but not l . Let us recall that for an electron ($s = \frac{1}{2}$), according to Eq. (5.189) with $0 \leq l \leq n-1$, the quantum number j may take n positive half-integer values, from $\frac{1}{2}$ to $n - \frac{1}{2}$. Hence, Eq. (60) shows that the fine structure of the n^{th} Bohr's energy level has n sub-levels – see Fig. 4.

Please note that according to Eq. (5.175), each of these sub-levels is still $(2j + 1)$ -times degenerate in the quantum number m_j . This degeneracy is very natural, because in the absence of an external field the system is still isotropic. Moreover, on each fine-structure level (besides the highest one with $j = n - \frac{1}{2}$), each of the m_j -states is doubly-degenerate in the orbital quantum number $l = j \mp \frac{1}{2}$ – see the labels of l in Fig. 4. (According to Eq. (5.190), each of these states, with fixed j and m_j , may be

¹⁴ The factor l in the denominator does not give a divergence at $l = 0$, because in this case $j = s = \frac{1}{2}$, so that $j(j+1) = \frac{3}{4}$, and the numerator turns into 0 as well. A careful analysis of this case (which may be found, e.g., in G. Woolgate, *Elementary Atomic Structure*, 2nd ed., Oxford, 1983), as well as the exact analysis of the hydrogen atom using the Dirac theory (see Sec. 9.7), show that Eq. (60), which does not include l , is valid even in this case.

¹⁵ This is natural, because the magnetic interaction of charged particles is essentially a relativistic effect, of the same order ($\sim v^2/c^2$) as the kinetic correction (47) – see, e.g., EM Sec. 5.1, in particular Eq. (5.3).

represented as a linear combination of two states with adjacent values of l , and hence different electron spin orientations, $m_s = \pm \frac{1}{2}$, weighed with the Clebsch-Gordan coefficients.)

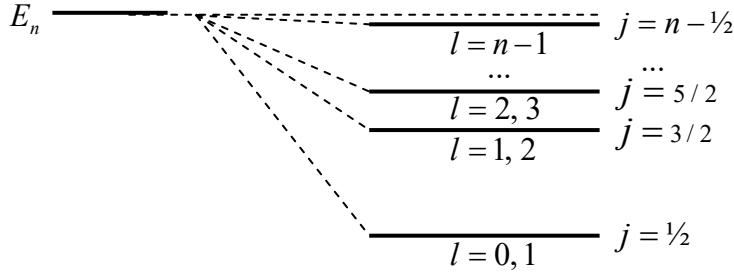

Fig. 6.4. The fine structure of a hydrogen-like atom's level.

These details aside, one may crudely say that the relativistic corrections combined make the total eigenenergy grow with l , contributing to the effect already mentioned at our analysis of the periodic table of elements in Sec. 3.7. The relative scale of this increase may be scaled by the largest deviation from the unperturbed energy E_n , reached for s -states (with $l = 0, j = \frac{1}{2}$):

$$\left| \frac{E_{\max}^{(1)}}{E_n} \right| = \frac{E_n}{m_e c^2} \left(2n - \frac{3}{2} \right) \equiv \left(\frac{Ze^2}{4\pi\epsilon_0 \hbar c} \right)^2 \left(\frac{1}{n} - \frac{3}{4n^2} \right) \equiv Z^2 \alpha^2 \left(\frac{1}{n} - \frac{3}{4n^2} \right). \quad (6.61)$$

where α is the *fine-structure* (“Sommerfeld’s”) *constant*,

$$\alpha \equiv \frac{e^2}{4\pi\epsilon_0 \hbar c} \approx \frac{1}{137}, \quad (6.62)$$

(already mentioned in Sec. 4.4), which characterizes the relative strength (or rather weakness :-)) of the electromagnetic effects in quantum mechanics – which in particular makes the perturbative quantum electrodynamics possible.¹⁶ These expressions show that the fine-structure splitting is a very small effect ($\sim \alpha^2 \sim 10^{-6}$) for the hydrogen atom, but it rapidly grows (as Z^2) with the nuclear charge (i.e. the atomic number) Z , and becomes rather substantial for the heaviest stable atoms with $Z \sim 10^2$.

6.4. The Zeeman effect

Now, we are ready to review the *Zeeman effect* – the atomic level splitting by an external magnetic field.¹⁷ Using Eq. (3.26), with $q = -e$, for the description of the electron’s orbital motion in the field, and the Pauli Hamiltonian (4.163), with $\gamma = -e/m_e$, for the electron spin’s interaction with the field, we see that even for a hydrogen-like (i.e. single-electron) atom/ion, neglecting the relativistic effects, the full Hamiltonian is rather involved:

$$\hat{H} = \frac{1}{2m_e} (\hat{\mathbf{p}} + e\hat{\mathbf{A}})^2 - \frac{Ze^2}{4\pi\epsilon_0 r} + \frac{e}{m_e} \mathcal{B} \cdot \hat{\mathbf{S}}. \quad (6.63)$$

¹⁶ The expression $\alpha^2 = E_H/m_e c^2$, where E_H is the Hartree energy (1.13), i.e. the scale of energies E_n , is also very revealing.

¹⁷ It was discovered experimentally in 1896 by Pieter Zeeman who, amazingly, was fired from the University of Leiden for unauthorized use of lab equipment for this work – just to receive a Nobel Prize for it in a few years!

There are several simplifications we may make. First, let us assume that the external field is spatial-uniform on the atomic scale (which is a very good approximation for most cases), so that we can take its vector potential in an axially-symmetric gauge – cf. Eq. (3.132):

$$\mathbf{A} = \frac{1}{2} \mathcal{B} \times \mathbf{r}. \quad (6.64)$$

Second, let us neglect the terms proportional to \mathcal{B}^2 , which are small in practical magnetic fields of the order of a few teslas.¹⁸ The remaining term in the effective kinetic energy, describing the interaction with the magnetic field, is linear in the momentum operator, so that we may repeat the standard classical calculation¹⁹ to reduce it to the product of \mathcal{B} by the orbital magnetic moment's component $m_z = -eL_z/2m_e$ – besides that both m_z and L_z should be understood as operators now. As a result, the Hamiltonian (63) reduces to Eq. (1), $\hat{H}^{(0)} + \hat{H}^{(1)}$, where $\hat{H}^{(0)}$ is that of the atom at $\mathcal{B} = 0$, and

$$\hat{H}^{(1)} = \frac{e\mathcal{B}}{2m_e} (\hat{L}_z + 2\hat{S}_z). \quad (6.65)$$

Zeeman effect's perturbation

This expression immediately reveals the major complication with the Zeeman effect's analysis. Namely, in comparison with the equal orbital and spin contributions to the total angular momentum (5.170) of the electron, its spin produces a twice larger contribution to the magnetic moment, so that the right-hand side of Eq. (65) is *not* proportional to the total angular moment \mathbf{J} . As a result, the effect's description is simple only in two limits.

If the magnetic field is so *high* that its effects are much stronger than the relativistic (fine-structure) effects discussed in the previous section, we may treat the two terms in Eq. (65) as independent perturbations of different (orbital and spin) degrees of freedom. Since each of the perturbation matrices is diagonal in its own z -basis, we can again use Eq. (27) to write

$$E - E^{(0)} = \frac{e\mathcal{B}}{2m_e} (\langle n, l, m_l | \hat{L}_z | n, l, m_l \rangle + 2\langle m_s | \hat{S}_z | m_s \rangle) = \frac{e\mathcal{B}}{2m_e} (\hbar m_l + 2\hbar m_s) = \mu_B \mathcal{B} (m_l \pm 1). \quad (6.66)$$

Paschen-Back effect

This result describes splitting of each $2 \times (2l + 1)$ -degenerate energy level, with certain n and l , into $(2l + 3)$ levels (Fig. 5), with the adjacent level distance of $\mu_B \mathcal{B}$, of the order of 10^{-4} eV per tesla.

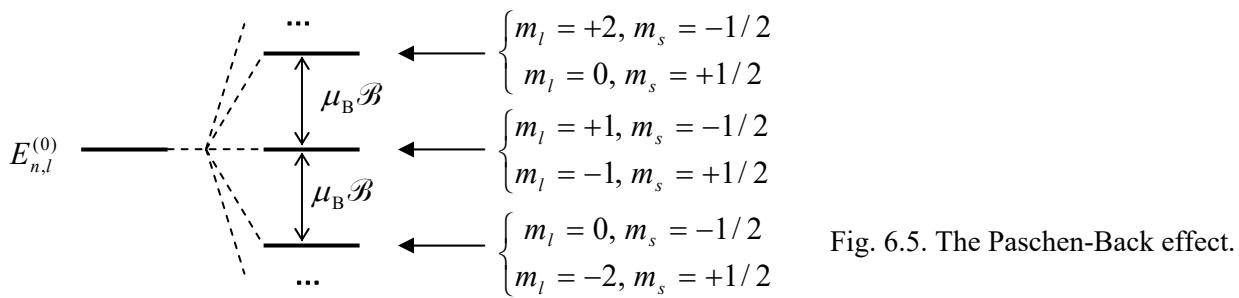

Fig. 6.5. The Paschen-Back effect.

¹⁸ Despite its smallness, the quadratic term is necessary for a description of the negative contribution of the orbital motion to the magnetic susceptibility χ_m (the so-called *orbital diamagnetism*, see EM Sec. 5.5), whose analysis, using Eq. (63), is left for the reader's exercise.

¹⁹ See, e.g., EM Sec. 5.4, in particular Eqs. (5.95) and (5.100).

Note that all the levels, these besides the top and bottom ones, remain doubly degenerate. This limit of the Zeeman effect is sometimes called the *Paschen-Back effect* – whose simplicity was recognized only in the 1920s, due to the need in very high magnetic fields for its observation.

In the opposite limit of relatively *low* magnetic fields, the Zeeman effect takes place on the background of the much larger fine-structure splitting. As was discussed in Sec. 3, at $\mathcal{B} = 0$ each split sub-level has a $2 \times (2j + 1)$ -fold degeneracy corresponding to $(2j + 1)$ different values of the half-integer quantum number m_j , ranging from $-j$ to $+j$, and two values of the integer $l = j \mp \frac{1}{2}$ – see Fig. 4.²⁰ The magnetic field lifts this degeneracy. Indeed, in the coupled representation discussed in Sec. 5.7, the perturbation (65) is described by the matrix with elements

$$\begin{aligned} H^{(1)} &= \frac{e\mathcal{B}}{2m_e} \langle j, m_j | \hat{L}_z + 2\hat{S}_z | j', m_{j'} \rangle \equiv \frac{e\mathcal{B}}{2m_e} \langle j, m_j | \hat{J}_z + \hat{S}_z | j', m_{j'} \rangle \\ &= \frac{e\mathcal{B}}{2m_e} \left(\hbar m_j \delta_{m_j m_{j'}} + \langle j, m_j | \hat{S}_z | j', m_{j'} \rangle \right). \end{aligned} \quad (6.67)$$

To spell out the second term, let us use the general expansion (5.183) for the particular case $s = \frac{1}{2}$, when (as was discussed in the end of Sec. 5.7) it has at most two non-vanishing terms, with the Clebsch-Gordan coefficients (5.190):

$$\begin{aligned} &|j = l \pm \frac{1}{2}, m_j\rangle \\ &= \pm \left(\frac{l \pm m_j + \frac{1}{2}}{2l+1} \right)^{1/2} |m_l = m_j - \frac{1}{2}, m_s = +\frac{1}{2}\rangle + \left(\frac{l \mp m_j + \frac{1}{2}}{2l+1} \right)^{1/2} |m_l = m_j + \frac{1}{2}, m_s = -\frac{1}{2}\rangle. \end{aligned} \quad (6.68)$$

Taking into account that the operator \hat{S}_z gives non-zero brackets only for $m_s = m_{s'}$, the 2×2 matrix of elements $\langle m_l = m_j \pm \frac{1}{2}, m_s = \mp \frac{1}{2} | \hat{S}_z | m_l = m_j \pm \frac{1}{2}, m_s = \mp \frac{1}{2} \rangle$ is diagonal, so we may use Eq. (27) to get

$$\begin{aligned} E - E^{(0)} &= \frac{e\mathcal{B}}{2m_e} \left[\hbar m_j + \frac{\hbar (l \pm m_j + \frac{1}{2})}{2l+1} - \frac{\hbar (l \mp m_j + \frac{1}{2})}{2l+1} \right] \\ &\equiv \frac{e\mathcal{B}}{2m_e} \hbar m_j \left(1 \pm \frac{1}{2l+1} \right) \equiv \mu_B \mathcal{B} m_j \left(1 \pm \frac{1}{2l+1} \right), \quad \text{for } -j \leq m_j \leq +j, \end{aligned} \quad (6.69)$$

Anomalous
Zeeman
effect
for $s = 1/2$

where the two signs correspond to the two possible values of $l = j \mp \frac{1}{2}$ – see Fig. 6.

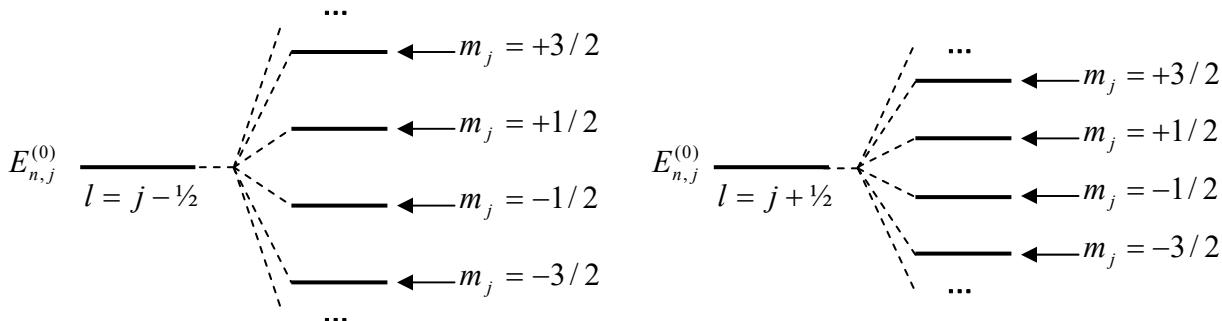

Fig. 6.6. The anomalous Zeeman effect in a hydrogen-like atom/ion.

²⁰ In the almost-hydrogen-like, but more complex atoms (such as those of alkali metals), the degeneracy in l may be lifted by electron-electron Coulomb interaction even in the absence of external magnetic field.

We see that the magnetic field splits each sub-level of the fine structure, with a given l , into $2j + 1$ equidistant levels, with the distance between the levels depending on l . In the late 1890s, when the Zeeman effect was first observed, there was no notion of spin at all, so that this puzzling result was called the *anomalous Zeeman effect*. (In this terminology, the *normal Zeeman effect* is the one with no spin splitting, i.e. without the second terms in the parentheses of Eqs. (66), (67), and (69); it was first observed in 1898 by Preston Thomas in atoms with zero net spin.)

The strict quantum-mechanical analysis of the anomalous Zeeman effect for arbitrary s (which is important for applications to multi-electron atoms) is conceptually not complex, but requires explicit expressions for the corresponding Clebsch-Gordan coefficients, which are rather bulky. Let me just cite the unexpectedly simple result of this analysis:

$$\Delta E = \mu_B \mathcal{B} m_j g, \quad (6.70a)$$

where g is the so-called *Lande factor*:²¹

$$g = 1 + \frac{j(j+1) + s(s+1) - l(l+1)}{2j(j+1)}. \quad (6.70b)$$

Anomalous
Zeeman
effect
for arbitrary s

For $s = \frac{1}{2}$ (and hence $j = l \pm \frac{1}{2}$), this factor is reduced to the parentheses in the last forms of Eq. (69).

It is remarkable that Eqs. (70) may be readily derived using very plausible classical arguments, similar to those used in Sec. 5.7 – see Fig. 5.13 and its discussion. As was discussed in Sec. 5.6, in the absence of spin, the quantization of the observable L_z is an extension of the classical picture of the torque-induced precession of the vector \mathbf{L} about the magnetic field's direction, so that the interaction energy, proportional to $\mathcal{B}L_z = \mathcal{B} \cdot \mathbf{L}$, remains constant – see Fig. 7a. On the other hand, at the spin-orbit interaction without an external magnetic field, the Hamiltonian function of the system includes the product $\mathbf{S} \cdot \mathbf{L}$, so that in the stationary state it has to be constant, together with J^2 , L^2 , and S^2 . Hence, this system's classical image is a joint precession of the vectors \mathbf{S} and \mathbf{L} about the direction of the vector $\mathbf{J} = \mathbf{L} + \mathbf{S}$, in such a manner that the spin-orbit interaction energy, proportional to the product $\mathbf{L} \cdot \mathbf{S}$, remains constant (Fig. 7b). On this backdrop, the anomalous Zeeman effect in a relatively weak magnetic field $\mathcal{B} = \mathcal{B}n_z$ corresponds to a much slower precession of the vector \mathbf{J} about the z -axis, “dragging” with it the vectors \mathbf{L} and \mathbf{S} , rapidly rotating around it.

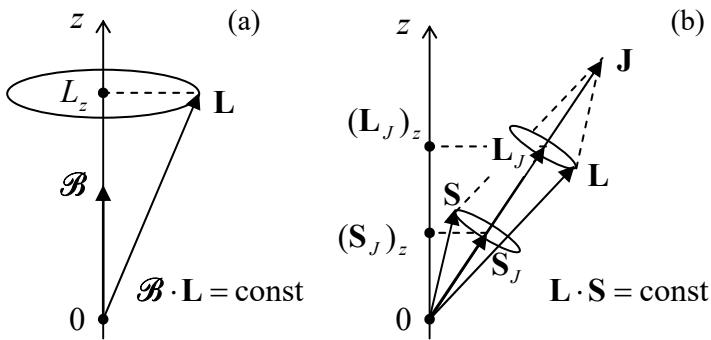

Fig. 6.7. Classical images of (a) the orbital angular momentum's quantization in a magnetic field, and (b) the fine-structure level splitting.

²¹ This formula is frequently used with capital letters J , S , and L , which denote the quantum numbers of the atom as a whole.

This physical picture allows us to conjecture that what is important for the slow precession rate are only the vectors \mathbf{L} and \mathbf{S} averaged over the period of their much faster precession around vector \mathbf{J} – in other words, only their components \mathbf{L}_J and \mathbf{S}_J along the vector \mathbf{J} . Classically, these components may be calculated as

$$\mathbf{L}_J = \frac{\mathbf{L} \cdot \mathbf{J}}{J^2} \mathbf{J}, \quad \text{and} \quad \mathbf{S}_J = \frac{\mathbf{S} \cdot \mathbf{J}}{J^2} \mathbf{J}. \quad (6.71)$$

The scalar products participating in these expressions may be readily expressed via the squared lengths of the vectors, using the following geometric formulas:

$$S^2 = (\mathbf{J} - \mathbf{L})^2 \equiv J^2 + L^2 - 2\mathbf{L} \cdot \mathbf{J}, \quad L^2 = (\mathbf{J} - \mathbf{S})^2 \equiv J^2 + S^2 - 2\mathbf{J} \cdot \mathbf{S}. \quad (6.72)$$

As a result, we get the following time average:

$$\begin{aligned} \overline{L_z + 2S_z} &= (\mathbf{L}_J + 2\mathbf{S}_J)_z = \left(\frac{\mathbf{L} \cdot \mathbf{J}}{J^2} \mathbf{J} + 2 \frac{\mathbf{S} \cdot \mathbf{J}}{J^2} \mathbf{J} \right)_z = \frac{J_z}{J^2} (\mathbf{L} \cdot \mathbf{J} + 2\mathbf{S} \cdot \mathbf{J}) \\ &= J_z \frac{(J^2 + L^2 - S^2) + 2(J^2 + S^2 - L^2)}{2J^2} \equiv J_z \left(1 + \frac{J^2 + S^2 - L^2}{2J^2} \right). \end{aligned} \quad (6.73)$$

The last move is to smuggle in some quantum mechanics by using, instead of the vector lengths squared and the z -component of J_z , their eigenvalues given by Eqs. (5.169), (5.175), and (5.177). As a result, we immediately arrive at the exact Eqs. (70). This coincidence encourages thinking about quantum mechanics of angular momenta in the classical terms of torque-induced precession, which turns out to be very fruitful in some more complex problems of atomic and molecular physics.

The high-field limit and low-field limits of the Zeeman effect, described respectively by Eqs. (66) and (69), are separated by a medium field range, in which the Zeeman splitting is of the order of the fine-structure splitting analyzed in Sec. 3. There is no time in this course for a quantitative analysis of this crossover.²²

6.5. Time-dependent perturbations

Now let us proceed to the case when the perturbation $\hat{H}^{(1)}$ in Eq. (1) is a function of time, while $\hat{H}^{(0)}$ is time-independent. The adequate perturbative approach to this problem, and its results, depend critically on the relation between the characteristic frequency ω of the perturbation and the distance between the initial system's energy levels:

$$\hbar\omega \leftrightarrow |E_n - E_{n'}|. \quad (6.74)$$

In the case when all essential frequencies of a perturbation are very small in the sense of Eq. (74), we are dealing with the so-called *adiabatic* change of parameters, that may be treated essentially as a time-independent perturbation – see the previous sections of this chapter). The most interesting observation here is that the adiabatic perturbation does not allow any significant transfer of system's

²² For a more complete discussion of the Stark, Zeeman, and fine-structure effects in atoms, I can recommend, for example, either the monograph by G. Woolgate cited above, or the one by I. Sobelman, *Theory of Atomic Spectra*, Alpha Science, 2006.

probability from one eigenstate to another. For example, in the WKB limit of the orbital motion, the Bohr quantization rule and its Wilson-Sommerfeld modification (2.110) guarantee that the integral

$$\oint_C \mathbf{p} \cdot d\mathbf{r}, \quad (6.75)$$

taken along the particle's classical trajectory, is an *adiabatic invariant*, i.e. does not change at a slow change of system's parameters. (It is curious that classical mechanics also guarantees the invariance of the integral (75), but its proof there²³ is much harder than the quantum-mechanical derivation of this fact, carried out in Sec. 2.4.) This is why even if the perturbation becomes large with time (while changing sufficiently slowly), we can expect the classification of eigenstates and eigenvalues to persist.

Let us proceed to the harder case when both sides of Eq. (74) are comparable, using for this discussion the Schrödinger picture of quantum dynamics, given by Eq. (4.158). Combining it with Eq. (1), we get the Schrödinger equation in the form

$$i\hbar \frac{\partial}{\partial t} |\alpha(t)\rangle = (\hat{H}^{(0)} + H^{(1)}(t)) |\alpha(t)\rangle. \quad (6.76)$$

Very much in the spirit of our treatment of the time-independent case in Sec. 1, let us represent the time-dependent ket-vector of the system with its expansion,

$$|\alpha(t)\rangle = \sum_n |n\rangle \langle n| \alpha(t)\rangle, \quad (6.77)$$

over the full and orthonormal set of the unperturbed, stationary ket-vectors defined by equation

$$\hat{H}^{(0)} |n\rangle = E_n |n\rangle. \quad (6.78)$$

(Note that these kets $|n\rangle$ are exactly what was called $|n^{(0)}\rangle$ in Sec. 1; we may afford a less bulky notation in this section, because only the lowest orders of the perturbation theory will be discussed.) Plugging the expansion (77), with n replaced with n' , into both sides of Eq. (76), and then inner-multiplying both its sides by the bra-vector $\langle n|$ of another unperturbed (and hence time-independent) state of the system, we get the following set of linear, ordinary differential equations for the expansion coefficients:

$$i\hbar \frac{d}{dt} \langle n| \alpha(t)\rangle = E_n \langle n| \alpha(t)\rangle + \sum_{n'} H_{nn'}^{(1)}(t) \langle n'| \alpha(t)\rangle, \quad (6.79)$$

where the matrix elements of the perturbation, in the *unperturbed* state basis, defined similarly to Eq. (8), are now functions of time:

$$H_{nn'}^{(1)}(t) \equiv \langle n| \hat{H}^{(1)}(t) |n'\rangle. \quad (6.80)$$

The set of differential equations (79), which are still exact, may be useful for numerical calculations.²⁴ However, it has a certain technical inconvenience, which becomes clear if we consider its (evident) solution in the absence of perturbation:²⁵

²³ See, e.g., CM Sec. 10.2.

²⁴ Even if the problem under analysis may be described by the wave-mechanics Schrödinger equation (1.25), a direct numerical integration of that *partial* differential equation is typically less convenient than that of the *ordinary* differential equations (79).

²⁵ This is of course just a more general form of Eq. (1.62) of the wave mechanics of time-independent systems.

$$\langle n | \alpha(t) \rangle = \langle n | \alpha(0) \rangle \exp \left\{ -i \frac{E_n}{\hbar} t \right\}. \quad (6.81)$$

We see that these solutions oscillate very fast, and their numerical modeling may represent a challenge for even the fastest computers. These spurious oscillations (whose frequency, in particular, depends on the energy reference level) may be partly tamed by looking for the general solution of Eqs. (79) in a form inspired by Eq. (81):

$$\langle n | \alpha(t) \rangle \equiv a_n(t) \exp \left\{ -i \frac{E_n}{\hbar} t \right\}. \quad (6.82)$$

Here $a_n(t)$ are new functions of time (essentially, the stationary states' probability amplitudes), which may be used, in particular, to calculate the time-dependent *level occupancies*, i.e. the probabilities W_n to find the perturbed system on the corresponding energy levels of the unperturbed system:

$$W_n(t) = |\langle n | \alpha(t) \rangle|^2 = |a_n(t)|^2. \quad (6.83)$$

Plugging Eq. (82) into Eq. (79), for these functions we readily get a slightly modified system of equations:

$$i\hbar \dot{a}_n = \sum_{n'} a_{n'} H_{nn'}^{(1)}(t) e^{i\omega_{nn'} t}, \quad (6.84)$$

where the factors $\omega_{nn'}$, defined by the relation

$$\hbar \omega_{nn'} \equiv E_n - E_{n'}, \quad (6.85)$$

have the physical sense of frequencies of *potential* quantum transitions between the n^{th} and n'^{th} energy levels of the unperturbed system. (The conditions when such transitions indeed take place will be clear soon.) The advantages of Eq. (84) over Eq. (79), for both analytical and numerical calculations, is their independence of the energy reference, and lower frequencies of oscillations of the right-hand side terms, especially when the energy levels of interest are close to each other.²⁶

In order to continue our analytical treatment, let us focus on a particular but very important problem of a sinusoidal perturbation *turned on* at some moment – which may be taken for $t = 0$:

$$\hat{H}^{(1)}(t) = \begin{cases} 0, & \text{for } t < 0, \\ \hat{A}e^{-i\omega t} + \hat{A}^\dagger e^{+i\omega t}, & \text{for } t \geq 0, \end{cases} \quad (6.86)$$

where the *perturbation amplitude operators* \hat{A} and \hat{A}^\dagger ,²⁷ and hence their matrix elements,

²⁶ Note that the relation of Eq. (84) to the initial Eq. (79) is very close to the relation of the interaction picture of quantum dynamics, discussed at the end of Sec. 4.6, to its Schrödinger picture, with the perturbation Hamiltonian playing the role of the interaction one – compare Eqs. (1) and Eq. (4.206). Indeed, Eq. (84) could be readily obtained from the interaction picture, and I did not do this just to avoid using this heavy bra-ket artillery for our current (relatively) simple problem, and hence to keep its physics more transparent.

²⁷ The notation of the amplitude operators in Eq. (86) is justified by the fact that the perturbation Hamiltonian has to be self-adjoint (Hermitian), and hence each term on the right-hand side of that relation has to be a Hermitian conjugate of its counterpart, which is evidently true only if the amplitude operators are also the Hermitian conjugates of each other. Note, however, that each of these amplitude operators is generally *not* Hermitian.

$$\langle n | \hat{A} | n' \rangle = A_{nn'}, \quad \langle n | \hat{A}^\dagger | n' \rangle = A_{n'n}^*, \quad (6.87)$$

are time-independent after the turn-on moment. In this case, Eq. (84) yields

$$i\hbar \dot{a}_n = \sum_{n'} a_{n'} \left[A_{nn'} e^{i(\omega_{nn'} - \omega)t} + A_{n'n}^* e^{i(\omega_{nn'} + \omega)t} \right], \quad \text{for } t > 0. \quad (6.88)$$

This is, generally, still a nontrivial system of coupled differential equations; however, it allows simple and explicit solutions in two very important limits. First, let us assume that our system initially was definitely in one eigenstate n' (usually, though not necessarily, in the ground state), and that the occupancies W_n of all other levels stay very low all the time. (We will find the condition when the second assumption is valid *a posteriori* – from the solution.) With these assumptions,

$$a_{n'} = 1; \quad |a_n| \ll 1, \quad \text{for } n \neq n', \quad (6.89)$$

Eq. (88) may be readily integrated, giving

$$a_n = -\frac{A_{nn'}}{\hbar(\omega_{nn'} - \omega)} \left[e^{i(\omega_{nn'} - \omega)t} - 1 \right] - \frac{A_{n'n}^*}{\hbar(\omega_{nn'} + \omega)} \left[e^{i(\omega_{nn'} + \omega)t} - 1 \right], \quad \text{for } n \neq n'. \quad (6.90)$$

This expression describes what is colloquially called the *ac excitation of (other) energy levels*. Qualitatively, it shows that the probability W_n (83) of finding the system in each state (“on each energy level”) of the system does not tend to any constant value but rather oscillates in time. It also shows that that the ac-field-induced transfer of the system from one state to the other one has a clearly resonant character: the maximum occupancy W_n of a level number $n \neq n'$ grows infinitely when the corresponding *detuning*²⁸

$$\Delta_{nn'} \equiv \omega - \omega_{nn'}, \quad (6.91)$$

tends to zero. This conclusion is clearly unrealistic, and is an artifact of our initial assumption (89); according to Eq. (90), it is satisfied only if²⁹

$$|A_{nn'}| \ll \hbar |\omega \pm \omega_{nn'}|, \quad (6.92)$$

and hence which does not allow a more deep analysis of the resonant excitation.

In order to overcome this limitation, we may perform the following trick – very similar to the one we used for the transfer to the degenerate case in Sec. 1. Let us assume that for a certain level n ,

$$|\Delta_{nn'}| \ll \omega, |\omega \pm \omega_{n''n}|, |\omega \pm \omega_{n''n'}|, \quad \text{for all } n'' \neq n, n' \quad (6.93)$$

– the condition illustrated in Fig. 8. Then, according to Eq. (90), we may ignore the occupancy of all but two levels, n and n' , and also the second, non-resonant term with frequency $\omega_{nn'} + \omega \approx 2\omega \gg |\Delta_{nn'}|$ in Eqs. (88),³⁰ now written for two probability amplitudes, a_n and $a_{n'}$.

²⁸ The notion of detuning is also very useful in the classical theory of oscillations (see, e.g., CM Chapter 5), where the role of $\omega_{nn'}$ is played by the own frequency ω_0 of the oscillator.

²⁹ Strictly speaking, one more condition is that the number of “resonance” levels is also not too high – see Sec. 6.

³⁰ The second assumption, i.e. the omission of non-resonant terms in the equations for amplitudes is called the *Rotating Wave Approximation* (RWA); the same idea in the classical theory of oscillations is the basis of what is usually called the *van der Pol method*, and its result, the *reduced equations* – see, e.g., CM Secs. 5.3-5.5.

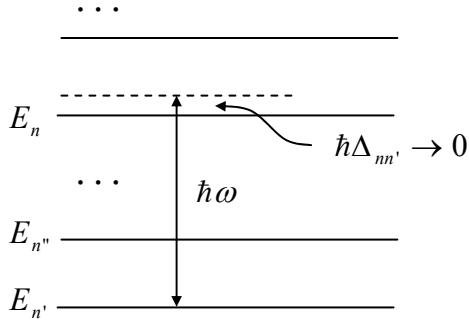

Fig. 6.8. The resonant excitation of an energy level.

The result is the following system of two linear equations:

$$i\hbar\dot{a}_n = a_{n'} A e^{-i\Delta t}, \quad i\hbar\dot{a}_{n'} = a_n A^* e^{i\Delta t}, \quad (6.94)$$

which uses the shorthand notation $A \equiv A_{nn'}$ and $\Delta \equiv \Delta_{nn'}$. (I will use this notation for a while – until other energy levels become involved, at the beginning of the next section). This system may be readily reduced to a form without explicit time dependence of the right-hand parts – for example, by introducing the following new probability amplitudes, with the same moduli:

$$b_n \equiv a_n e^{i\Delta t/2}, \quad b_{n'} \equiv a_{n'} e^{-i\Delta t/2}, \quad (6.95)$$

so that

$$a_n = b_n e^{-i\Delta t/2}, \quad a_{n'} = b_{n'} e^{i\Delta t/2}. \quad (6.96)$$

Plugging these relations into Eq. (94), we get two usual linear first-order differential equations:

$$i\hbar\dot{b}_n = -\frac{\hbar\Delta}{2}b_n + Ab_{n'}, \quad i\hbar\dot{b}_{n'} = A^*b_n + \frac{\hbar\Delta}{2}b_{n'}. \quad (6.97)$$

As the reader knows very well by now, the general solution of such a system is a linear combination of two exponential functions, $\exp\{\lambda_{\pm}t\}$, with the exponents λ_{\pm} that may be found by plugging any of these functions into Eq. (97), and requiring the consistency of the two resulting linear algebraic equations. In our case, the consistency condition (i.e. the characteristic equation of the system) is

$$\begin{vmatrix} -\hbar\Delta/2 - i\hbar\lambda & A \\ A^* & \hbar\Delta/2 - i\hbar\lambda \end{vmatrix} = 0, \quad (6.98)$$

and has two solutions $\lambda_{\pm} = \pm i\Omega$, where

$$\Omega \equiv \left(\frac{\Delta^2}{4} + \frac{|A|^2}{\hbar^2} \right)^{1/2}, \quad \text{i.e. } 2\Omega = \left(\Delta^2 + 4 \frac{|A|^2}{\hbar^2} \right)^{1/2}. \quad (6.99)$$

The coefficients at the exponents are determined by initial conditions. If, as was assumed before, the system was completely on the level n' initially (at $t = 0$), i.e. if $a_{n'}(0) = 1$, $a_n(0) = 0$, so that $b_{n'}(0) = 1$, $b_n(0) = 0$ as well, then Eqs. (97) yield, in particular:

$$b_n(t) = -i \frac{A}{\hbar\Omega} \sin \Omega t, \quad (6.100)$$

so that the n^{th} level occupancy is

$$W_n = |b_n|^2 = \frac{|A|^2}{\hbar^2 \Omega^2} \sin^2 \Omega t \equiv \frac{|A|^2}{|A|^2 + (\hbar \Delta / 2)^2} \sin^2 \Omega t. \quad (6.101)$$

Rabi formula

This is the famous *Rabi oscillation formula*.³¹ If the detuning is large in comparison with $|A|/\hbar$, though still small in the sense of Eq. (93), the frequency 2Ω of the Rabi oscillations is completely determined by the detuning, and their amplitude is small:

$$W_n(t) = 4 \frac{|A|^2}{\hbar^2 \Delta^2} \sin^2 \frac{\Delta t}{2} \ll 1, \quad \text{for } |A|^2 \ll (\hbar \Delta)^2, \quad (6.102)$$

– the result which could be obtained directly from Eq. (90), just neglecting the second term on its right-hand side. However, now we may also analyze the results of an increase of the perturbation amplitude: it leads not only to an increase of the amplitude of the probability oscillations, but also of their frequency – see Fig. 9. Ultimately, at $|A| \gg \hbar|\Delta|$ (for example, at the exact resonance, $\Delta = 0$, i.e. $\omega_{nn'} = \omega$, so that $E_n = E_{n'} + \hbar\omega$), Eqs. (101)-(102) give $\Omega = |A|/\hbar$ and $(W_n)_{\max} = 1$, i.e. describe a periodic, full “repumping” of the system from one level to another and back, with a frequency proportional to the perturbation amplitude.³²

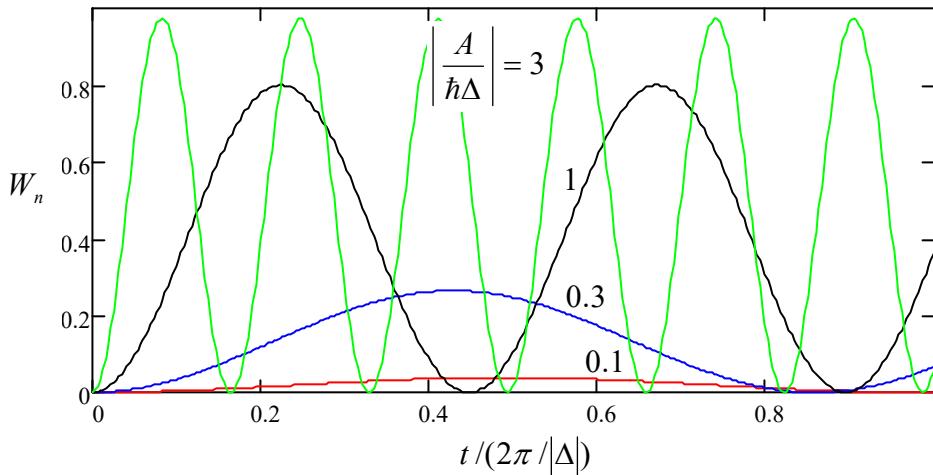

Fig. 6.9. The Rabi oscillations for several values of the normalized amplitude of ac perturbation.

This effect is a close analog of the quantum oscillations in two-level systems with time-independent Hamiltonians, which were discussed in Secs. 2.6 and 5.1. Indeed, let us revisit, for a moment, their discussion started at the end of Sec. 1 of this chapter, now paying more attention to the time evolution of the system under the perturbation. As was argued in that section, the most general perturbation Hamiltonian lifting the two-fold degeneracy of an energy level, in an arbitrary basis, has the matrix (28). Let us describe the system’s dynamics using, again, the Schrödinger picture, representing the ket-vector of an arbitrary state of the system in the form (5.1), where \uparrow and \downarrow are the

³¹ It was derived in 1952 by Isaac Rabi, in the context of his group’s pioneering experiments with the ac (practically, microwave) excitation of quantum states, using molecular beams in vacuum.

³² As Eqs. (82), (96), and (99) show, the lowest frequency in the system is $\omega_l = \omega_{n'} - \Delta/2 + \Omega$, so that at $A \rightarrow 0$, $\hbar\omega_l \approx \hbar\omega_{n'} + 2|A|^2/\hbar\Delta$. This effective shift of the lowest energy level (which may be measured by another “probe” field of a different frequency) is a particular case of the *ac Stark effect*, which was already mentioned in Sec. 2.

time-independent states of the basis in that Eq. (28) is written (now without any obligation to associate these states with the z -basis of any spin- $\frac{1}{2}$.) Then, the Schrödinger equation (4.158) yields

$$i\hbar \begin{pmatrix} \dot{\alpha}_\uparrow \\ \dot{\alpha}_\downarrow \end{pmatrix} = H^{(1)} \begin{pmatrix} \alpha_\uparrow \\ \alpha_\downarrow \end{pmatrix} \equiv \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix} \begin{pmatrix} \alpha_\uparrow \\ \alpha_\downarrow \end{pmatrix} \equiv \begin{pmatrix} H_{11}\alpha_\uparrow + H_{12}\alpha_\downarrow \\ H_{21}\alpha_\uparrow + H_{22}\alpha_\downarrow \end{pmatrix}. \quad (6.103)$$

As we know (for example, from the discussion in Sec. 5.1), the average of the diagonal elements of the matrix gives just a common shift of the system's energy; for the purpose of the dynamics analysis, it may be absorbed into the energy reference level. Also, the Hamiltonian operator has to be Hermitian, so that the off-diagonal elements of its matrix have to be complex-conjugate. With this, Eqs. (103) are reduced to the form,

$$i\hbar \dot{\alpha}_\uparrow = -\frac{\xi}{2} \alpha_\uparrow + H_{12} \alpha_\downarrow, \quad i\hbar \dot{\alpha}_\downarrow = H_{12}^* \alpha_\uparrow + \frac{\xi}{2} \alpha_\downarrow, \quad \text{with } \hbar\xi \equiv H_{22} - H_{11}, \quad (6.104)$$

which is absolutely similar to Eqs. (97). In particular, these equations describe the quantum oscillations of the probabilities $W_\uparrow = |\alpha_\uparrow|^2$ and $W_\downarrow = |\alpha_\downarrow|^2$ with the frequency³³

$$2\Omega = \left(\xi^2 + 4 \frac{|H_{12}|^2}{\hbar^2} \right)^{1/2}. \quad (6.105)$$

The similarity of Eqs. (97) and (104), and hence of Eqs. (99) and (105), shows that the “usual” quantum oscillations and the Rabi oscillations have essentially the same physical nature, besides that in the latter case the external ac signal quantum $\hbar\omega$ bridges the separated energy levels, effectively reducing their difference $(E_n - E_{n'})$ to a much smaller difference $-\Delta \equiv (E_n - E_{n'}) - \hbar\omega$. Also, since the Hamiltonian (28) is similar to that given by Eq. (5.2), the dynamics of such a system with two ac-coupled energy levels, within the limits (93) of the perturbation theory, is completely similar to that of a time-independent two-level system. In particular, its state may be similarly represented by a point on the Bloch sphere shown in Fig. 5.3, with its dynamics described, in the Heisenberg picture, by Eq. (5.19). This fact is very convenient for the experimental implementation of quantum information systems (to be discussed in more detail in Sec. 8.5), because it enables qubit manipulations in a broad variety of physical systems with well-separated energy levels, using external ac (usually either microwave or optical) sources.

Note, however, that according to Eq. (90), if the system has energy levels other than n and n' , they also become occupied to some extent. Since the sum of all occupancies equals 1, this means that $(W_n)_{\max}$ may approach 1 only if the other excitation amplitude is very small, and hence the state manipulation time scale $\mathcal{T} = 2\pi/\Omega = 2\pi\hbar/|A|$ is very long. The ultimate limit in this sense is provided by the harmonic oscillator where all energy levels are equidistant, and the probability repumping between all of them occurs at comparable rates. In particular, in this system the implementation of the full Rabi oscillations is impossible even at the exact resonance.³⁴

³³ By the way, Eq. (105) gives a natural generalization of the relations obtained for the frequency of such oscillations in Sec. 2.6, where the coupled potential wells were assumed to be exactly similar, so that $\xi = 0$. Moreover, Eqs. (104) gives a long-promised proof of Eqs. (2.201), and hence a better justification of Eqs. (2.203).

³⁴ From Sec. 5.5, we already know what happens to the ground state of an oscillator at its external sinusoidal (or any other) excitation: it turns into a Glauber state, i.e. a superposition of *all* Fock states – see Eq. (5.134).

However, I would not like these the quantitative details to obscure from the reader the most important qualitative (OK, maybe semi-quantitative :-) conclusion of this section's analysis: a resonant increase of the interlevel transition intensity at $\omega \rightarrow \omega_{nn'}$. As will be shown later in the course, in a quantum system coupled to its environment at least slightly (hence in reality, in *any* quantum system), such increase is accompanied by a sharp increase of the external field's *absorption*, which may be measured. This effect has numerous practical applications including spectroscopies based on the electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR), which are broadly used in material science, chemistry, and medicine. Unfortunately, I will not have time to discuss the related technical issues and methods (in particular, interesting ac pulsing techniques, including the so-called *Ramsey interferometry*) in detail, and have to refer the reader to special literature.³⁵

6.6. Quantum-mechanical Golden Rule

One of the results of the past section, Eq. (102), may be used to derive one of the most important and nontrivial results of quantum mechanics. For that, let us consider the case when the perturbation causes quantum transitions from a *discrete* energy level E_n into a group of eigenstates with a very dense (essentially *continuous*) spectrum $E_{n'}$ – see Fig. 10a.

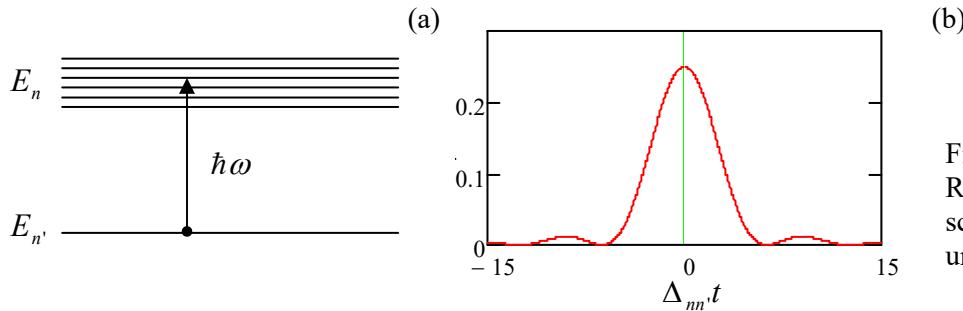

Fig. 6.10. Deriving the Golden Rule: (a) the energy level scheme, and (b) the function under the integral (108).

If, for all states n of the group, the following conditions are satisfied

$$|A_{nn'}|^2 \ll (\hbar\Delta_{nn'})^2 \ll (\hbar\omega_{nn'})^2, \quad (6.106)$$

then Eq. (102) coincides with the result that would follow from Eq. (90). This means that we may apply Eq. (102), with the indices n and n' duly restored, to any level n of our tight group. As a result, the total probability of having our system transferred from the initial level n' to that group is

$$W_\Sigma(t) = \sum_n W_n(t) = \frac{4}{\hbar^2} \sum_n \frac{|A_{nn'}|^2}{\Delta_{nn'}^2} \sin^2 \frac{\Delta_{nn'} t}{2}. \quad (6.107)$$

Now comes the main, absolutely beautiful trick: let us assume that the summation over n is limited to a tight group of very similar states whose matrix elements $A_{nn'}$ are virtually similar (we will check the validity of this assumption later on), so that we can take $|A_{nn'}|^2$ out of the sum in Eq. (107) and then replace the sum with the corresponding integral:

³⁵ For introductions see, e.g., J. Wertz and J. Bolton, *Electron Spin Resonance*, 2nd ed., Wiley, 2007; J. Keeler, *Understanding NMR Spectroscopy*, 2nd ed., Wiley, 2010.

$$W_{\Sigma}(t) = \frac{4|A_{nn'}|^2}{\hbar^2} \int \frac{1}{\Delta_{nn'}^2} \sin^2 \frac{\Delta_{nn'} t}{2} d_n \equiv \frac{4|A_{nn'}|^2 \rho_n t}{\hbar} \int \frac{1}{(\Delta_{nn'} t)^2} \sin^2 \frac{\Delta_{nn'} t}{2} d(-\Delta_{nn'} t), \quad (6.108)$$

where ρ_n is the density of the states n on the energy axis:

$$\boxed{\rho_n \equiv \frac{dn}{dE_n}}. \quad (6.109)$$

Density of states
This density and the matrix element $A_{nn'}$ have to be evaluated at $\Delta_{nn'} = 0$, i.e. at energy $E_n = E_{n'} + \hbar\omega$, and are assumed to be constant within the final state group. At fixed $E_{n'}$, the function under integral (108) is even and decreases fast at $|\Delta_{nn'} t| \gg 1$ – see Fig. 10b. Hence we may introduce a dimensionless integration variable $\xi \equiv \Delta_{nn'} t$, and extend the integration over it formally from $-\infty$ to $+\infty$. Then the integral in Eq. (108) is reduced to a table one,³⁶ and yields

$$W_{\Sigma}(t) = \frac{4|A_{nn'}|^2 \rho_n t}{\hbar} \int_{-\infty}^{+\infty} \frac{1}{\xi^2} \sin^2 \frac{\xi}{2} d\xi = \frac{4|A_{nn'}|^2 \rho_n t}{\hbar} \frac{\pi}{2} \equiv \Gamma t, \quad (6.110)$$

where the constant

$$\boxed{\Gamma = \frac{2\pi}{\hbar} |A_{nn'}|^2 \rho_n} \quad (6.111)$$

Golden Rule
is called the *transition rate*.³⁷ This is one of the most famous and useful results of quantum mechanics, its *Golden Rule*³⁸, which deserves much discussion.

First of all, let us reproduce the reasoning already used in Sec. 2.5 to show that the meaning of the rate Γ is much deeper than Eq. (110) seems to imply. Indeed, due to the conservation of the total probability, $W_{n'} + W_{\Sigma} = 1$, we can rewrite that equation as

$$\dot{W}_{n'}|_{t=0} = -\Gamma. \quad (6.112)$$

Evidently, this result cannot be true for all times, otherwise the probability $W_{n'}$ would become negative. The reason for this apparent contradiction is that Eq. (110) was obtained in the assumption that initially, the system was completely on level n' : $W_{n'}(0) = 1$. Now, if at the initial moment the value of $W_{n'}$ is different, the result (110) has to be multiplied by that number, due to the linear relation (88) between da_n/dt and a_n . Hence, instead of Eq. (112) we get a differential equation similar to Eq. (2.159),

$$\dot{W}_{n'}|_{t \geq 0} = -\Gamma W_{n'}, \quad (6.113)$$

which, for a time-independent Γ , has the evident solution,

³⁶ See, e.g., MA Eq. (6.12).

³⁷ In some texts, the density of states in Eq. (111) is replaced with a formal expression $\Sigma_n \delta(E_n - E_{n'} - \hbar\omega)$. Indeed, applied to a finite energy interval ΔE_n with $\Delta n \gg 1$ levels, it gives the same result: $\Delta n \equiv (dn/dE_n)\Delta E_n \equiv \rho_n \Delta E_n$. Such replacement may be technically useful in some cases, but is incorrect for $\Delta n \sim 1$, and hence should be used with the utmost care, so that for most applications the more explicit form (111) is preferable.

³⁸ Sometimes Eq. (111) is called “Fermi’s Golden Rule”. This is rather unfair, because this result was developed mostly by the same P. A. M. Dirac in 1927, and Enrico Fermi’s role was not much more than advertising it, under the name of “Golden Rule No. 2”, in his influential lecture notes on nuclear physics, which were published much later, in 1950. (To be fair to Fermi, he has never tried to pose as the Golden Rule’s author.)

$$W_{n'}(t) = W_{n'}(0)e^{-\Gamma t}, \quad (6.114)$$

Initial occupancy's decay

describing the exponential decay of the initial state's occupancy, with the time constant $\tau = 1/\Gamma$.

I am inviting the reader to review this fascinating result again: by the summation of *periodic oscillations* (102) over many levels n , we have got an *exponential decay* (114) of the probability. This trick becomes possible because the effective range ΔE_n of the state energies E_n giving substantial contributions to the integral (108), shrinks with time: $\Delta E_n \sim \hbar/t$.³⁹ However, since most of the decay (114) takes place within the time interval of the order of $\tau \equiv 1/\Gamma$, the range of the participating final energies may be estimated as

$$\Delta E_n \sim \frac{\hbar}{\tau} \equiv \hbar\Gamma. \quad (6.115)$$

This estimate is very instrumental for the formulation of conditions of the Golden Rule's validity. First, we have assumed that the matrix elements of the perturbation and the density of states are independent of the energy within the interval (115). This gives the following requirement

$$\Delta E_n \sim \hbar\Gamma \ll E_n - E_{n'} \sim \hbar\omega, \quad (6.116)$$

Second, for the transfer from the sum (107) to the integral (108), we need the number of states within that energy interval, $\Delta N_n = \rho_n \Delta E_n$, to be much larger than 1. Merging Eq. (116) with Eq. (92) for all the energy levels $n'' \neq n, n'$ not participating in the resonant transition, we may summarize all conditions of the Golden Rule validity as

$$\rho_n^{-1} \ll \hbar\Gamma \ll \hbar|\omega \pm \omega_{n'n''}|. \quad (6.117)$$

Golden Rule's validity

(The reader may ask whether I have neglected the condition expressed by the first of Eqs. (106). However, for $\Delta_{nn'} \sim \Delta E_n / \hbar \sim \Gamma$, this condition is just $|A_{nn'}|^2 \ll (\hbar\Gamma)^2$, so that plugging it into Eq. (111),

$$\Gamma \ll \frac{2\pi}{\hbar}(\hbar\Gamma)^2 \rho_n, \quad (6.118)$$

and canceling one Γ and one \hbar , we see that it coincides with the first relation in Eq. (117) above.)

Let us have a look at whether these conditions may be satisfied in practice, at least in some cases. For example, let us consider the optical ionization of an atom, with the released electron confined in a volume of the order of $1 \text{ cm}^3 \equiv 10^{-6} \text{ m}^3$. According to Eq. (1.90), with E of the order of the atomic ionization energy $E_n - E_{n'} = \hbar\omega \sim 1 \text{ eV}$, the density of electron states in that volume is of the order of 10^{21} 1/eV , while the right-hand side of Eq. (117) is of the order of $E_n \sim 1 \text{ eV}$. Thus the conditions (117) provide an approximately 20-orders-of magnitude range for acceptable values of $\hbar\Gamma$. This illustration should give the reader a taste of why the Golden Rule is applicable to so many situations.

Finally, the physical picture of the initial state's decay (which will also be the key to our discussion of quantum-mechanical “open” systems in the next chapter) is also very important. According to Eq. (114), the external excitation transfers the system into the continuous spectrum of levels n , and it never comes back to the initial level n' . However, it was derived from the quantum mechanics of Hamiltonian systems, whose equations are invariant with respect to time reversal. This

³⁹ This is one more appearance of the “energy-time uncertainty relation”, which was discussed in Sec. 2.5.

paradox is a result of our generalization (113) of the exact result (112). This trick, breaking the time-reversal symmetry, is absolutely adequate for the physics under study. Indeed, some gut feeling of the physical sense of this irreversibility may be obtained from the following observation. As Eq. (1.86) illustrates, the distance between the adjacent orbital energy levels tends to zero only if the system's size goes to infinity. This means that our assumption of the continuous energy spectrum of the final states n essentially requires these states to be broadly extended in space – being either free, or essentially free de Broglie waves. Thus the Golden Rule corresponds to the (physically justified) assumption that in an infinitely large system, the traveling de Broglie waves excited by a local source and propagating outward from it, would never come back, and even if they did, unpredictable phase shifts introduced by minor uncontrollable perturbations on their way would never allow them to sum up in the coherent way necessary to bring the system back into the initial state n' . (This is essentially the same situation which was discussed, for a particular 1D wave-mechanical system, in Sec. 2.5.)⁴⁰

To get a feeling of the Golden Rule at work, let us apply it to the following simple problem – which is a toy model of the photoelectric effect, briefly discussed in Sec. 1.1(ii). A 1D particle is initially trapped in the ground state of a narrow potential well, described by Eq. (2.158):

$$U(x) = -\omega \delta(x), \quad \text{with } \omega > 0. \quad (6.119)$$

Let us calculate the rate Γ of the particle's “ionization” (i.e. its excitation into a group of extended, delocalized states) by a weak classical sinusoidal force of amplitude F_0 and frequency ω , suddenly turned on at some instant, say $t = 0$.

As a reminder, the initial localized state (in our current notation, n') of such a particle was already found in Sec. 2.6:

$$\psi_{n'}(x) = \kappa^{1/2} \exp\{-\kappa|x|\}, \quad \text{with } \kappa \equiv \frac{m\omega}{\hbar^2}, \quad E_{n'} \equiv -\frac{\hbar^2 \kappa^2}{2m} = -\frac{m\omega^2}{2\hbar^2}. \quad (6.120)$$

The final, extended states n , with a continuous spectrum, for this problem exist only at energies $E_n > 0$, so that the excitation rate is different from zero only for frequencies

$$\omega > \omega_{\min} \equiv \frac{|E_{n'}|}{\hbar} = \frac{m\omega^2}{2\hbar^3}. \quad (6.121)$$

The weak sinusoidal force may be described by the following perturbation Hamiltonian,

$$\hat{H}^{(1)} = -F(t)\hat{x} = -F_0 \hat{x} \cos \omega t \equiv -\frac{F_0}{2} \hat{x} \left(e^{i\omega t} + e^{-i\omega t} \right), \quad \text{for } t > 0, \quad (6.122)$$

so that according to Eq. (86), which serves as the amplitude operator's definition, in this case

$$\hat{A} = \hat{A}^\dagger = -\frac{F_0}{2} \hat{x}. \quad (6.123)$$

The matrix elements $A_{nn'}$ that participate in Eq. (111) may be readily calculated in the coordinate representation:

⁴⁰ This situation is also similar to the irreversible increase of entropy of macroscopic systems, despite the fact that their microscopic components obey reversible laws of motion, which is postulated in thermodynamics and explained in statistical physics – see, e.g., SM Secs. 1.2 and 2.2.

$$A_{nn'} = \int_{-\infty}^{+\infty} \psi_n^*(x) \hat{A}(x) \psi_{n'}(x) dx = -\frac{F_0}{2} \int_{-\infty}^{+\infty} \psi_n^*(x) x \psi_{n'}(x) dx. \quad (6.124)$$

Since, according to Eq. (120), the initial ψ_n is a *symmetric* function of x , non-vanishing contributions to this integral are given only by *antisymmetric* functions $\psi_n(x)$, proportional to $\sin k_n x$, with the wave number k_n related to the final energy by the well-familiar equality (1.89):

$$\frac{\hbar^2 k_n^2}{2m} = E_n. \quad (6.125)$$

As we know from Sec. 2.6 (see in particular Eq. (2.167) and its discussion), such antisymmetric functions, with $\psi_n(0) = 0$, are not affected by the zero-centered delta-functional potential (119), so that their density ρ_n is the same as that in completely free space, and we could use Eq. (1.100). However, since that relation was derived for traveling waves, it is more prudent to repeat its derivation for standing waves, confining them to an artificial segment $[-l/2, +l/2]$ – long in the sense

$$k_n l, \kappa l \gg 1, \quad (6.126)$$

so it does not affect the initial localized state and the excitation process. Then the confinement requirement $\psi_n(\pm l/2) = 0$ immediately yields the condition $k_n l/2 = n\pi$, so that Eq. (1.100) is indeed valid, but only for positive values of k_n , because $\sin k_n x$ with $k_n \rightarrow -k_n$ does not describe an independent standing-wave eigenstate. Hence the final state density is

$$\rho_n \equiv \frac{dn}{dE_n} \equiv \frac{dn}{dk_n} \Big/ \frac{dE_n}{dk_n} = \frac{l}{2\pi} \Big/ \frac{\hbar^2 k_n}{m} \equiv \frac{lm}{2\pi\hbar^2 k_n}. \quad (6.127)$$

It may look troubling that the density of states depends on the artificial segment's length l , but the same l also participates in the final wavefunctions' normalization factor,⁴¹

$$\psi_n = \left(\frac{2}{l} \right)^{1/2} \sin k_n x, \quad (6.128)$$

and hence in the matrix element (124):

$$A_{nn'} = -\frac{F_0}{2} \left(\frac{2\kappa}{l} \right)^{1/2} \int_{-l}^{+l} \sin k_n x e^{-\kappa|x|} x dx = -\frac{F_0}{2i} \left(\frac{2\kappa}{l} \right)^{1/2} \left(\int_0^l e^{(ik_n - \kappa)x} x dx - \int_0^l e^{-(ik_n + \kappa)x} x dx \right). \quad (6.129)$$

These two integrals may be readily worked out by parts. Taking into account that due to the condition (126), their upper limits may be extended to ∞ , the result is

$$A_{nn'} = -\left(\frac{2\kappa}{l} \right)^{1/2} F_0 \frac{2k_n \kappa}{(k_n^2 + \kappa^2)^2}. \quad (6.130)$$

Note that the matrix element is a smooth function of k_n (and hence of E_n), so that an important condition of the Golden Rule, the virtual constancy of $A_{nn'}$ on the interval $\Delta E_n \sim \hbar\Gamma \ll E_n$, is satisfied. So, the general Eq. (111) is reduced, for our problem, to the following expression:

⁴¹ The normalization to infinite volume, using Eq. (4.263), is also possible, but physically less transparent.

$$\Gamma = \frac{2\pi}{\hbar} \left[\left(\frac{2\kappa}{l} \right)^{1/2} F_0 \frac{2k_n \kappa}{(k_n^2 + \kappa^2)^2} \right]^2 \frac{lm}{2\pi\hbar^2 k_n} \equiv \frac{8F_0^2 m k_n \kappa^3}{\hbar^3 (k_n^2 + \kappa^2)^4}, \quad (6.131)$$

which is independent of the artificially introduced l – thus justifying its use.

Note that due to the above definitions of k_n and κ , the expression in the parentheses in the denominator of the last expression does not depend on the potential well's "weight" \mathcal{W} , and is a function of only the excitation frequency ω (and the particle's mass):

$$\frac{\hbar^2 (k_n^2 + \kappa^2)}{2m} = E_n - E_{n'} = \hbar\omega. \quad (6.132)$$

As a result, Eq. (131) may be recast simply as

$$\hbar\Gamma = \frac{F_0^2 \mathcal{W}^3 k_n}{2(\hbar\omega)^4}. \quad (6.133)$$

What is hidden here is that k_n , defined by Eq. (125) with $E_n = E_{n'} + \hbar\omega$, is a function of the external force's frequency, changing as $\omega^{1/2}$ at $\omega \gg \omega_{\min}$ (so that Γ drops as $\omega^{-7/2}$ at $\omega \rightarrow \infty$), and as $(\omega - \omega_{\min})^{1/2}$ when ω approaches the "red boundary" (121) of the ionization effect, so that $\Gamma \propto (\omega - \omega_{\min})^{1/2} \rightarrow 0$ in that limit as well.

A conceptually very similar, but a bit more involved analysis of such effect in a more realistic 3D case, namely the hydrogen atom's ionization by an optical wave, is left for the reader's exercise.

6.7. Golden Rule for step-like perturbations

Now let us reuse some of our results for a perturbation being turned on at $t = 0$, but after that time-independent:

Step-like perturbation

$$\hat{H}^{(1)}(t) = \begin{cases} 0, & \text{for } t < 0, \\ \hat{H} = \text{const}, & \text{for } t \geq 0. \end{cases} \quad (6.134)$$

A superficial comparison of this equality and the former Eq. (86) seems to indicate that we may use all our previous results, taking $\omega = 0$ and replacing $\hat{A} + \hat{A}^\dagger$ with $\hat{H}^{(1)}$. However, that conclusion (which would give us a wrong factor of 2 in the result) does not take into account the fact that analyzing both the two-level approximation in Sec. 5, and the Golden Rule in Sec. 6, we have dropped the second (non-resonant) term in Eq. (90). In our current case (134), with $\omega = 0$, there is no such difference between these terms. This why it is more prudent to use the general Eq. (84),

$$i\hbar\dot{a}_n = \sum_{n'} a_{n'} H_{nn'} e^{i\omega_{nn'} t}, \quad (6.135)$$

in which the matrix element of the perturbation is now time-independent at $t > 0$. We see that it is formally equivalent to Eq. (88) with only the first (resonant) term kept, if we make the following replacements:

$$\hat{A} \rightarrow \hat{H}, \quad \Delta_{nn'} \equiv \omega - \omega_{nn'} \rightarrow -\omega_{nn'}. \quad (6.136)$$

Let us use this equivalency to consider the results of coupling between a discrete-energy state n' , into which the particle is initially placed, and a dense group of states with a quasi-continuum spectrum, in the same energy range. Figure 11a shows an example of such a system: a particle is initially (say, at $t = 0$) placed into a potential well separated by a penetrable potential barrier from a formally infinite region with a continuous energy spectrum. Let me hope that the physical discussion in the last section makes the outcome of such an experiment evident: the particle will gradually and irreversibly tunnel out of the well, so that the probability $W_n(t)$ of its still residing in the well will decay in accordance with Eq. (114). The rate of this decay may be found by making the replacements (136) in Eq. (111):

$$\Gamma = \frac{2\pi}{\hbar} |H_{nn'}|^2 \rho_n, \quad (6.137)$$

where the states n and n' now have virtually the same energy.⁴²

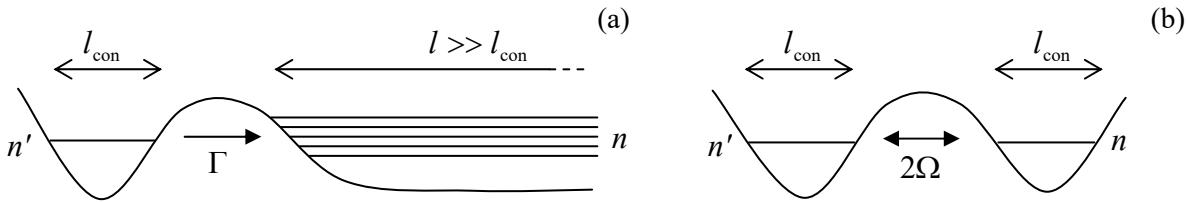

Fig. 6.11. Tunneling from a discrete-energy state n' : (a) to a state continuum, and (b) to another discrete-energy state n .

It is very informative to compare this result, semi-quantitatively, with Eq. (105) for a symmetric ($E_n = E_{n'}$) system of two potential wells separated by a similar potential barrier – see Fig. 11b. For the symmetric case, i.e. $\xi = 0$, Eq. (105) is reduced to simply

$$\Omega = \frac{1}{\hbar} |H_{nn'}|_{\text{con}}. \quad (6.138)$$

Here I have used the index “con” (from “confinement”) to emphasize that this matrix element is somewhat different from the one participating in Eq. (137), even if the potential barriers are similar. Indeed, in the latter case, the matrix element,

$$H_{nn'} = \langle n | \hat{H} | n' \rangle = \int \psi_{n'}^* \hat{H} \psi_n dx, \quad (6.139)$$

has to be calculated for two wavefunctions ψ_n and $\psi_{n'}$ confined to spatial intervals of the same scale l_{con} , while in Eq. (137), the wavefunctions ψ_n are extended over a much larger distance $l \gg l_{\text{con}}$ – see Fig. 11. As Eq. (128) tells us, in the 1D model this means an additional small factor of the order of $(l_{\text{con}}/l)^{1/2}$. Now using Eq. (128) as a crude but suitable model for the final-state wavefunctions, we arrive at the following estimate, independent of the artificially introduced length l :

$$\hbar\Gamma \sim 2\pi |H_{nn'}|_{\text{con}}^2 \frac{l_{\text{con}}}{l} \rho_n \sim 2\pi |H_{nn'}|_{\text{con}}^2 \frac{l_{\text{con}}}{l} \frac{lm}{2\pi\hbar^2 k_n} \sim \frac{|H_{nn'}|_{\text{con}}^2}{\Delta E_{n'}} \equiv \frac{(\hbar\Omega)^2}{\Delta E_{n'}}, \quad (6.140)$$

where $\Delta E_{n'} \sim \hbar^2/ml_{\text{con}}^2$ is the scale of the differences between the eigenenergies of the particle in an unperturbed potential well. Since the condition of validity of Eq. (138) is $\hbar\Omega \ll \Delta E_{n'}$, we see that

⁴² The condition of validity of Eq. (137) is again given by Eq. (117), just with $\omega = 0$ in the upper limit for Γ .

$$\hbar\Gamma \sim \frac{\hbar\Omega}{\Delta E_n} \hbar\Omega \ll \hbar\Omega.. \quad (6.141)$$

This (sufficiently general⁴³) perturbative result confirms the conclusion of a more particular analysis carried out in the end of Sec. 2.6: the rate of the (irreversible) quantum tunneling into a state continuum is always *much lower* than the frequency of (reversible) quantum oscillations between discrete states separated with the same potential barrier – at least for the case when both are much lower than $\Delta E_n/\hbar$, so that the perturbation theory is valid. A very handwaving interpretation of this result is that the particle oscillates between the confined state in the well and the space-extended states behind the barrier many times before finally “deciding to perform” an irreversible transition into the unconfined continuum. This qualitative picture is consistent with experimentally observable effects of dispersive electromagnetic environments on electron tunneling.⁴⁴

Let me conclude this section (and this chapter) with the application of Eq. (137) to a very important case, which will provide a smooth transition to the next chapter’s topic. Consider a *composite* system consisting of two *component* systems, *a* and *b*, with the energy spectra sketched in Fig. 12.

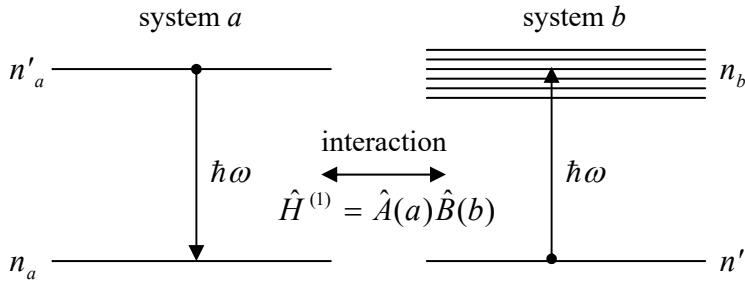

Fig. 6.12. Energy relaxation in system *a* due to its weak coupling to system *b* (which serves as the environment of *a*).

Let the systems be completely independent initially. The independence means that in the absence of their coupling, the total Hamiltonian of the system may be represented as a sum of two operators:

$$\hat{H}^{(0)} = \hat{H}_a(a) + \hat{H}_b(b), \quad (6.142)$$

where the arguments *a* and *b* symbolize the non-overlapping sets of the degrees of freedom of the two systems. Such operators, belonging to their individual, different Hilbert spaces, naturally commute. Similarly, the eigenkets of the system may be naturally factored as

$$|n\rangle = |n_a\rangle \otimes |n_b\rangle. \quad (6.143)$$

The *direct product* sign \otimes is used here (and below) to denote the formation of a joint ket-vector from the kets of the independent systems, belonging to different Hilbert spaces. Evidently, the order of operands in such a product may be changed at will. As a result, its eigenenergies separate into a sum, just as the Hamiltonian (142) does:

$$\hat{H}^{(0)}|n\rangle = (\hat{H}_a + \hat{H}_b)|n_a\rangle \otimes |n_b\rangle \equiv (\hat{H}_a|n_a\rangle) \otimes |n_b\rangle + (\hat{H}_b|n_b\rangle) \otimes |n_a\rangle = (E_{na} + E_{nb})|n\rangle. \quad (6.144)$$

⁴³ It is straightforward to verify that the estimate (141) is valid for similar problems of any spatial dimensionality, not just for the 1D case we have analyzed.

⁴⁴ See, e.g., P. Delsing *et al.*, *Phys. Rev. Lett.* **63**, 1180 (1989).

In such composite systems, the relatively weak interaction of its components may be usually represented as a *bilinear* product of two Hermitian operators, each depending only on the degrees of freedom of one component system:

$$\hat{H}^{(1)} = \hat{A}(a)\hat{B}(b). \quad (6.145)$$

A very common example of such an interaction is the electric-dipole interaction between an atomic-scale system (with a linear size of the order of the Bohr radius $r_B \sim 10^{-10}$ m) and the electromagnetic field at optical frequencies $\omega \sim 10^{16}$ s⁻¹, with the wavelength $\lambda = 2\pi c/\omega \sim 10^{-6}$ m $>> r_B$:⁴⁵

$$\hat{H}^{(1)} = -\hat{\mathbf{d}} \cdot \hat{\mathcal{E}}, \quad \text{with } \hat{\mathbf{d}} \equiv \sum_k q_k \hat{\mathbf{r}}_k, \quad (6.146)$$

where the dipole electric moment \mathbf{d} depends only on the positions \mathbf{r}_k of the charged particles (numbered with index k) of the atomic system, while that of electric field \mathcal{E} is a function of only the electromagnetic field's degrees of freedom – to be discussed in Chapter 9 below.

Returning to the general situation shown in Fig. 12, if the component system a was initially in an excited state n'_a , the interaction (145), turned on at some moment of time, may bring it into another discrete state n_a of a lower energy – for example, the ground state. In the process of this transition, the released energy, in the form of an energy quantum

$$\hbar\omega \equiv E_{n'a} - E_{na}, \quad (6.147)$$

is picked up by the system b :

$$E_{nb} = E_{n'b} + \hbar\omega \equiv E_{n'b} + (E_{n'a} - E_{na}), \quad (6.148)$$

so that the total energy $E = E_a + E_b$ of the system does not change. (If the states n_a and n'_b are the ground states of the two component systems, as they are in most applications of this analysis, and we take the ground state energy $E_g = E_{na} + E_{n'b}$ of the composite system for the reference, then Eq. (148) gives merely $E_{nb} = E_{n'a}$.) If the final state n_b of the system b is inside a state group with a quasi-continuous energy spectrum (Fig. 12), the process has the exponential character (114)⁴⁶ and may be interpreted as the effect of *energy relaxation* of the system a , with the released energy quantum $\hbar\omega$ absorbed by the system b . Note that since the quasi-continuous spectrum essentially requires a system of large spatial size, such a model is very convenient for description of the *environment* b of the quantum system a . (In physics, the “environment” typically means all the Universe – less the system under consideration.)

If the relaxation rate Γ is sufficiently low, it may be described by the Golden Rule (137). Since the perturbation (145) does not depend on time explicitly, and the total energy E does not change, this relation, with the account of Eqs. (143) and (145), takes the form

$$\Gamma = \frac{2\pi}{\hbar} |A_{nn'}|^2 |B_{nn'}|^2 \rho_n, \quad \text{where } A_{nn'} \equiv \langle n_a | \hat{A} | n'_a \rangle, \quad \text{and } B_{nn'} = \langle n_b | \hat{B} | n'_b \rangle, \quad (6.149)$$

Golden
Rule
for coupled
systems

where ρ_n is the density of the final states of the system b at the relevant energy (147). In particular, Eq. (149), with the dipole Hamiltonian (146), enables a very straightforward calculation of the natural linewidth of atomic electric-dipole transitions. However, such calculation has to be postponed until Chapter 9, in which we will discuss the electromagnetic field quantization – i.e., the exact nature of the

⁴⁵ See, e.g., EM Sec. 3.1, in particular Eq. (3.16), in which letter \mathbf{p} is used for the electric dipole moment.

⁴⁶ Such process is *spontaneous*: it does not require any external agent, and starts as soon as either the interaction (145) has been turned on, or (if it is always on) as soon as the system a is placed into the excited state n'_a .

states n_b and $n_{\bar{b}}$ for this problem, and hence will be able to calculate $B_{nn'}$ and ρ_n . Instead, I will now proceed to a general discussion of the effects of quantum systems interaction with their environment, toward which the situation shown in Fig. 12 provides a clear conceptual path.

6.8. Exercise problems

6.1. Use Eq. (14) to prove the following general form of the Hellmann-Feynman theorem (whose proof in the wave-mechanics domain was the task of Problem 1.5):

$$\frac{\partial E_n}{\partial \lambda} = \left\langle n \left| \frac{\partial \hat{H}}{\partial \lambda} \right| n \right\rangle,$$

where λ is an arbitrary *c*-number parameter.

6.2. Establish a relation between Eq. (16) and the result of the classical theory of weakly anharmonic (“nonlinear”) oscillations at negligible damping.

Hint: You may like to use N. Bohr’s reasoning discussed in Problem 1.1.

6.3. A weak, time-independent force F is exerted on a 1D particle that was placed into a hard-wall potential well

$$U(x) = \begin{cases} 0, & \text{for } 0 < x < a, \\ +\infty, & \text{otherwise.} \end{cases}$$

Calculate, sketch, and discuss the 1st-order perturbation of its ground-state wavefunction.

6.4. A time-independent force $\mathbf{F} = \mu(\mathbf{n}_x y + \mathbf{n}_y x)$, where μ is a small constant, is applied to a 3D harmonic oscillator of mass m and frequency ω_0 , located at the origin. Calculate, in the first order of the perturbation theory, the effect of the force upon the ground state energy of the oscillator, and its lowest excited energy level. How small should the constant μ be for your results to be quantitatively correct?

6.5. A 1D particle of mass m is localized at a narrow potential well that may be approximated with a delta function:

$$U(x) = -w\delta(x), \quad \text{with } w > 0.$$

Calculate the change of its ground state energy by an additional weak, time-independent force F , in the first non-vanishing approximation of the perturbation theory. Discuss the limits of validity of this result, taking into account that at $F \neq 0$, the localized state of the particle is metastable.

6.6. Use the perturbation theory to calculate the eigenvalues of the operator \hat{L}^2 in the limit $|m| \approx l \gg 1$, by purely wave-mechanical means.

Hint: Try the following substitution: $\Theta(\theta) = f(\theta)/\sin^{1/2}\theta$.

6.7. In the lowest non-vanishing order of the perturbation theory, calculate the shift of the ground-state energy of an electrically charged spherical rotator (i.e. a particle of mass m , free to move over a spherical surface of radius R) due to a weak, uniform, time-independent electric field \mathcal{E} .

6.8. Use the perturbation theory to evaluate the effect of a time-independent, uniform electric field \mathcal{E} on the ground state energy E_g of a hydrogen atom. In particular:

- (i) calculate the 2nd-order shift of E_g , neglecting the extended unperturbed states with $E > 0$, and bring the result to the simplest analytical form you can,
- (ii) find the lower and the upper bounds on the shift, and
- (iii) discuss the simplest experimental manifestations of this *quadratic Stark effect*.

6.9. A particle of mass m , with electric charge q , is in its ground s -state with a given energy $E_g < 0$, being localized by a very short-range, spherically-symmetric potential well. Calculate its static electric polarizability α .

6.10. In some atoms, the charge-screening effect of other electrons on the motion of each of them may be reasonably well approximated by the replacement of the Coulomb potential (3.190), $U = -C/r$, with the so-called *Hulthén potential*

$$U = -\frac{C/a}{\exp\{r/a\}-1} \rightarrow -C \times \begin{cases} 1/r, & \text{for } r \ll a, \\ \exp\{-r/a\}/a, & \text{for } a \ll r. \end{cases}$$

Assuming that the effective screening radius a is much larger than $r_0 \equiv \hbar^2/mC$, use the perturbation theory to calculate the energy spectrum of a single particle of mass m , moving in this potential, in the lowest order needed to lift the l -degeneracy of the levels.

6.11. In the lowest non-vanishing order of the perturbation theory, calculate the correction to energies of the ground state and all lowest excited states of a hydrogen-like atom/ion, due to electron's penetration into its nucleus, modeling it as a spinless, uniformly charged sphere of radius $R \ll r_B/Z$.

6.12. Prove that the kinetic-relativistic correction operator (48) indeed has only diagonal matrix elements in the basis of unperturbed Bohr atom states (3.200).

6.13. Calculate the lowest-order relativistic correction to the ground-state energy of a 1D harmonic oscillator.

6.14. Use the perturbation theory to calculate the contribution to the magnetic susceptibility χ_m of a dilute gas, that is due to the orbital motion of a single electron inside each gas particle. Spell out your result for a spherically-symmetric ground state of the electron, and give an estimate of the magnitude of this *orbital susceptibility*.

6.15. How to calculate the energy level degeneracy lifting, by a time-independent perturbation, in the 2nd order of the perturbation in $\hat{H}^{(1)}$, assuming that it is not lifted in the 1st order? Carry out such calculation for a plane rotator of mass m and radius R , carrying electric charge q , and placed into a weak, uniform, constant electric field \mathcal{E} .

6.16.* The Hamiltonian of a quantum system is slowly changed in time.

- (i) Develop a theory of quantum transitions in the system, and spell out its result in the 1st order in the speed of the change.

- (ii) Use the 1st-order result to calculate the probability that a finite-time pulse of a slowly changing force $F(t)$ drives a 1D harmonic oscillator, initially in its ground state, into an excited state.
 (iii) Compare the last result with the exact one.

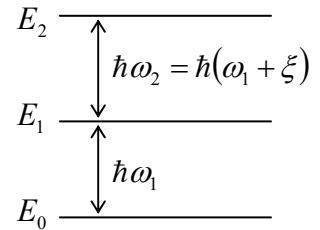

6.17. Use the single-particle model to calculate the complex electric permittivity $\alpha(\omega)$ of a dilute gas of similar atoms, due to their induced electric polarization by a weak external ac field, for a field frequency ω very close to one of quantum transition frequencies $\omega_{nn'}$. Based on the result, calculate and estimate the absorption cross-section of each atom.

Hint: In the single-particle model, atom's properties are determined by Z similar, non-interacting electrons, each moving in a similar static attracting potential, generally different from the Coulomb one, because it is contributed not only by the nucleus, but also by other electrons.

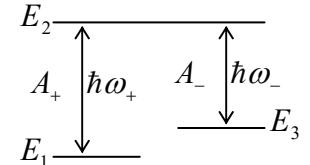

6.18. Use the solution of the previous problem to generalize the expression for the London dispersion force between two atoms (whose calculation in the harmonic-oscillator model was the subject of Problems 3.16 and 5.15) to the single-particle model with an arbitrary energy spectrum.

6.19. Use the solution of the previous problem to calculate the potential energy of interaction of two hydrogen atoms, both in their ground state, separated by distance $r \gg r_B$.

6.20. In a certain quantum system, distances between the three lowest energy levels are slightly different – see the figure on the right ($|\xi| \ll \omega_{1,2}$). Assuming that the involved matrix elements of the perturbation Hamiltonian are known, and are all proportional to the external ac field's amplitude, find the time necessary to populate the first excited level almost completely (with a given precision $\varepsilon \ll 1$), using the Rabi oscillation effect, if at $t = 0$ the system is completely in its ground state.

6.21.* Analyze the possibility of a slow transfer of a system from one of its energy levels to another one (in the figure on the right, from level 1 to level 3), using the scheme shown in that figure, in which the monochromatic external excitation amplitudes A_+ and A_- may be slowly changed at will.

6.22. A weak external force pulse $F(t)$, of a finite time duration, is applied to a 1D harmonic oscillator that initially was in its ground state.

- (i) Calculate, in the lowest non-vanishing order of the perturbation theory, the probability that the pulse drives the oscillator into its lowest excited state.
- (ii) Compare the result with the exact solution of the problem.
- (iii) Spell out the perturbative result for a Gaussian-shaped waveform,

$$F(t) = F_0 \exp\left\{-t^2 / \tau^2\right\},$$

and analyze its dependence on the scale τ of the pulse duration.

6.23. A spatially-uniform, but time-dependent external electric field $\mathcal{E}(t)$ is applied, starting from $t = 0$, to a charged plane rotator, initially in its ground state.

(i) Calculate, in the lowest non-vanishing order in the field's strength, the probability that by time $t > 0$, the rotator is in its n^{th} excited state.

(ii) Spell out and analyze your results for a constant-magnitude field rotating, with a constant angular velocity ω , within the rotator's plane.

(iii) Do the same for a monochromatic field of frequency ω , with a fixed polarization.

6.24. A spin- $\frac{1}{2}$ with a gyromagnetic ratio γ is placed into a magnetic field including a time-independent component \mathcal{B}_0 , and a perpendicular field of a constant magnitude \mathcal{B}_r , rotated with a constant angular velocity ω . Can this *magnetic resonance* problem be reduced to one already discussed in Chapter 6?

6.25. Develop general theory of quantum excitations of the higher levels of a discrete-spectrum system, initially in the ground state, by a weak time-dependent perturbation, up to the 2nd order. Spell out and discuss the result for the case of monochromatic excitation, with a nearly perfect tuning of its frequency ω to *the half* of a certain quantum transition frequency $\omega_{n0} \equiv (E_n - E_0)/\hbar$.

6.26. A heavy, relativistic particle, with electric charge $q = Ze$, passes by a hydrogen atom, initially in its ground state, with an impact parameter b within the range $r_B \ll b \ll r_B/\alpha$, where $\alpha \approx 1/137$ is the fine structure constant. Calculate the probabilities of the atom's transition to its lowest excited states.

6.27. A particle of mass m is initially in the localized ground state, with energy $E_g < 0$, of a very small, spherically-symmetric potential well. Calculate the rate of its delocalization by an applied classical force $\mathbf{F}(t) = \mathbf{n}F_0\cos\omega t$ with a time-independent direction \mathbf{n} .

6.28.* Calculate the rate of ionization of a hydrogen atom, initially in its ground state, by a classical, linearly polarized electromagnetic wave with an electric field's amplitude \mathcal{E}_0 , and a frequency ω within the range

$$\hbar/m_e r_B^2 \ll \omega \ll c/r_B,$$

where r_B is the Bohr radius. Recast your result in terms of the cross-section of electromagnetic wave absorption. Discuss briefly what changes of the theory would be necessary if either of the above conditions had been violated.

6.29.* Use the quantum-mechanical Golden Rule to derive the general expression for the electric current I through a weak tunnel junction between two conductors, biased with dc voltage V , treating the conductors as degenerate Fermi gases of electrons with negligible direct interaction. Simplify the result in the low-voltage limit.

Hint: The electric current flowing through a weak tunnel junction is so low that it does not substantially perturb the electron states inside each conductor.

6.30.* Generalize the result of the previous problem to the case when a weak tunnel junction is biased with voltage $V(t) = V_0 + A\cos\omega t$, with $\hbar\omega$ generally comparable with eV_0 and eA .

6.31.* Use the quantum-mechanical Golden Rule to derive the Landau-Zener formula (2.257).

Chapter 7. Open Quantum Systems

This chapter discusses the effects of a weak interaction of a quantum system with its environment. Some part of this material is on the fine line between quantum mechanics and (quantum) statistical physics. Here I will only cover those aspects of the latter field¹ that are of key importance for the major goals of this course, including the discussion of quantum measurements in Chapter 10.

7.1. Open systems, and the density matrix

All the way until the last part of the previous chapter, we have discussed quantum systems isolated from their environment. Indeed, from the very beginning, we have assumed that we are dealing with the statistical ensembles of systems as similar to each other as only allowed by the laws of quantum mechanics. Each member of such an ensemble, called *pure* or *coherent*, may be described by the same state vector $|\alpha\rangle$ – in the wave mechanics case, by the same wavefunction Ψ_α . Even the discussion at the end of the last chapter, in which one component system (in Fig. 6.13, system *b*) may be used as a model of the environment of its counterpart (system *a*), was still based on the assumption of a pure initial state (6.143) of the composite system. If the interaction of the two components of such a system is described by a certain Hamiltonian (the one given by Eq. (6.145) for example), and the energy spectrum of each component system is discrete, for state α of the composite system at an arbitrary instant we may write

$$|\alpha\rangle = \sum_n \alpha_n |n\rangle = \sum_n \alpha_n |n_a\rangle \otimes |n_b\rangle, \quad (7.1)$$

with a *unique* correspondence between the eigenstates n_a and n_b .

However, in many important cases, our knowledge of a quantum system's state is even less complete.² These cases fall into two categories. The first case is when a relatively simple quantum system *s* of our interest (say, an electron or an atom) is in a weak³ but substantial contact with its environment *e* – here understood in the most general sense, say, as all the whole Universe less system *s* – see Fig. 1. Then there is virtually no chance of making two or more experiments with exactly the same composite system because that would imply a repeated preparation of the whole environment (including the experimenter :-) in a certain quantum state – a rather challenging task, to put it mildly. Then it makes much more sense to consider a statistical ensemble of another kind – a *mixed ensemble*, with *random* states of the environment, though possibly with its macroscopic parameters (e.g., temperature, pressure, etc.) known with high precision. Such ensembles will be the focus of the analysis in this chapter.

Much of this analysis will pertain also to another category of cases – when the system of our interest is isolated from its environment, at present, with acceptable precision, but our knowledge of its state is still incomplete for some other reason. Most typically, the system could be in contact with its

¹ A broader discussion of statistical mechanics and physical kinetics, including those of quantum systems, may be found in the SM part of this series.

² Indeed, a system, possibly apart from our Universe as a whole (who knows? – see below), is never *exactly* coherent, though in many cases, such as the ones discussed in the previous chapters, deviations from the coherence may be ignored with *acceptable accuracy*.

³ If the interaction between a system and its environment is very strong, their very partition is impossible.

environment at earlier times, and its reduction to a pure state is impracticable. So, this second category of cases may be considered as a particular case of the first one, and may be described by the results of its analysis, with certain simplifications – which will be spelled out in appropriate places of my narrative.

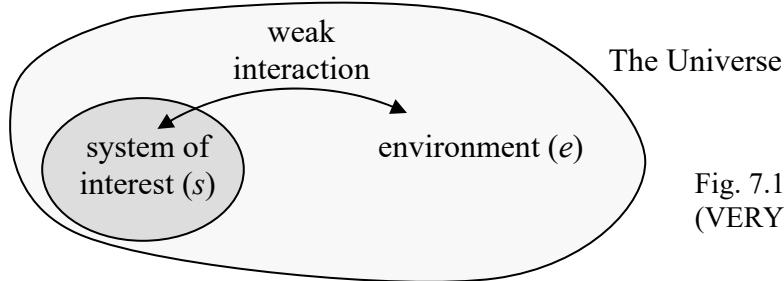

Fig. 7.1. A quantum system and its environment (VERY schematically :-).

In classical physics, the analysis of mixed statistical ensembles is based on the notion of the probability W (or the probability density w) of each detailed (“microscopic”) state of the system of interest.⁴ Let us see how such an ensemble may be described in quantum mechanics. In the case when the coupling between the system of our interest and its environment is so weak that they may be clearly separated, we can still use state vectors of their states, defined in completely different Hilbert spaces. Then the most general quantum state of the whole Universe, still assumed to be pure,⁵ may be described as the following linear superposition:

$$|\alpha\rangle = \sum_{j,k} \alpha_{jk} |s_j\rangle \otimes |e_k\rangle. \quad (7.2)$$

Universe:
quantum
state

The “only” difference of such a state from the superposition described by Eq. (1), is that there is no one-to-one correspondence between the states of our system and its environment. In other words, a certain quantum state s_j of the system of interest may coexist with different states e_k of its environment. This is exactly the quantum-mechanical description of a *mixed state* of the system s .

Of course, the huge size of the Hilbert space of the environment, i.e. of the number of the $|e_k\rangle$ factors in the superposition (2), strips us of any practical opportunity to make direct calculations using that sum. For example, according to the basic Eq. (4.125), to find the expectation value of an arbitrary observable A in the state (2), we would need to calculate the long bracket

$$\langle A \rangle = \langle \alpha | \hat{A} | \alpha \rangle \equiv \sum_{j,j';k,k'} \alpha_{jk}^* \alpha_{j'k'} \langle e_k | \otimes \langle s_j | \hat{A} | s_{j'} \rangle \otimes | e_{k'} \rangle. \quad (7.3)$$

Even if we assume that each of the sets $\{s\}$ and $\{e\}$ is full and orthonormal, Eq. (3) still includes a double sum over the enormous basis state set of the environment!

However, let us consider a limited, but the most important subset of operators – those of *intrinsic* observables, which depend only on the degrees of freedom of the system of our interest (s). These operators do not act upon the environment’s degrees of freedom, and hence in Eq. (3), we may move the environment’s bra-vectors $\langle e_k |$ over all the way to the ket-vectors $| e_k \rangle$. Assuming, again, that the set of environmental eigenstates is full and orthonormal, Eq. (3) is now reduced to

⁴ See, e.g., SM Sec. 2.1.

⁵ Whether this assumption is true is an interesting issue, still being debated (more by philosophers than by physicists), but it is widely believed that its solution is not critical for the validity of the results of this approach.

$$\langle A \rangle = \sum_{j,j';k,k'} \alpha_{jk}^* \alpha_{j'k'} \langle s_j | \hat{A} | s_{j'} \rangle \langle e_k | e_{k'} \rangle = \sum_{jj'} A_{jj'} \sum_k \alpha_{jk}^* \alpha_{j'k}. \quad (7.4)$$

This is already a big relief because we have “only” a single sum over k , but the main trick is still ahead. After the summation over k , the second sum in the last form of Eq. (4) is some function w of the indices j and j' , so that, according to Eq. (4.96), this relation may be represented as

$$\langle A \rangle = \sum_{jj'} A_{jj'} w_{j'j} \equiv \text{Tr}(Aw), \quad (7.5)$$

where the matrix w , with the elements

$$w_{jj'} \equiv \sum_k \alpha_{jk}^* \alpha_{j'k}, \quad \text{i.e. } w_{jj'} \equiv \sum_k \alpha_{jk} \alpha_{j'k}^*, \quad (7.6)$$

is called the *density matrix* of the system.⁶ Most importantly, Eq. (5) shows that the knowledge of this matrix allows the calculation of the expectation value of *any* intrinsic observable A (and, according to the general Eqs. (1.33)-(1.34), its r.m.s. fluctuation as well, if needed), even for the very general state (2). This is why let us have a good look at the density matrix.

First of all, we know from the general discussion in Chapter 4, fully applicable to the pure state (2), the expansion coefficients in superpositions of this type may be always expressed as short brackets of the type (4.40); in our current case, we may write

$$\alpha_{jk} = (\langle e_k | \otimes \langle s_j |) |\alpha\rangle. \quad (7.7)$$

Plugging this expression into Eq. (6), we get

$$w_{jj'} \equiv \sum_k \alpha_{jk} \alpha_{j'k}^* = \langle s_j | \otimes \left(\sum_k \langle e_k | \alpha \rangle \langle \alpha | e_k \rangle \right) \otimes |s_{j'} \rangle = \langle s_j | \hat{w} | s_{j'} \rangle. \quad (7.8)$$

We see that from the point of our system (i.e. in its Hilbert space whose basis states may be numbered by the index j only), the density matrix is indeed just the matrix of some construct,⁷

$$\hat{w} \equiv \sum_k \langle e_k | \alpha \rangle \langle \alpha | e_k \rangle, \quad (7.9)$$

which is called the *density* (or “statistical”) *operator*. As it follows from the definition (9), in contrast to the density matrix this operator does not depend on the choice of a particular basis s_j – just as all linear operators considered earlier in this course. However, in contrast to them, the density operator *does* depend on the composite system’s state α , including the state of the system s as well. Still, in the j -space it is mathematically just an operator whose matrix elements obey all relations of the bra-ket formalism.

In particular, due to its definition (6), the density operator is Hermitian:

$$w_{jj'}^* = \sum_k \alpha_{jk}^* \alpha_{j'k} = \sum_k \alpha_{j'k} \alpha_{jk}^* = w_{j'j}, \quad (7.10)$$

⁶ This notion was suggested in 1927 by John von Neumann.

⁷ Note that the “short brackets” in this expression are not *c*-numbers, because the state α is defined in a larger Hilbert space (of the environment plus the system of interest) than the basis states e_k (of the environment only).

so that according to the general analysis of Sec. 4.3, in the Hilbert space of the system s , there should be a certain basis $\{w\}$ in that the matrix of this operator is diagonal:

$$w_{jj'}|_{in w} = w_j \delta_{jj'}. \quad (7.11)$$

Since any operator, in any basis, may be represented in the form (4.59), in the basis $\{w\}$ we may write

$$\hat{w} = \sum_j |w_j\rangle w_j \langle w_j|. \quad (7.12)$$

Statistical operator in w -basis

This expression reminds, but is not equivalent to Eq. (4.44) for the identity operator, that has been used so many times in this course, and in the basis w_j has the form

$$\hat{I} = \sum_j |w_j\rangle \langle w_j|. \quad (7.13)$$

In order to comprehend the meaning of the coefficients w_j participating in Eq. (12), let us use Eq. (5) to calculate the expectation value of any observable A whose eigenstates coincide with those of the special basis $\{w\}$, and whose matrix is, therefore, diagonal in this basis:

$$\langle A \rangle = \text{Tr}(Aw) = \sum_{jj'} A_{jj'} w_j \delta_{jj'} = \sum_j A_j w_j, \quad (7.14)$$

Expectation value of w_j -compatible variable

where A_j is just the expectation value of the observable A in the state w_j . Hence, to comply with the general Eq. (1.37), the real c -number w_j must have the physical sense of the probability W_j of finding the system in the state j . As the result, we may rewrite Eq. (12) in the form

$$\hat{w} = \sum_j |w_j\rangle W_j \langle w_j|. \quad (7.15)$$

In the ultimate case when only one of the probabilities (say, $W_{j''}$) is different from zero,

$$W_j = \delta_{jj''}, \quad (7.16)$$

the system is in a coherent (pure) state $w_{j''}$. Indeed, it is fully described by one ket-vector $|w_{j''}\rangle$, and we can use the general rule (4.86) to represent it in another (arbitrary) basis $\{s\}$ as a coherent superposition

$$|w_{j''}\rangle = \sum_{j'} U_{j''j'}^\dagger |s_{j'}\rangle = \sum_{j'} U_{j''j'}^* |s_{j'}\rangle, \quad (7.17)$$

where U is the unitary matrix of transform from the basis $\{w\}$ to the basis $\{s\}$. According to Eqs. (11) and (16), in such a pure state the density matrix is diagonal in the $\{w\}$ basis,

$$w_{jj'}|_{in w} = \delta_{j,j''} \delta_{j',j''}, \quad (7.18a)$$

but not in an arbitrary basis. Indeed, using the general rule (4.92), we get

$$w_{jj'}|_{in s} = \sum_{l,l'} U_{jl}^\dagger w_{ll'}|_{in w} U_{l'j'} = U_{jj''}^\dagger U_{j''j'} = U_{jj''}^* U_{j''j'}, \quad (7.18b)$$

To make this result more transparent, let us denote the matrix elements $U_{j''j} \equiv \langle w_{j''}|s_j\rangle$ (which, for a fixed j'' , depend on just one index j) by α_j ; then

$$w_{jj'}|_{in s} = \alpha_j^* \alpha_{j'}, \quad (7.19)$$

Density matrix: pure state

so that N^2 elements of the whole $N \times N$ matrix is determined by just *one* string of N *c-numbers* α_j . For example, for a two-level system ($N = 2$),

$$\mathbf{w}|_{\text{in } s} = \begin{pmatrix} \alpha_1 \alpha_1^* & \alpha_2 \alpha_1^* \\ \alpha_1 \alpha_2^* & \alpha_2 \alpha_2^* \end{pmatrix}. \quad (7.20)$$

We see that the off-diagonal terms are, colloquially, “as large as the diagonal ones”, in the following sense:

$$w_{12} w_{21} = w_{11} w_{22}. \quad (7.21)$$

Since the diagonal terms have the sense of the probabilities $W_{1,2}$ to find the system in the corresponding state, we may represent Eq. (20) in the form

$$\mathbf{w}|_{\text{pure state}} = \begin{pmatrix} W_1 & (W_1 W_2)^{1/2} e^{i\varphi} \\ (W_1 W_2)^{1/2} e^{-i\varphi} & W_2 \end{pmatrix}. \quad (7.22)$$

The physical sense of the (real) constant φ is the phase shift between the coefficients in the linear superposition (17), which represents the pure state w_j in the basis $\{s_{1,2}\}$.

Now let us consider a different statistical ensemble of two-level systems, that includes the member states identical in all aspects (including similar probabilities $W_{1,2}$ in the same basis $s_{1,2}$), besides that the phase shifts φ are random, with the phase probability uniformly distributed over the trigonometric circle. Then the ensemble averaging is equivalent to the averaging over φ from 0 to 2π ,⁸ which kills the off-diagonal terms of the density matrix (22), so that the matrix becomes diagonal:

$$\mathbf{w}|_{\text{classical mixture}} = \begin{pmatrix} W_1 & 0 \\ 0 & W_2 \end{pmatrix}. \quad (7.23)$$

The mixed statistical ensemble with the density matrix diagonal in the stationary state basis is called the *classical mixture* and represents the limit opposite to the pure (coherent) state.

After this example, the reader should not be much shocked by the main claim⁹ of statistical mechanics that any large ensemble of similar systems in *thermodynamic* (or “thermal”) *equilibrium* is exactly such a *classical mixture*. Moreover, for systems in the thermal equilibrium with a much larger environment of a fixed temperature T (such an environment is usually called a *heat bath*) the statistical physics gives a very simple expression, called the *Gibbs distribution*, for the probabilities W_n :¹⁰

$$W_n = \frac{1}{Z} \exp\left\{-\frac{E_n}{k_B T}\right\}, \quad \text{with } Z \equiv \sum_n \exp\left\{-\frac{E_n}{k_B T}\right\}. \quad (7.24)$$

⁸ For a system with a time-independent Hamiltonian, such averaging is especially plausible in the basis of the stationary states n of the system, in which the phase φ is just the difference of integration constants in Eq. (4.158), and its randomness may be naturally produced by minor fluctuations of the energy difference $E_1 - E_2$. In Sec. 3 below, we will study the dynamics of this *dephasing* process.

⁹ This fact follows from the basic postulate of statistical physics, called the *microcanonical distribution* – see, e.g., SM Sec. 2.2.

¹⁰ See, e.g., SM Sec. 2.4. The Boltzmann constant k_B is only needed if the temperature is measured in non-energy units – say in kelvins.

where E_n is the eigenenergy of the corresponding stationary state, and the normalization coefficient Z is called the *statistical sum*.

A detailed analysis of classical and quantum ensembles in thermodynamic equilibrium is a major focus of statistical physics courses (such as the SM of this series) rather than this course of quantum mechanics. However, I would still like to attract the reader's attention to the key fact that, in contrast with the similarly-looking Boltzmann distribution for single particles,¹¹ the Gibbs distribution is *general, not limited to classical statistics*. In particular, for a quantum gas of indistinguishable particles, it is absolutely compatible with the quantum statistics (such as the Bose-Einstein or Fermi-Dirac distributions) of the component particles. For example, if we use Eq. (24) to calculate the average energy of a 1D harmonic oscillator of frequency ω_0 in thermal equilibrium, we easily get¹²

$$W_n = \exp\left\{-n \frac{\hbar\omega_0}{k_B T}\right\} \left(1 - \exp\left\{-\frac{\hbar\omega_0}{k_B T}\right\}\right), \quad Z = \exp\left\{-\frac{\hbar\omega_0}{2k_B T}\right\} / \left(1 - \exp\left\{-\frac{\hbar\omega_0}{k_B T}\right\}\right). \quad (7.25)$$

$$\langle E \rangle \equiv \sum_{n=0}^{\infty} W_n E_n = \frac{\hbar\omega_0}{2} \coth \frac{\hbar\omega_0}{2k_B T} \equiv \frac{\hbar\omega_0}{2} + \frac{\hbar\omega_0}{\exp\{\hbar\omega_0/k_B T\} - 1}. \quad (7.26a)$$

The final form of the last result,

$$\langle E \rangle = \frac{\hbar\omega_0}{2} + \hbar\omega_0 \langle n \rangle, \quad \text{with } \langle n \rangle = \frac{1}{\exp\{\hbar\omega_0/k_B T\} - 1} \rightarrow \begin{cases} 0, & \text{for } k_B T \ll \hbar\omega_0, \\ k_B T / \hbar\omega_0, & \text{for } \hbar\omega_0 \ll k_B T, \end{cases} \quad (7.26b)$$

may be interpreted as an addition, to the ground-state energy $\hbar\omega_0/2$, of the average number $\langle n \rangle$ of thermally-induced excitations, with the energy $\hbar\omega_0$ each. In the harmonic oscillator, whose energy levels are equidistant, such a language is completely appropriate, because the transfer of the system from any level to the one just above it adds the same amount of energy, $\hbar\omega_0$. Note that the above expression for $\langle n \rangle$ is actually the Bose-Einstein distribution (for the particular case of zero chemical potential); we see that it does not contradict the Gibbs distribution (24) of the total energy of the system, but rather immediately follows from it.

Because of the fundamental importance of Eq. (26) for virtually all fields of physics, let me draw the reader's attention to its main properties. At low temperatures, $k_B T \ll \hbar\omega_0$, there are virtually no excitations, $\langle n \rangle \rightarrow 0$, and the average energy of the oscillator is dominated by that of its ground state. In the opposite limit of high temperatures, $\langle n \rangle \rightarrow k_B T / \hbar\omega_0 \gg 1$, and $\langle E \rangle$ approaches the classical value $k_B T$.

7.2. Coordinate representation, and the Wigner function

For many applications of the density operator, its coordinate representation is convenient. (I will only discuss it for the 1D case; the generalization to multi-dimensional cases is straightforward.) Following Eq. (4.47), it is natural to define the following function of two arguments (traditionally, also called the *density matrix*):

¹¹ See, e.g., SM Sec. 2.8.

¹² See, e.g., SM Sec. 2.5 – but mind a different energy reference level, $E_0 = \hbar\omega_0/2$, used for example in SM Eqs. (2.68)-(2.69), affecting the expression for Z . Actually, the calculation, using Eqs. (24) and (5.86), is so straightforward that it is highly recommended to the reader as a simple exercise.

$$w(x, x') \equiv \langle x | \hat{w} | x' \rangle. \quad (7.27)$$

Inserting, into the right-hand side of this definition, two closure conditions (4.44) for an arbitrary (but full and orthonormal) basis $\{s\}$, and then using Eq. (4.233),¹³ we get

$$w(x, x') = \sum_{j, j'} \langle x | s_j \rangle \langle s_j | \hat{w} | s_{j'} \rangle \langle s_{j'} | x' \rangle = \sum_{j, j'} \psi_j(x) w_{jj'}|_{in_s} \psi_{j'}^*(x'). \quad (7.28)$$

In the special basis $\{w\}$, in which the density matrix is diagonal, this expression is reduced to

$$w(x, x') = \sum_j \psi_j(x) W_j \psi_j^*(x'). \quad (7.29)$$

Let us discuss the properties of this function. At coinciding arguments, $x' = x$, this is just the probability density:¹⁴

$$w(x, x) = \sum_j \psi_j(x) W_j \psi_j^*(x) = \sum_j w_j(x) W_j = w(x). \quad (7.30)$$

However, the density matrix gives more information about the system than just the probability density. As the simplest example, let us consider a pure quantum state, with $W_j = \delta_{jj'}$, so that $\psi(x) = \psi_j(x)$, and

$$w(x, x') = \psi_{j'}(x) \psi_{j'}^*(x') \equiv \psi(x) \psi^*(x'). \quad (7.31)$$

We see that the density matrix carries the information not only about the modulus but also the phase of the wavefunction. (Of course one may argue rather convincingly that in this ultimate limit the density-matrix description is redundant because all this information is contained in the wavefunction itself.)

How may be the density matrix interpreted? In the simple case (31), we can write

$$|w(x, x')|^2 \equiv w(x, x') w^*(x, x') = \psi(x) \psi^*(x) \psi(x') \psi^*(x') = w(x) w(x'), \quad (7.32)$$

so that the modulus squared of the density matrix is just as the joint probability density to find the system at the point x and the point x' . For example, for a simple wave packet with a spatial extent δx , $w(x, x')$ has an appreciable magnitude only if both points are not farther than $\sim \delta x$ from the packet center, and hence from each other. The interpretation becomes more complex if we deal with an incoherent mixture of several wavefunctions, for example, the classical mixture describing the thermodynamic equilibrium. In this case, we can use Eq. (24) to rewrite Eq. (29) as follows:

$$w(x, x') = \sum_n \psi_n(x) W_n \psi_n^*(x') = \frac{1}{Z} \sum_n \psi_n(x) \exp\left\{-\frac{E_n}{k_B T}\right\} \psi_n^*(x'). \quad (7.33)$$

As the simplest example, let us see what is the density matrix of a *free* (1D) particle in the thermal equilibrium. As we know very well by now, in this case, the set of energies $E_p = p^2/2m$ of stationary states (monochromatic waves) forms a continuum, so that we need to replace the sum (33) with an integral, using for example the “delta-normalized” traveling-wave eigenfunctions (4.264):

¹³ For now, I will focus on a fixed time instant (say, $t = 0$), and hence write $\psi(x)$ instead of $\Psi(x, t)$.

¹⁴ This fact is the origin of the density matrix’s name.

$$w(x, x') = \frac{1}{2\pi\hbar Z} \int_{-\infty}^{+\infty} \exp\left\{-\frac{ipx}{\hbar}\right\} \exp\left\{-\frac{p^2}{2mk_B T}\right\} \exp\left\{\frac{ipx'}{\hbar}\right\} dp. \quad (7.34)$$

This is a usual Gaussian integral, and may be worked out, as we have done repeatedly in Chapter 2 and beyond, by complementing the exponent to the full square of the momentum p plus a constant. The statistical sum Z may be also readily calculated,¹⁵

$$Z = (2\pi m k_B T)^{1/2}, \quad (7.35)$$

However, for what follows it is more useful to write the result for the product wZ (the so-called *un-normalized density matrix*):

$$w(x, x')Z = \left(\frac{mk_B T}{2\pi\hbar^2}\right)^{1/2} \exp\left\{-\frac{mk_B T(x - x')^2}{2\hbar^2}\right\}. \quad (7.36)$$

Free
particle:
thermal
equilibrium

This is a very interesting result: the density matrix depends only on the difference of its arguments, dropping to zero fast as the distance between the points x and x' exceeds the following characteristic scale (called the *correlation length*)

$$x_c \equiv \langle (x - x')^2 \rangle^{1/2} = \frac{\hbar}{(mk_B T)^{1/2}}. \quad (7.37)$$

Correlation
length

This length may be interpreted in the following way. It is straightforward to use Eq. (24) to verify that the average energy $\langle E \rangle = \langle p^2/2m \rangle$ of a free particle in the thermal equilibrium, i.e. in the classical mixture (33), equals $k_B T/2$. Hence the average magnitude of the particle's momentum may be estimated as

$$p_c \equiv \langle p^2 \rangle^{1/2} = (2m\langle E \rangle)^{1/2} = (mk_B T)^{1/2}, \quad (7.38)$$

so that x_c is of the order of the minimal length allowed by the Heisenberg-like “uncertainty relation”:

$$x_c = \hbar / p_c. \quad (7.39)$$

Note that with the growth of temperature, the correlation length (37) goes to zero, and the density matrix (36) tends to a delta function:

$$w(x, x')Z \Big|_{T \rightarrow \infty} \rightarrow \delta(x - x'). \quad (7.40)$$

Since in this limit the average kinetic energy of the particle is not smaller than its potential energy in *any* fixed potential profile, Eq. (40) is the general property of the density matrix (33).

Let us discuss the following curious feature of Eq. (36): if we replace $k_B T$ with $\hbar/i(t - t_0)$, and x' with x_0 , the un-normalized density matrix wZ for a free particle turns into the particle's propagator – cf. Eq. (2.49). This is not just an occasional coincidence. Indeed, in Chapter 2 we saw that the propagator of a system with an arbitrary stationary Hamiltonian may be expressed via the stationary eigenfunctions as

¹⁵ Due to the delta-normalization of the eigenfunction, the density matrix (34) for the free particle (and any system with a continuous eigenvalue spectrum) is normalized as

$$\int_{-\infty}^{+\infty} w(x, x')Z dx' = \int_{-\infty}^{+\infty} w(x, x')Z dx = 1.$$

$$G(x, t; x_0, t_0) = \sum_n \psi_n(x) \exp\left\{-i \frac{E_n}{\hbar}(t - t_0)\right\} \psi_n^*(x_0). \quad (7.41)$$

Comparing this expression with Eq. (33), we see that the replacements

$$\frac{i(t - t_0)}{\hbar} \rightarrow \frac{1}{k_B T}, \quad x_0 \rightarrow x', \quad (7.42)$$

turn the pure-state propagator G into the un-normalized density matrix wZ of the same system in thermodynamic equilibrium. This important fact, rooted in the formal similarity of the Gibbs distribution (24) with the Schrödinger equation's solution (1.69), enables a theoretical technique of the so-called *thermodynamic Green's functions*, which is especially productive in condensed matter physics.¹⁶

For our current purposes, we can employ Eq. (42) to re-use some of the wave mechanics results, in particular, the following formula for the harmonic oscillator's propagator

$$G(x, t; x_0, t_0) = \left(\frac{m\omega_0}{2\pi i \hbar \sin[\omega_0(t - t_0)]} \right)^{1/2} \exp\left\{ -\frac{m\omega_0[(x^2 + x_0^2)\cos[\omega_0(t - t_0)] - 2xx_0]}{2i\hbar \sin[\omega_0(t - t_0)]} \right\}. \quad (7.43)$$

which may be readily proved to satisfy the Schrödinger equation for the Hamiltonian (5.62), with the appropriate initial condition: $G(x, t_0; x_0, t_0) = \delta(x - x_0)$. Making the substitution (42), we immediately get

Harmonic oscillator in thermal equilibrium

$$w(x, x')Z = \left[\frac{m\omega_0}{2\pi i \hbar \sinh(\hbar\omega_0/k_B T)} \right]^{1/2} \exp\left\{ -\frac{m\omega_0[(x^2 + x'^2)\cosh(\hbar\omega_0/k_B T) - 2xx']}{2\hbar \sinh(\hbar\omega_0/k_B T)} \right\}. \quad (7.44)$$

As a sanity check, at very low temperatures, $k_B T \ll \hbar\omega_0$, both hyperbolic functions participating in this expression are very large and nearly equal, and it yields

$$w(x, x')Z|_{T \rightarrow 0} \rightarrow \left[\left(\frac{m\omega_0}{\pi\hbar} \right)^{1/4} \exp\left\{ -\frac{m\omega_0 x^2}{\hbar} \right\} \right] \times \exp\left\{ -\frac{\hbar\omega_0}{2k_B T} \right\} \times \left[\left(\frac{m\omega_0}{\pi\hbar} \right)^{1/4} \exp\left\{ -\frac{m\omega_0 x'^2}{\hbar} \right\} \right]. \quad (7.45)$$

In each of the expressions in square brackets we can readily recognize the ground state's wavefunction (2.275) of the oscillator, while the middle exponent is just the statistical sum (24) in the low-temperature limit when it is dominated by the ground-level contribution:

$$Z|_{T \rightarrow 0} \rightarrow \exp\left\{ -\frac{\hbar\omega_0}{2k_B T} \right\}. \quad (7.46)$$

As a result, Z in both parts of Eq. (45) may be canceled, and the density matrix in this limit is described by Eq. (31), with the ground state as the only state of the system. This is natural when the temperature is too low for the thermal excitation of any other state.

¹⁶ I will have no time to discuss this technique and have to refer the interested reader to special literature. Probably, the most famous text of that field is A. Abrikosov, L. Gor'kov, and I. Dzyaloshinski, *Methods of Quantum Field Theory in Statistical Physics*, Prentice-Hall, 1963. (Later reprintings are available from Dover.)

Returning to arbitrary temperatures, Eq. (44) in coinciding arguments gives the following expression for the probability density:¹⁷

$$w(x, x)Z \equiv w(x)Z = \left[\frac{m\omega_0}{2\pi\hbar \sinh(\hbar\omega_0/k_B T)} \right]^{1/2} \exp\left\{ -\frac{m\omega_0 x^2}{\hbar} \tanh \frac{\hbar\omega_0}{2k_B T} \right\}. \quad (7.47)$$

This is just a Gaussian function of x , with the following variance:

$$\langle x^2 \rangle = \frac{\hbar}{2m\omega_0} \coth \frac{\hbar\omega_0}{2k_B T}. \quad (7.48)$$

To compare this result with our earlier ones, it is useful to recast it as

$$\langle U \rangle = \frac{m\omega_0^2}{2} \langle x^2 \rangle = \frac{\hbar\omega_0}{4} \coth \frac{\hbar\omega_0}{2k_B T}. \quad (7.49)$$

Comparing this expression with Eq. (26), we see that the average value of potential energy is exactly one-half of the total energy – the other half being the average kinetic energy. This is what we could expect, because according to Eqs. (5.96)-(5.97), such relation holds for each Fock state and hence should also hold for their classical mixture.

Unfortunately, besides the trivial case (30) of coinciding arguments, it is hard to give a straightforward interpretation of the density function in terms of the system's measurements. This is a fundamental difficulty, which has been well explored in terms of the *Wigner function* (sometimes called the “Wigner-Ville distribution”)¹⁸ defined as

$$W(X, P) \equiv \frac{1}{2\pi\hbar} \int w\left(X + \frac{\tilde{X}}{2}, X - \frac{\tilde{X}}{2}\right) \exp\left\{-\frac{iP\tilde{X}}{\hbar}\right\} d\tilde{X}. \quad (7.50)$$

[Wigner function: definition](#)

From the mathematical standpoint, this is just the Fourier transform of the density matrix in one of two new coordinates defined by the following relations (see Fig. 2):

$$X \equiv \frac{x+x'}{2}, \quad \tilde{X} \equiv x-x', \quad \text{so that } x \equiv X + \frac{\tilde{X}}{2}, \quad x' \equiv X - \frac{\tilde{X}}{2}. \quad (7.51)$$

Physically, the new argument X may be interpreted as the average position of the particle during the time interval $(t-t')$, while \tilde{X} , as the distance passed by it during that time interval, so that P characterizes the momentum of the particle during that motion. As a result, the Wigner function is a mathematical construct intended to characterize the system's probability distribution simultaneously in the coordinate and the momentum space – for 1D systems, on the phase plane $[X, P]$, which we had discussed earlier – see Fig. 5.8. Let us see how fruitful this intention is.

¹⁷ I have to confess that this notation is imperfect, because strictly speaking, $w(x, x')$ and $w(x)$ are different functions, and so are the functions $w(p, p')$ and $w(p)$ used below. In the perfect world, I would use different letters for them all, but I desperately want to stay with “ w ” for all the probability densities, and there are not so many good fonts for this letter. Let me hope that the difference between these functions is clear from their arguments and the context.

¹⁸ It was introduced in 1932 by Eugene Wigner on the basis of a general (*Weyl-Wigner*) transform suggested by Hermann Weyl in 1927 and re-derived in 1948 by Jean Ville on a different mathematical basis.

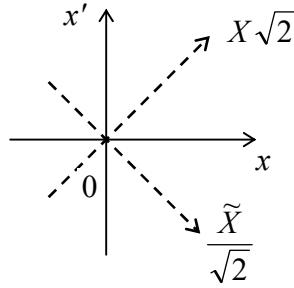

Fig. 7.2. The coordinates X and \tilde{X} employed in the Weyl-Wigner transform (50). They differ from the coordinates obtained by the rotation of the reference frame by the angle $\pi/4$ only by factors $\sqrt{2}$ and $1/\sqrt{2}$, describing scale stretch.

First of all, we may write the Fourier transform reciprocal to Eq. (50):

$$w\left(X + \frac{\tilde{X}}{2}, X - \frac{\tilde{X}}{2}\right) = \int W(X, P) \exp\left\{\frac{iP\tilde{X}}{\hbar}\right\} dP. \quad (7.52)$$

For the particular case $\tilde{X} = 0$, this relation yields

$$w(X) \equiv w(X, X) = \int W(X, P) dP. \quad (7.53)$$

Hence the integral of the Wigner function over the momentum P gives the probability density to find the system at point X – just as it does for a classical distribution function $w_{\text{cl}}(X, P)$.¹⁹

Next, the Wigner function has the similar property for integration over X . To prove this fact, we may first introduce the momentum representation of the density matrix, in full analogy with its coordinate representation (27):

$$w(p, p') \equiv \langle p | \hat{w} | p' \rangle. \quad (7.54)$$

Inserting, as usual, two identity operators, in the form given by Eq. (4.252), into the right-hand side of this equality, we get the following relation between the momentum and coordinate representations:

$$w(p, p') = \iint dx dx' \langle p | x \rangle \langle x | \hat{w} | x' \rangle \langle x' | p' \rangle = \frac{1}{2\pi\hbar} \iint dx dx' \exp\left\{-\frac{ipx}{\hbar}\right\} w(x, x') \exp\left\{+\frac{ip'x'}{\hbar}\right\}. \quad (7.55)$$

This is of course nothing else than the unitary transform of an operator from the x -basis to the p -basis, similar to the first form of Eq. (4.272). For coinciding arguments, $p = p'$, Eq. (55) is reduced to

$$w(p) \equiv w(p, p) = \frac{1}{2\pi\hbar} \iint dx dx' w(x, x') \exp\left\{-\frac{ip(x-x')}{\hbar}\right\}. \quad (7.56)$$

Now using Eq. (29) and then Eq. (4.265), this function may be represented as

$$w(p) = \frac{1}{2\pi\hbar} \sum_j W_j \iint dx dx' \psi_j(x) \psi_j^*(x) \exp\left\{-\frac{ip(x-x')}{\hbar}\right\} = \sum_j W_j \varphi_j(p) \varphi_j^*(p), \quad (7.57)$$

and hence interpreted as the probability density of the particle's momentum at value p . Now, in the variables (51), Eq. (56) has the form

¹⁹ Such function, used to express the probability dW to find the system in a small area of the phase plane as $dW = w_{\text{cl}}(X, P)dXdP$, is a major notion of the (1D) classical statistics – see, e.g., SM Sec. 2.1.

$$w(p) = \frac{1}{2\pi\hbar} \int \int w\left(X + \frac{\tilde{X}}{2}, X - \frac{\tilde{X}}{2}\right) \exp\left\{-\frac{ip\tilde{X}}{\hbar}\right\} d\tilde{X} dX. \quad (7.58)$$

Comparing this equality with the definition (50) of the Wigner function, we see that

$$w(P) = \int W(X, P) dX. \quad (7.59)$$

Thus, according to Eqs. (53) and (59), the integrals of the Wigner function over either the coordinate or momentum give the probability densities to find the system at a certain value of the counterpart variable. This is of course the main requirement to any quantum-mechanical candidate for the best analog of the classical probability density, $w_c(X, P)$.

Let us see at how does the Wigner function look for the simplest systems at thermodynamic equilibrium. For a free 1D particle, we can use Eq. (34), ignoring for simplicity the normalization issues:

$$W(X, P) \propto \int_{-\infty}^{+\infty} \exp\left\{-\frac{mk_B T \tilde{X}^2}{2\hbar^2}\right\} \exp\left\{-\frac{iP\tilde{X}}{\hbar}\right\} d\tilde{X}. \quad (7.60)$$

The usual Gaussian integration yields:

$$W(X, P) = \text{const} \times \exp\left\{-\frac{P^2}{2mk_B T}\right\}. \quad (7.61)$$

We see that the function is independent of X (as it should be for this translational-invariant system), and coincides with the Gibbs distribution (24). We could get the same result directly from classical statistics. This is natural because as we know from Sec. 2.2, the free motion is essentially not quantized – at least in terms of its energy and momentum.

Now let us consider a substantially quantum system, the harmonic oscillator. Plugging Eq. (44) into Eq. (50), for that system in thermal equilibrium it is easy to show (and hence is left for reader's exercise) that the Wigner function is also Gaussian, now in both its arguments:

$$W(X, P) = \text{const} \times \exp\left\{-C\left[\frac{m\omega_0^2 X^2}{2} + \frac{P^2}{2m}\right]\right\}, \quad (7.62)$$

though the coefficient C is now different from $1/k_B T$, and tends to that limit only at high temperatures, $k_B T \gg \hbar\omega_0$. Moreover, for a Glauber state, the Wigner function also gives a very plausible result – a Gaussian distribution similar to Eq. (62), but properly shifted from the origin to the central point of the state – see Sec. 5.5.²⁰

Unfortunately, for some other possible states of the harmonic oscillator, e.g., any pure Fock state with $n > 0$, the Wigner function takes negative values in some regions of the $[X, P]$ plane – see Fig. 3.²¹ (Such plots were the basis of my, admittedly very imperfect, classical images of the Fock states in Fig. 5.8.)

²⁰ Please note that in the notation of Sec. 5.5, the capital letters X and P mean not the arguments of the Wigner function, but the Cartesian coordinates of the central point (5.102), i.e. the classical complex amplitude of the oscillations.

²¹ Spectacular experimental measurements of this function (for $n = 0$ and $n = 1$) were carried out recently by E. Bimbard *et al.*, *Phys. Rev. Lett.* **112**, 033601 (2014).

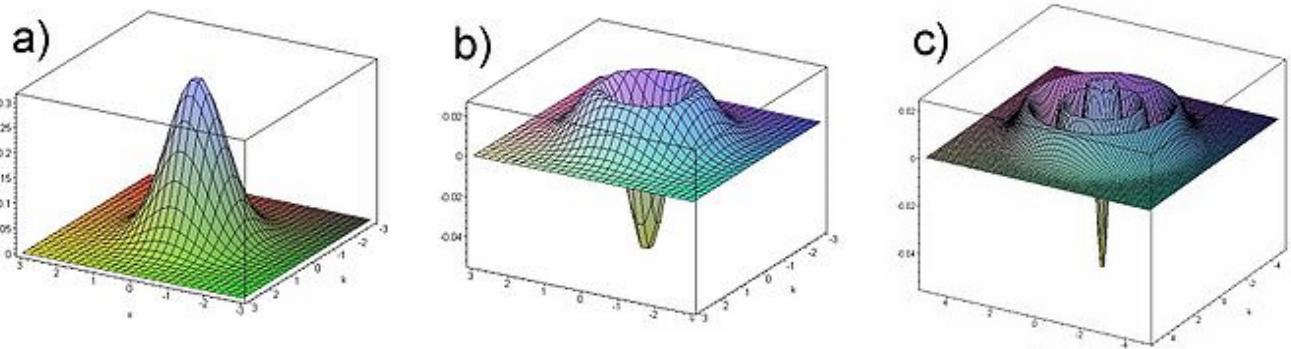

Fig. 7.3. The Wigner functions $W(X, P)$ of a harmonic oscillator, in a few of its stationary (Fock) states n : (a) $n = 0$, (b) $n = 1$; (c) $n = 5$. Graphics by J. S. Lundeen; adapted from http://en.wikipedia.org/wiki/Wigner_function as a public-domain material.

The same is true for most other quantum systems and their states. Indeed, this fact could be predicted just by looking at the definition (50) applied to a pure quantum state, in which the density function may be factored – see Eq. (31):

$$W(X, P) = \frac{1}{2\pi\hbar} \int \psi\left(X + \frac{\tilde{X}}{2}\right) \psi^*\left(X - \frac{\tilde{X}}{2}\right) \exp\left\{-\frac{iP\tilde{X}}{\hbar}\right\} d\tilde{X}. \quad (7.63)$$

Changing the argument P (say, at fixed X), we are essentially changing the spatial “frequency” (wave number) of the wavefunction product’s Fourier component we are calculating, and we know that their Fourier images typically change sign as the frequency is changed. Hence the wavefunctions should have some high-symmetry properties to avoid this effect. Indeed, the Gaussian functions (describing, for example, the Glauber states, and in their particular case, the ground state of the harmonic oscillator) have such symmetry, but many other functions do not.

Hence if the Wigner function was taken seriously as the quantum-mechanical analog of the classical probability density $w_{\text{cl}}(X, P)$, we would need to interpret the negative probability of finding the particle in certain elementary intervals $dXdP$ – which is hard to do. However, the function is still used for a semi-quantitative interpretation of mixed states of quantum systems.

7.3. Open system dynamics: Dephasing

So far we have discussed the density operator as something *given* at a particular time instant. Now let us discuss how it *formed*, i.e. its evolution in time, starting from the simplest case when the probabilities W_j participating in Eq. (15) are *time-independent* – by this or that reason, to be discussed in a moment. In this case, in the Schrödinger picture, we may rewrite Eq. (15) as

$$\hat{w}(t) = \sum_j |w_j(t)\rangle W_j \langle w_j(t)|. \quad (7.64)$$

Taking a time derivative of both sides of this equation, multiplying them by $i\hbar$, and applying Eq. (4.158) to the basis states w_j , with the account of the fact that the Hamiltonian operator is Hermitian, we get

$$\begin{aligned}
i\hbar\dot{\hat{w}} &= i\hbar \sum_j \left(|\dot{w}_j(t)\rangle W_j \langle w_j(t)| + |w_j(t)\rangle W_j \langle \dot{w}_j(t)| \right) \\
&= \sum_j \left(\hat{H} |w_j(t)\rangle W_j \langle w_j(t)| - |w_j(t)\rangle W_j \langle w_j(t)| \hat{H} \right) \\
&\equiv \hat{H} \sum_j |w_j(t)\rangle W_j \langle w_j(t)| - \sum_j |w_j(t)\rangle W_j \langle w_j(t)| \hat{H}.
\end{aligned} \tag{7.65}$$

Now using Eq. (64) again (twice), we get the so-called *von Neumann equation*²²

$$i\hbar\dot{\hat{w}} = [\hat{H}, \hat{w}]. \tag{7.66}$$
von Neumann
equation

Note that this equation is similar in structure to Eq. (4.199) describing the time evolution of time-independent operators in the Heisenberg picture operators:

$$i\hbar\dot{\hat{A}} = [\hat{A}, \hat{H}], \tag{7.67}$$

besides the opposite order of the operators in the commutator – equivalent to the change of sign of the right-hand side. This should not be too surprising, because Eq. (66) belongs to the Schrödinger picture of quantum dynamics, while Eq. (67), to its Heisenberg picture.

The most important case when the von Neumann equation is (approximately) valid is when the “own” Hamiltonian \hat{H}_s of the system s of our interest is time-independent, and its interaction with the environment is so small that its effect on the system’s evolution during the considered time interval is negligible, but it had lasted so long that it gradually put the system into a non-pure state – for example, but not necessarily, into the classical mixture (24).²³ (This is an example of the second case discussed in Sec. 1, when we need the mixed-ensemble description of the system even if its current interaction with the environment is negligible.) If the interaction with the environment is stronger, and hence is not negligible at the considered time interval, Eq. (66) is generally *not* valid,²⁴ because the probabilities W_j may change in time. However, this equation may still be used for a discussion of one major effect of the environment, namely *dephasing* (also called “decoherence”), within a simple model.

Let us start with the following general model a system interacting with its environment, which will be used throughout this chapter:

$$\hat{H} = \hat{H}_s + \hat{H}_e \{\lambda\} + \hat{H}_{\text{int}}, \tag{7.68}$$
Interaction
with
environment

²² In some texts, it is called the “Liouville equation”, due to its philosophical proximity to the classical Liouville theorem for the classical distribution function $w_{\text{cl}}(X, P)$ – see, e.g., SM Sec. 6.1 and in particular Eq. (6.5).

²³ In the last case, the statistical operator is diagonal in the stationary state basis and hence commutes with the Hamiltonian. Hence the right-hand side of Eq. (66) vanishes, and it shows that in this basis, the density matrix is completely time-independent.

²⁴ Very unfortunately, this fact is not explained in some textbooks, which quote the von Neumann equation without proper qualifications.

where $\{\lambda\}$ denotes the (huge) set of degrees of freedom of the environment.²⁵ Evidently, this model is useful only if we may somehow tame the enormous size of the Hilbert space of these degrees of freedom, and so work out the calculations all way to a practicably simple result. This turns out to be possible mostly if the elementary act of interaction of the system and its environment is in some sense small. Below, I will describe several cases when this is true; the classical example is the *Brownian particle* interacting with the molecules of the surrounding gas or fluid.²⁶ (In this example, a single hit by a molecule changes the particle's momentum by a minor fraction.) On the other hand, the model (68) is not very productive for a particle interacting with the environment consisting of *similar* particles, when a single collision may change its momentum dramatically. In such cases, the methods discussed in the next chapter are more relevant.

Now let us analyze a very simple model of an open two-level quantum system, with its intrinsic Hamiltonian having the form

$$\hat{H}_s = c_z \hat{\sigma}_z, \quad (7.69)$$

similar to the Pauli Hamiltonian (4.163),²⁷ and a factorable, bilinear interaction – cf. Eq. (6.145) and its discussion:

$$\hat{H}_{\text{int}} = \hat{f}\{\lambda\} \hat{\sigma}_z, \quad (7.70)$$

where \hat{f} is a Hermitian operator depending only on the set $\{\lambda\}$ of environmental degrees of freedom (“coordinates”), defined in their Hilbert space – different from that of the two-level system. As a result, the operators $\hat{f}\{\lambda\}$ and $\hat{H}_e\{\lambda\}$ commute with $\hat{\sigma}_z$ – and with any other intrinsic operator of the two-level system. Of course, any realistic $\hat{H}_e\{\lambda\}$ is extremely complex, so that how much we will be able to achieve without specifying it, may be a pleasant surprise for the reader.

Before we proceed to the analysis, let us recognize two examples of two-level systems that may be described by this model. The first example is a spin- $1/2$ in an external magnetic field of a fixed direction (taken for the axis z), which includes both an average component $\bar{\mathcal{B}}$ and a random (fluctuating) component $\tilde{\mathcal{B}}_z(t)$ induced by the environment. As it follows from Eq. (4.163b), it may be described by the Hamiltonian (68)-(70) with

$$c_z = -\frac{\hbar\gamma}{2} \bar{\mathcal{B}}_z, \quad \text{and} \quad \hat{f} = -\frac{\hbar\gamma}{2} \hat{\tilde{\mathcal{B}}}_z(t). \quad (7.71)$$

²⁵ Note that by writing Eq. (68), we are treating the whole system, including the environment, as a Hamiltonian one. This can always be done if the accounted part of the environment is large enough so that the processes in the system s of our interest do not depend on the type of boundary between this part and the “external” (even larger) environment; in particular, we may assume the total system to be closed, i.e. Hamiltonian.

²⁶ The theory of the Brownian motion, the effect first observed experimentally by biologist Robert Brown in the 1820s, was pioneered by Albert Einstein in 1905 and developed in detail by Marian Smoluchowski in 1906-1907 and Adriaan Fokker in 1913. Due to this historic background, in some older texts, the approach described in the balance of this chapter is called the “quantum theory of the Brownian motion”. Let me, however, emphasize that due to the later progress of experimental techniques, quantum-mechanical behaviors, including the environmental effects in them, have been observed in a rapidly growing number of various quasi-macroscopic systems, for which this approach is quite applicable. In particular, this is true for most systems being explored as possible qubits of prospective quantum computing and encryption systems – see Sec. 8.5 below.

²⁷ As we know from Secs. 4.6 and 5.1, such Hamiltonian is sufficient to lift the energy level degeneracy.

Another example is a particle in a symmetric double-well potential $U_s(x)$ (Fig. 4), with a barrier between them sufficiently high to be practically impenetrable, and an additional force $F(t)$, exerted by the environment, so that the total potential energy is $U(x, t) = U_s(x) - F(t)x$. If the force, including its static part \bar{F} and fluctuations $\tilde{F}(t)$, is sufficiently weak, we can neglect its effects on the shape of potential wells and hence on the localized wavefunctions $\psi_{L,R}$, so that the force effect is reduced to the variation of the difference $E_L - E_R = F(t)\Delta x$ between the eigenenergies. As a result, the system may be described by Eqs. (68)-(70) with

$$c_z = -\bar{F}\Delta x/2; \quad \hat{f} = -\tilde{F}(t)\Delta x/2. \quad (7.72)$$

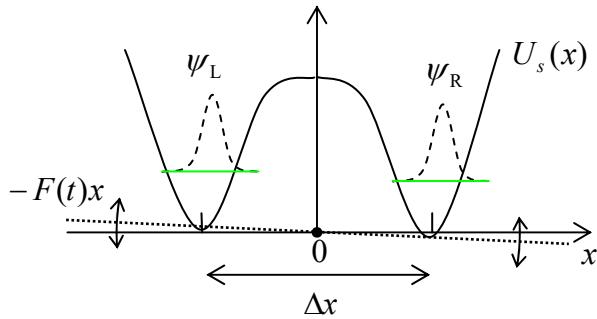

Fig. 7.4. Dephasing in a double-well system.

Let us start our general analysis of the model described by Eqs. (68)-(70) by writing the equation of motion for the Heisenberg operator $\hat{\sigma}_z(t)$:

$$i\hbar\dot{\hat{\sigma}}_z = [\hat{\sigma}_z, \hat{H}] = (c_z + \hat{f})[\hat{\sigma}_z, \hat{\sigma}_z] = 0, \quad (7.73)$$

showing that in our simple model (68)-(70), the operator $\hat{\sigma}_z$ does not evolve in time. What does this mean for the observables? For an arbitrary density matrix of any two-level system,

$$w = \begin{pmatrix} w_{11} & w_{12} \\ w_{21} & w_{22} \end{pmatrix}, \quad (7.74)$$

we can readily calculate the trace of operator $\hat{\sigma}_z w$. Indeed, since the operator traces are basis-independent, we can do this in any basis, in particular in the usual z -basis:

$$\text{Tr}(\hat{\sigma}_z w) = \text{Tr}(\sigma_z w) = \text{Tr} \left[\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} w_{11} & w_{12} \\ w_{21} & w_{22} \end{pmatrix} \right] = w_{11} - w_{22} = W_1 - W_2. \quad (7.75)$$

Since, according to Eq. (5), $\hat{\sigma}_z$ may be considered the operator for the difference of the number of particles in the basis states 1 and 2, in the case (73) the difference $W_1 - W_2$ does not depend on time, and since the sum of these probabilities is also fixed, $W_1 + W_2 = 1$, both of them are constant. The physics of this simple result is especially clear for the model shown in Fig. 4: since the potential barrier separating the potential wells is so high that tunneling through it is negligible, the interaction with the environment cannot move the system from one well into another one.

It may look like nothing interesting may happen in such a simple situation, but in a minute we will see that this is not true. Due to the time independence of W_1 and W_2 , we may use the von Neumann equation (66) to describe the density matrix evolution. In the usual z -basis:

$$\begin{aligned} i\hbar \dot{\mathbf{w}} &\equiv i\hbar \begin{pmatrix} \dot{w}_{11} & \dot{w}_{12} \\ \dot{w}_{21} & \dot{w}_{22} \end{pmatrix} = [\mathbf{H}, \mathbf{w}] \equiv (c_z + \hat{f})[\sigma_z, \mathbf{w}] \\ &\equiv (c_z + \hat{f}) \left[\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \begin{pmatrix} w_{11} & w_{12} \\ w_{21} & w_{22} \end{pmatrix} \right] = (c_z + \hat{f}) \begin{pmatrix} 0 & 2w_{12} \\ -2w_{21} & 0 \end{pmatrix}. \end{aligned} \quad (7.76)$$

This result means that while the diagonal elements, i.e., the probabilities of the states, do not evolve in time (as we already know), the off-diagonal elements do change; for example,

$$i\hbar \dot{w}_{12} = 2(c_z + \hat{f})w_{12}, \quad (7.77)$$

with a similar but complex-conjugate equation for w_{21} . The solution of this linear differential equation (77) is straightforward, and yields

$$w_{12}(t) = w_{12}(0) \exp \left\{ -i \frac{2c_z}{\hbar} t \right\} \exp \left\{ -i \frac{2}{\hbar} \int_0^t \hat{f}(t') dt' \right\}. \quad (7.78)$$

The first exponent is a deterministic c -number factor, while in the second one $\hat{f}(t) \equiv \hat{f}\{\lambda(t)\}$ is still an operator in the Hilbert space of the environment, but from the point of view of the two-level system of our interest, it is a random function of time. The time-average part of this function may be included in c_z , so in what follows, we will assume that it equals zero.

Let us start from the limit when the environment behaves classically.²⁸ In this case, the operator in Eq. (78) may be considered as a *classical* random function of time $f(t)$, provided that we average its effects over a statistical ensemble of many functions $f(t)$ describing many (macroscopically similar) experiments. For a small time interval $t = dt \rightarrow 0$, we can use the Taylor expansion of the exponent, truncating it after the quadratic term:

$$\begin{aligned} \left\langle \exp \left\{ -i \frac{2}{\hbar} \int_0^t f(t') dt' \right\} \right\rangle &\approx 1 + \left\langle -i \frac{2}{\hbar} \int_0^t f(t') dt' \right\rangle + \left\langle \frac{1}{2} \left(-i \frac{2}{\hbar} \int_0^t f(t') dt' \right) \left(-i \frac{2}{\hbar} \int_0^t f(t'') dt'' \right) \right\rangle \\ &\equiv 1 - i \frac{2}{\hbar} \int_0^t \langle f(t') \rangle dt' - \frac{2}{\hbar^2} \int_0^t dt' \int_0^t dt'' \langle f(t') f(t'') \rangle \equiv 1 - \frac{2}{\hbar^2} \int_0^t dt' \int_0^t dt'' K_f(t' - t''). \end{aligned} \quad (7.79)$$

Here we have used the facts that the statistical average of $f(t)$ is equal to zero, while the second average, called the *correlation function*, in a statistically- (i.e. macroscopically-) stationary state of any environment may only depend on the time difference $\tau \equiv t' - t''$:

$$\langle f(t') f(t'') \rangle = K_f(t' - t'') \equiv K_f(\tau). \quad (7.80)$$

If this difference is much larger than some time scale τ_c , called the *correlation time* of the environment, the values $f(t')$ and $f(t'')$ are completely independent (*uncorrelated*), as illustrated in Fig. 5a, so that at $\tau \rightarrow \infty$, the correlation function has to tend to zero. On the other hand, at $\tau = 0$, i.e. $t' = t''$, the correlation function is just the variance of f :

²⁸ This assumption is not in contradiction with the need for the quantum treatment of the two-level system s , because a typical environment is large, and hence has a very dense energy spectrum, with the distances adjacent levels that may be readily bridged by thermal excitations of small energies, often making it essentially classical.

$$K_f(0) = \langle f^2 \rangle, \quad (7.81)$$

and has to be positive. As a result, the function looks (semi-quantitatively) as shown in Fig. 5b.

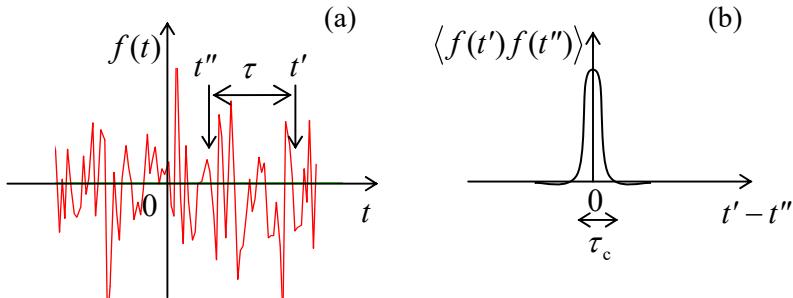

Fig. 7.5. (a) A typical random process and (b) its correlation function – schematically.

Hence, if we are only interested in time differences τ much longer than τ_c , which is typically very short, we may approximate $K_f(\tau)$ well with a delta function of the time difference. Let us take it in the following form, convenient for later discussion:

$$K_f(\tau) \approx \hbar^2 D_\phi \delta(\tau), \quad (7.82)$$

Phase diffusion coefficient

where D_ϕ is a positive constant called the *phase diffusion coefficient*. The origin of this term stems from the very similar effect of classical diffusion of Brownian particles in a highly viscous medium. Indeed, the particle's velocity in such a medium is approximately proportional to the external force. Hence, if the random hits of a particle by the medium's molecules may be described by a force that obeys a law similar to Eq. (82), the velocity (along any Cartesian coordinate) is also *delta-correlated*:

$$\langle v(t) \rangle = 0, \quad \langle v(t')v(t'') \rangle = 2D\delta(t' - t''). \quad (7.83)$$

Now we can integrate the kinematic relation $\dot{x} = v$, to calculate particle's displacement from its initial position during a time interval $[0, t]$ and its variance:

$$x(t) - x(0) = \int_0^t v(t') dt', \quad (7.84)$$

$$\langle (x(t) - x(0))^2 \rangle = \left\langle \int_0^t v(t') dt' \int_0^t v(t'') dt'' \right\rangle = \int_0^t dt' \int_0^t dt'' \langle v(t')v(t'') \rangle = \int_0^t dt' \int_0^t dt'' 2D\delta(t' - t'') = 2Dt. \quad (7.85)$$

This is the famous law of diffusion, showing that the r.m.s. deviation of the particle from the initial point grows with time as $(2Dt)^{1/2}$, where the constant D is called the *diffusion coefficient*.

Returning to the diffusion of the quantum-mechanical phase, with Eq. (82) the last double integral in Eq. (79) yields $\hbar^2 D_\phi dt$, so that the statistical average of Eq. (78) is

$$\langle w_{12}(dt) \rangle = w_{12}(0) \exp \left\{ -i \frac{2c_z}{\hbar} dt \right\} (1 - 2D_\phi dt). \quad (7.86)$$

Applying this formula to sequential time intervals,

$$\langle w_{12}(2dt) \rangle = \langle w_{12}(dt) \rangle \exp \left\{ -i \frac{2c_z}{\hbar} dt \right\} (1 - 2D_\phi dt) = w_{12}(0) \exp \left\{ -i \frac{2c_z}{\hbar} 2dt \right\} (1 - 2D_\phi dt)^2, \quad (7.87)$$

etc., for a finite time $t = Ndt$, in the limit $N \rightarrow \infty$ and $dt \rightarrow 0$ (at fixed t) we get

$$\langle w_{12}(t) \rangle = w_{12}(0) \exp\left\{-i \frac{2c_z}{\hbar} t\right\} \times \lim_{N \rightarrow \infty} \left(1 - 2D_\phi t \frac{1}{N}\right)^N. \quad (7.88)$$

By the definition of the natural logarithm base e ,²⁹ this limit is just $\exp\{-2D_\phi t\}$, so that, finally:

Two-level system:
dephasing

$$\langle w_{12}(t) \rangle = w_{12}(0) \exp\left\{-i \frac{2a}{\hbar} t\right\} \exp\{-2D_\phi t\} \equiv w_{12}(0) \exp\left\{-i \frac{2a}{\hbar} t\right\} \exp\left\{-\frac{t}{T_2}\right\}. \quad (7.89)$$

So, due to coupling to the environment, the off-diagonal elements of the density matrix decay with some *dephasing time* $T_2 = 1/2D_\phi$, providing a natural evolution from the density matrix (22) of a pure state to the diagonal matrix (23), with the same probabilities $W_{1,2}$, describing a fully dephased (incoherent) classical mixture.³⁰

This simple model offers a very clear look at the nature of the decoherence: the random “force” $f(t)$, exerted by the environment, “shakes” the energy difference between two eigenstates of the system and hence the instantaneous velocity $2(c_z + f)/\hbar$ of their mutual phase shift $\phi(t)$ – cf. Eq. (22). Due to the randomness of the force, $\phi(t)$ performs a random walk around the trigonometric circle, so that the average of its trigonometric functions $\exp\{\pm i\phi\}$ over time gradually tends to zero, killing the off-diagonal elements of the density matrix. Our analysis, however, has left open two important issues:

- (i) Is this approach valid for a *quantum* description of a typical environment?
- (ii) If yes, what is physically the D_ϕ that was formally defined by Eq. (82)?

7.4. Fluctuation-dissipation theorem

Similar questions may be asked about a more general situation, when the Hamiltonian \hat{H}_s of the system of interest (s), in the composite Hamiltonian (68), is not specified at all, but the interaction between that system and its environment still has a bilinear form similar to Eqs. (70) and (6.130):

$$\hat{H}_{\text{int}} = -\hat{F}\{\lambda\} \hat{x}, \quad (7.90)$$

where x is some observable of our system s – say, its generalized coordinate or generalized momentum. It may look incredible that in this very general situation one still can make a very simple and powerful statement about the statistical properties of the generalized force F , under only two (interrelated) conditions – which are satisfied in a huge number of cases of interest:

- (i) the coupling of system s of interest to its environment e is weak – in the sense that the perturbation theory (see Chapter 6) is applicable, and

²⁹ See, e.g., MA Eq. (1.2a) with $n = -N/2D_\phi t$.

³⁰ Note that this result is valid only if the approximation (82) may be applied at time interval dt which, in turn, should be much smaller than the T_2 in Eq. (88), i.e. if the dephasing time is much longer than the environment’s correlation time τ_c . This requirement may be always satisfied by making the coupling to the environment sufficiently weak. In addition, in typical environments, τ_c is very short. For example, in the original Brownian motion experiments with a-few-μm pollen grains in water, it is of the order of the average interval between sequential molecular impacts, of the order of 10^{-21} s.

(ii) the environment may be considered as staying in thermodynamic equilibrium, with a certain temperature T , regardless of the process in the system of interest.³¹

This famous statement is called the *fluctuation-dissipation theorem* (FDT).³² Due to the importance of this fundamental result, let me derive it.³³ Since by writing Eq. (68) we treat the whole system ($s + e$) as a Hamiltonian one, we may use the Heisenberg equation (4.199) to write

$$i\hbar \dot{\hat{F}} = [\hat{F}, \hat{H}] = [\hat{F}, \hat{H}_e], \quad (7.91)$$

because, as was discussed in the last section, operator $\hat{F}\{\lambda\}$ commutes with both \hat{H}_s and \hat{x} . Generally, very little may be done with this equation, because the time evolution of the environment's Hamiltonian depends, in turn, on that of the force. This is where the perturbation theory becomes indispensable. Let us decompose the force operator into the following sum:

$$\hat{F}\{\lambda\} = \langle \hat{F} \rangle + \hat{\tilde{F}}(t), \quad \text{with } \langle \hat{\tilde{F}}(t) \rangle = 0, \quad (7.92)$$

where (here and on, until further notice) the sign $\langle \dots \rangle$ means the statistical averaging *over the environment alone*, i.e. over an ensemble with absolutely similar evolutions of the system s , but random states of its environment.³⁴ From the point of view of the system s , the first term of the sum (still an operator!) describes the average response of the environment to the system dynamics (possibly, including such irreversible effects as friction), and has to be calculated with a proper account of their interaction – as we will do later in this section. On the other hand, the last term in Eq. (92) represents random *fluctuations* of the environment, which exist even in the absence of the system s . Hence, in the first non-zero approximation in the interaction strength, the fluctuation part may be calculated ignoring the interaction, i.e. treating the environment as being in thermodynamic equilibrium:

$$i\hbar \dot{\hat{\tilde{F}}} = \left[\hat{\tilde{F}}, \hat{H}_e \Big|_{\text{eq}} \right]. \quad (7.93)$$

Since in this approximation the environment's Hamiltonian does not have an explicit dependence on time, the solution of this equation may be written by combining Eqs. (4.190) and (4.175):

³¹ The most frequent example of the violation of this condition is the environment's overheating by the energy flow from system s . Let me leave it to the reader to estimate the overheating of a standard physical laboratory room by a typical dissipative quantum process – the emission of an optical photon by an atom. (*Hint*: it is extremely small.)

³² The FDT was first derived by Herbert Callen and Theodore Allen Welton in 1951, on the background of an earlier derivation of its classical limit by Harry Nyquist in 1928.

³³ The FDT may be proved in several ways that are shorter than the one given below – see, e.g., either the proof in SM Secs. 5.5 and 5.6 (based on H. Nyquist's arguments), or the original paper by H. Callen and T. Welton, *Phys. Rev.* **83**, 34 (1951) – wonderful in its clarity. The longer approach I will describe here, besides giving the important *Green-Kubo formula* (109) as a byproduct, is a very useful exercise in the operator manipulation and the perturbation theory in its integral form – different from the differential forms used in Chapter 6. If the reader is not interested in this exercise, they may skip the derivation and jump straight to the result expressed by Eq. (134), which uses the notions defined by Eqs. (114) and (123).

³⁴ For usual (“ergodic”) environments, without intrinsic long-term memories, this statistical averaging over an ensemble of environments is equivalent to averaging over intermediate times – much longer than the correlation time τ_c of the environment, but still much shorter than the characteristic time of evolution of the system under analysis, such as the dephasing time T_2 and the energy relaxation time T_1 – both still to be calculated.

$$\hat{F}(t) = \exp\left\{ +\frac{i}{\hbar} \hat{H}_e |_{\text{eq}} t \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e |_{\text{eq}} t \right\}. \quad (7.94)$$

Let us use this relation to calculate the correlation function of the fluctuations $F(t)$, defined similarly to Eq. (80), but taking care of the order of the time arguments (very soon we will see why):

$$\langle \tilde{F}(t)\tilde{F}(t') \rangle = \left\langle \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t \right\} \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t' \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t' \right\} \right\rangle. \quad (7.95)$$

(Here, for the notation brevity, the thermal equilibrium of the environment is just implied.) We may calculate this expectation value in any basis, and the best choice for it is evident: in the environment's stationary-state basis, the density operator of the environment, its Hamiltonian, and hence the exponents in Eq. (95) are all represented by diagonal matrices. Using Eq. (5), the correlation function becomes

$$\begin{aligned} \langle \tilde{F}(t)\tilde{F}(t') \rangle &= \text{Tr} \left[\hat{w} \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t \right\} \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t' \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t' \right\} \right] \\ &\equiv \sum_n \left[\hat{w} \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t \right\} \exp\left\{ +\frac{i}{\hbar} \hat{H}_e t' \right\} \hat{F}(0) \exp\left\{ -\frac{i}{\hbar} \hat{H}_e t' \right\} \right]_{nn} \\ &= \sum_{n,n'} W_n \exp\left\{ +\frac{i}{\hbar} E_n t \right\} \hat{F}_{nn'} \exp\left\{ -\frac{i}{\hbar} E_n t \right\} \exp\left\{ +\frac{i}{\hbar} E_{n'} t' \right\} \hat{F}_{n'n} \exp\left\{ -\frac{i}{\hbar} E_{n'} t' \right\} \\ &\equiv \sum_{n,n'} W_n |F_{nn'}|^2 \exp\left\{ +\frac{i}{\hbar} (E_n - E_{n'}) (t - t') \right\}. \end{aligned} \quad (7.96)$$

Here W_n are the Gibbs distribution probabilities given by Eq. (24), with the environment's temperature T , and $F_{nn'} \equiv F_{nn'}(0)$ are the Schrödinger-picture matrix elements of the interaction force operator.

We see that though the correlator (96) is a function of the difference $\tau \equiv t - t'$ only (as it should be for fluctuations in a macroscopically stationary system), it may depend on the order of its arguments. This is why let us mark this particular correlation function with the upper index “+”,

$$K_F^+(\tau) \equiv \langle \tilde{F}(t)\tilde{F}(t') \rangle = \sum_{n,n'} W_n |F_{nn'}|^2 \exp\left\{ +\frac{i\tilde{E}\tau}{\hbar} \right\}, \quad \text{where } \tilde{E} \equiv E_n - E_{n'}, \quad (7.97)$$

while its counterpart, with the swapped times t and t' , with the upper index “-”:

$$K_F^-(\tau) \equiv K_F^+(-\tau) = \langle \tilde{F}(t')\tilde{F}(t) \rangle = \sum_{n,n'} W_n |F_{nn'}|^2 \exp\left\{ -\frac{i\tilde{E}\tau}{\hbar} \right\}. \quad (7.98)$$

So, in contrast with classical processes, in quantum mechanics the correlation function of fluctuations \tilde{F} is not necessarily time-symmetric:

$$K_F^+(\tau) - K_F^-(\tau) \equiv K_F^+(\tau) - K_F^+(-\tau) = \langle \tilde{F}(t)\tilde{F}(t') - \tilde{F}(t')\tilde{F}(t) \rangle = 2i \sum_{n,n'} W_n |F_{nn'}|^2 \sin \frac{\tilde{E}\tau}{\hbar} \neq 0, \quad (7.99)$$

so that $\hat{F}(t)$ gives one more example of a Heisenberg-picture operator whose “values”, taken in different moments of time, generally do not commute – see Footnote 49 in Chapter 4. (A good sanity check here is that at $\tau = 0$, i.e. at $t = t'$, the difference (99) between K_F^+ and K_F^- vanishes.)

Now let us return to the force operator's decomposition (92), and calculate its first (average) component. To do that, let us write the formal solution of Eq. (91) as follows:

$$\hat{F}(t) = \frac{1}{i\hbar} \int_{-\infty}^t [\hat{F}(t'), \hat{H}_e(t')] dt'. \quad (7.100)$$

On the right-hand side of this relation, we still cannot treat the Hamiltonian of the environment as an unperturbed (equilibrium) one, even if the effect of our system (s) on the environment is very weak, because this would give zero statistical average of the force $F(t)$. Hence, we should make one more step of our perturbative treatment, taking into account the effect of the force on the environment. To do this, let us use Eqs. (68) and (90) to write the (so far, exact) Heisenberg equation of motion for the environment's Hamiltonian,

$$i\hbar \dot{\hat{H}}_e = [\hat{H}_e, \hat{H}] = -\hat{x} [\hat{H}_e, \hat{F}], \quad (7.101)$$

and its formal solution, similar to Eq. (100), but for time t' rather than t :

$$\hat{H}_e(t') = -\frac{1}{i\hbar} \int_{-\infty}^{t'} \hat{x}(t'') [\hat{H}_e(t''), \hat{F}(t'')] dt''. \quad (7.102)$$

Plugging this equality into the right-hand side of Eq. (100), and averaging the result (again, over the environment only!), we get

$$\langle \hat{F}(t) \rangle = \frac{1}{\hbar^2} \int_{-\infty}^t dt' \int_{-\infty}^{t'} dt'' \hat{x}(t'') \langle [\hat{F}(t'), [\hat{H}_e(t''), \hat{F}(t'')]] \rangle. \quad (7.103)$$

This is still an exact result, but now it is ready for an approximate treatment, implemented by averaging in its right-hand side over the unperturbed (thermal-equilibrium) state of the environment. This may be done absolutely similarly to that in Eq. (96), at the last step using Eq. (94):

$$\begin{aligned} \langle [\hat{F}(t'), [\hat{H}_e(t''), \hat{F}(t'')]] \rangle &= \text{Tr}\{w[F(t'), [H_e F(t'')]]\} \\ &\equiv \text{Tr}\{w[F(t') H_e F(t'') - F(t') F(t'') H_e - H_e F(t'') F(t') + F(t'') H_e F(t')]\} \\ &= \sum_{n,n'} W_n [F_{nn'}(t') E_{n'} F_{n'n}(t'') - F_{nn'}(t') F_{n'n}(t'') E_n - E_n F_{nn'}(t'') F_{n'n}(t') + F_{nn'}(t'') E_{n'} F_{n'n}(t'')] \\ &\equiv -\sum_{n,n'} W_n \tilde{E} |F_{nn'}|^2 \left[\exp\left\{\frac{i\tilde{E}(t'-t'')}{\hbar}\right\} + \text{c.c.} \right]. \end{aligned} \quad (7.104)$$

Now, if we try to integrate each term of this sum, as Eq. (103) seems to require, we will see that the lower-limit substitution (at $t', t'' \rightarrow -\infty$) is uncertain because the exponents oscillate without decay. This mathematical difficulty may be overcome by the following physical reasoning. As illustrated by the example considered in the previous section, coupling to a disordered environment makes the “memory horizon” of the system of our interest (s) finite: its current state does not depend on its history beyond a certain time scale.³⁵ As a result, the function under the integrals of Eq. (103), i.e. the sum (104), should

³⁵ Actually, this is true for virtually any real physical system – in contrast to idealized models such as a dissipation-free oscillator that swings for ever and ever with the same amplitude and phase, thus “remembering” the initial conditions.

self-average at a certain finite time. A simplistic technique for expressing this fact mathematically is just dropping the lower-limit substitution; this would give the correct result for Eq. (103). However, a better (mathematically more acceptable) trick is to first multiply the functions under the integrals by, respectively, $\exp\{\varepsilon(t-t')\}$ and $\exp\{\varepsilon(t'-t'')\}$, where ε is a very small positive constant, then carry out the integration, and after that follow the limit $\varepsilon \rightarrow 0$. The physical justification of this procedure may be provided by saying that the system's behavior should not be affected if its interaction with the environment was not kept constant but rather turned on gradually – say, exponentially with an infinitesimal rate ε . With this modification, Eq. (103) becomes

$$\langle \hat{F}(t) \rangle = -\frac{1}{\hbar^2} \sum_{n,n'} W_n \tilde{E} |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \int_{-\infty}^t dt' \int_{-\infty}^{t'} dt'' \hat{x}(t'') \left[\exp\left\{ \frac{i\tilde{E}(t'-t'')}{\hbar} + \varepsilon(t''-t) \right\} + \text{c.c.} \right]. \quad (7.105)$$

This double integration is over the area shaded in Fig. 6, which makes it obvious that the order of integration may be changed to the opposite one as

$$\int_{-\infty}^t dt' \int_{-\infty}^{t'} dt'' \dots = \int_{-\infty}^{t''} dt'' \int_{t''}^{t'} dt' \dots = \int_{-\infty}^{t''} dt'' \int_{t''-t}^0 d(t'-t) \dots \equiv \int_{-\infty}^{t''} dt'' \int_0^\tau d\tau' \dots, \quad (7.106)$$

where $\tau' \equiv t - t'$, and $\tau \equiv t - t''$.

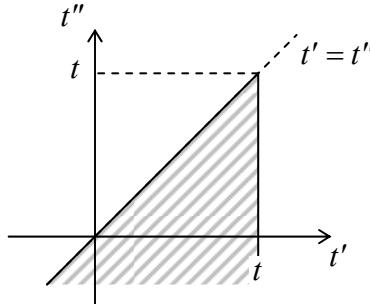

Fig. 7.6. The 2D integration area in Eqs. (105) and (106).

As a result, Eq. (105) may be rewritten as a single integral,

$$\langle \hat{F}(t) \rangle = \int_{-\infty}^t G(t-t'') \hat{x}(t'') dt'' \equiv \int_0^\infty G(\tau) \hat{x}(t-\tau) d\tau, \quad (7.107)$$

whose kernel,

$$\begin{aligned} G(\tau > 0) &\equiv -\frac{1}{\hbar^2} \sum_{n,n'} W_n \tilde{E} |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \int_0^\tau \left[\exp\left\{ \frac{i\tilde{E}(\tau-\tau')}{\hbar} - \varepsilon\tau \right\} + \text{c.c.} \right] d\tau' \\ &= \lim_{\varepsilon \rightarrow 0} \frac{2}{\hbar} \sum_{n,n'} W_n |F_{nn'}|^2 \sin \frac{\tilde{E}\tau}{\hbar} e^{-\varepsilon\tau} \equiv \frac{2}{\hbar} \sum_{n,n'} W_n |F_{nn'}|^2 \sin \frac{\tilde{E}\tau}{\hbar}, \end{aligned} \quad (7.108)$$

does not depend on the particular law of evolution of the system (s) under study, i.e. provides a general characterization of its coupling to the environment.

In Eq. (107) we may readily recognize the most general form of the linear response of a system (in our case, the environment), taking into account the causality principle, where $G(\tau)$ is the *response function* (also called the “temporal Green’s function”) of the environment. Now comparing Eq. (108) with Eq. (99), we get a wonderfully simple universal relation,

$$\left\langle \left[\hat{F}(\tau), \hat{F}(0) \right] \right\rangle = i\hbar G(\tau). \quad (7.109)$$

Green-Kubo formula

that emphasizes once again the quantum nature of the correlation function's time asymmetry. (This relation, called the *Green-Kubo* (or just “Kubo”) *formula* after the works by Melville Green (1954) and Ryogo Kubo (1957), does not come up in the easier derivations of the FDT, mentioned in the beginning of this section.)

However, for us the relation between the function $G(\tau)$ and the force's *anti-commutator*,

$$\left\langle \left[\hat{F}(t+\tau), \hat{F}(t) \right] \right\rangle \equiv \left\langle \hat{F}(t+\tau)\hat{F}(t) + \hat{F}(t)\hat{F}(t+\tau) \right\rangle \equiv K_F^+(\tau) + K_F^-(\tau), \quad (7.110)$$

is much more important, because of the following reason. Eqs. (97)-(98) show that the so-called *symmetrized correlation function*,

$$\begin{aligned} K_F(\tau) &\equiv \frac{K_F^+(\tau) + K_F^-(\tau)}{2} = \frac{1}{2} \left\langle \left[\hat{F}(\tau), \hat{F}(0) \right] \right\rangle = \lim_{\varepsilon \rightarrow 0} \sum_{n,n'} W_n |F_{nn'}|^2 \cos \frac{\tilde{E}\tau}{\hbar} e^{-2\varepsilon|\tau|} \\ &\equiv \sum_{n,n'} W_n |F_{nn'}|^2 \cos \frac{\tilde{E}\tau}{\hbar}, \end{aligned} \quad (7.111)$$

Symmetrized correlation function

which is an even function of the time difference τ , looks very similar to the response function (108), “only” with another trigonometric function under the sum, and a constant front factor.³⁶ This similarity may be used to obtain a direct algebraic relation between the Fourier images of these two functions of τ . Indeed, the function (111) may be represented as the Fourier integral³⁷

$$K_F(\tau) = \int_{-\infty}^{+\infty} S_F(\omega) e^{-i\omega\tau} d\omega = 2 \int_0^{+\infty} S_F(\omega) \cos \omega\tau d\omega, \quad (7.112)$$

with the reciprocal transform

$$S_F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} K_F(\tau) e^{i\omega\tau} d\tau = \frac{1}{\pi} \int_0^{+\infty} K_F(\tau) \cos \omega\tau d\tau, \quad (7.113)$$

of the *symmetrized spectral density* of the variable F , defined as

$$S_F(\omega) \delta(\omega - \omega') \equiv \frac{1}{2} \left\langle \hat{F}_\omega \hat{F}_{-\omega'} + \hat{F}_{-\omega'} \hat{F}_\omega \right\rangle \equiv \frac{1}{2} \left\langle \left\{ \hat{F}_\omega, \hat{F}_{-\omega'} \right\} \right\rangle, \quad (7.114)$$

Symmetrized spectral density

where the function \hat{F}_ω (also a Heisenberg operator rather than a *c*-number!) is defined as

$$\hat{F}_\omega \equiv \frac{1}{2\pi} \int_{-\infty}^{+\infty} \hat{F}(t) e^{i\omega t} dt, \quad \text{so that } \hat{F}(t) = \int_{-\infty}^{+\infty} \hat{F}_\omega e^{-i\omega t} d\omega. \quad (7.115)$$

The physical meaning of the function $S_F(\omega)$ becomes clear if we write Eq. (112) for the particular case $\tau = 0$:

³⁶ For the heroic reader who has suffered through the calculations up to this point: our conceptual work is done! What remains is just some simple math to bring the relation between Eqs. (108) and (111) to an explicit form.

³⁷ Due to their practical importance, and certain mathematical issues of their justification for random functions, Eqs. (112)-(113) have their own grand name, the *Wiener-Khinchin theorem*, though the math rigor aside, they are just a straightforward corollary of the standard Fourier integral transform (115).

$$K_F(0) \equiv \left\langle \hat{F}^2 \right\rangle = \int_{-\infty}^{+\infty} S_F(\omega) d\omega = 2 \int_0^{+\infty} S_F(\omega) d\omega. \quad (7.116)$$

This formula infers that if we pass the function $F(t)$ through a linear filter cutting from its frequency spectrum a narrow band $d\omega$ of physical (positive) frequencies, then the variance $\langle F_f^2 \rangle$ of the filtered signal $F_f(t)$ would be equal to $2S_F(\omega)d\omega$ – hence the name “spectral density”.³⁸

Let us use Eqs. (111) and (113) to calculate the spectral density of fluctuations $\tilde{F}(t)$ in our model, using the same ε -trick as at the deviation of Eq. (108), to quench the upper-limit substitution:

$$\begin{aligned} S_F(\omega) &= \sum_{n,n'} W_n |F_{nn'}|^2 \frac{1}{2\pi} \lim_{\varepsilon \rightarrow 0} \int_{-\infty}^{+\infty} \cos \frac{\tilde{E}\tau}{\hbar} e^{-\varepsilon|\tau|} e^{i\omega\tau} d\tau \\ &\equiv \frac{1}{2\pi} \sum_{n,n'} W_n |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \int_0^{+\infty} \left[\exp \left\{ \frac{i\tilde{E}\tau}{\hbar} \right\} + \text{c.c.} \right] e^{-\varepsilon\tau} e^{i\omega\tau} d\tau \\ &= \frac{1}{2\pi} \sum_{n,n'} W_n |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \left[\frac{1}{i(\tilde{E}/\hbar + \omega) - \varepsilon} + \frac{1}{i(-\tilde{E}/\hbar + \omega) - \varepsilon} \right]. \end{aligned} \quad (7.117)$$

Now it is a convenient time to recall that each of the two summations here is over the eigenenergies of the environment, whose spectrum is virtually continuous because of its large size, so that we may transform each sum into an integral – just as this was done in Sec. 6.6:

$$\sum_n \dots \rightarrow \int \dots dn = \int \dots \rho(E_n) dE_n, \quad (7.118)$$

where $\rho(E) \equiv dn/dE$ is the environment’s density of states at a given energy. This transformation yields

$$S_F(\omega) = \frac{1}{2\pi} \lim_{\varepsilon \rightarrow 0} \int dE_n W(E_n) \rho(E_n) \int dE_{n'} \rho(E_{n'}) |F_{nn'}|^2 \left[\frac{1}{i(\tilde{E}/\hbar - \omega) - \varepsilon} + \frac{1}{i(-\tilde{E}/\hbar - \omega) - \varepsilon} \right]. \quad (7.119)$$

Since the expression inside the square bracket depends only on a specific linear combination of two energies, namely on $\tilde{E} \equiv E_n - E_{n'}$, it is convenient to introduce also another, linearly-independent combination of the energies, for example, the average energy $\bar{E} \equiv (E_n + E_{n'})/2$, so that the state energies may be represented as

$$E_n = \bar{E} + \frac{\tilde{E}}{2}, \quad E_{n'} = \bar{E} - \frac{\tilde{E}}{2}. \quad (7.120)$$

With this notation, Eq. (119) becomes

$$\begin{aligned} S_F(\omega) &= -\frac{\hbar}{2\pi} \lim_{\varepsilon \rightarrow 0} \int d\bar{E} \left[\int d\tilde{E} W\left(\bar{E} + \frac{\tilde{E}}{2}\right) \rho\left(\bar{E} + \frac{\tilde{E}}{2}\right) \rho\left(\bar{E} - \frac{\tilde{E}}{2}\right) |F_{nn'}|^2 \frac{1}{i(\tilde{E}/\hbar - \omega) - \hbar\varepsilon} \right. \\ &\quad \left. + \int d\tilde{E} W\left(\bar{E} + \frac{\tilde{E}}{2}\right) \rho\left(\bar{E} + \frac{\tilde{E}}{2}\right) \rho\left(\bar{E} - \frac{\tilde{E}}{2}\right) |F_{nn'}|^2 \frac{1}{i(-\tilde{E}/\hbar - \omega) - \hbar\varepsilon} \right]. \end{aligned} \quad (7.121)$$

³⁸ An alternative popular measure of the spectral density of a process $F(t)$ is $S_F(\nu) \equiv \langle F_f^2 \rangle / d\nu = 4\pi S_F(\omega)$, where $\nu = \omega/2\pi$ is the “cyclic” frequency (measured in Hz).

Due to the smallness of the parameter $\hbar\omega$ (which should be much smaller than all genuine energies of the problem, including $k_B T$, $\hbar\omega$, E_n , and $E_{n'}$), each of the internal integrals in Eq. (121) is dominated by an infinitesimal vicinity of one point, $\tilde{E}_\pm = \pm\hbar\omega$. In these vicinities, the state densities, the matrix elements, and the Gibbs probabilities do not change considerably, and may be taken out of the integral, which may be then worked out explicitly:³⁹

$$\begin{aligned} S_F(\omega) &= -\frac{\hbar}{2\pi} \lim_{\varepsilon \rightarrow 0} \int d\tilde{E} \rho_+ \rho_- \left[W_+ |F_+|^2 \int_{-\infty}^{+\infty} \frac{d\tilde{E}}{i(\tilde{E} - \hbar\omega) - \hbar\varepsilon} + W_- |F_-|^2 \int_{-\infty}^{+\infty} \frac{d\tilde{E}}{i(-\tilde{E} - \hbar\omega) - \hbar\varepsilon} \right] \\ &\equiv -\frac{\hbar}{2\pi} \lim_{\varepsilon \rightarrow 0} \int d\tilde{E} \rho_+ \rho_- \left[W_+ |F_+|^2 \int_{-\infty}^{+\infty} \frac{-i(\tilde{E} - \hbar\omega) - \hbar\varepsilon}{\tilde{E}^2 + (\hbar\varepsilon)^2} d\tilde{E} + W_- |F_-|^2 \int_{-\infty}^{+\infty} \frac{i(\tilde{E} + \hbar\omega) - \hbar\varepsilon}{\tilde{E}^2 + (\hbar\varepsilon)^2} d\tilde{E} \right] \\ &= \frac{\hbar}{2} \int \rho_+ \rho_- [W_+ |F_+|^2 + W_- |F_-|^2] d\tilde{E}, \end{aligned} \quad (7.122)$$

where the indices \pm mark the functions' values at the special points $\tilde{E}_\pm = \pm\hbar\omega$, i.e. $E_n = E_{n'} \pm \hbar\omega$. The physics of these points becomes simple if we interpret the state n , for which the equilibrium Gibbs distribution function equals W_n , as the initial state of the environment, and n' as its final state. Then the top-sign point corresponds to $E_{n'} = E_n - \hbar\omega$, i.e. to the result of emission of one energy quantum $\hbar\omega$ of the "observation" frequency ω by the environment to the system s of our interest, while the bottom-sign point $E_{n'} = E_n + \hbar\omega$, corresponds to the absorption of such quantum by the environment. As Eq. (122) shows, both processes give similar, positive contributions into the force fluctuations.

The situation is different for the Fourier image of the response function $G(\tau)$,⁴⁰

$$\chi(\omega) \equiv \int_0^{+\infty} G(\tau) e^{i\omega\tau} d\tau,$$

(7.123) Generalized susceptibility

that is usually called either the *generalized susceptibility* or the *response function* – in our case, of the environment. Its physical meaning is that according to Eq. (107), the complex function $\chi(\omega) = \chi'(\omega) + i\chi''(\omega)$ relates the Fourier amplitudes of the generalized coordinate and the generalized force:⁴¹

$$\langle \hat{F}_\omega \rangle = \chi(\omega) \hat{x}_\omega. \quad (7.124)$$

The physics of its imaginary part $\chi''(\omega)$ is especially clear. Indeed, if x_ω represents a sinusoidal classical process, say

$$x(t) = x_0 \cos \omega t \equiv \frac{x_0}{2} e^{-i\omega t} + \frac{x_0}{2} e^{+i\omega t}, \quad \text{i.e. } x_\omega = x_{-\omega} = \frac{x_0}{2}, \quad (7.125)$$

³⁹ Using, e.g., MA Eq. (6.5a). (The imaginary parts of the integrals vanish, because the integration in infinite limits may be always re-centered to the finite points $\pm\hbar\omega$.) A math-enlightened reader may have noticed that the integrals might be taken without the introduction of small ε , using the Cauchy theorem – see MA Eq. (15.1).

⁴⁰ The integration in Eq. (123) may be extended to the whole time axis, $-\infty < \tau < +\infty$, if we complement the definition (107) of the function $G(\tau)$ for $\tau > 0$ with its definition as $G(\tau) = 0$ for $\tau < 0$, in correspondence with the causality principle.

⁴¹ In order to prove this relation, it is sufficient to plug expression $\hat{x}_s = \hat{x}_\omega e^{-i\omega t}$, or any sum of such exponents, into Eqs. (107) and then use the definition (123). This (simple) exercise is highly recommended to the reader.

then, in accordance with the correspondence principle, Eq. (124) should hold for the *c*-number complex amplitudes F_ω and x_ω , enabling us to calculate the time dependence of the force as

$$\begin{aligned} F(t) &= F_\omega e^{-i\omega t} + F_{-\omega} e^{+i\omega t} = \chi(\omega)x_\omega e^{-i\omega t} + \chi(-\omega)x_{-\omega} e^{+i\omega t} = \frac{x_0}{2} [\chi(\omega)e^{-i\omega t} + \chi^*(\omega)e^{+i\omega t}] \\ &= \frac{x_0}{2} [(\chi' + i\chi'')e^{-i\omega t} + (\chi' - i\chi'')e^{+i\omega t}] \equiv x_0 [\chi'(\omega)\cos\omega t + \chi''(\omega)\sin\omega t]. \end{aligned} \quad (7.126)$$

We see that $\chi''(\omega)$ weighs the force's part (frequently called *quadrature*) that is $\pi/2$ -shifted from the coordinate x , i.e. is in phase with its velocity, and hence characterizes the time-average power flow from the system into its environment, i.e. the *energy dissipation* rate:⁴²

$$\overline{\mathcal{P}} = \overline{-F(t)\dot{x}(t)} = \overline{-x_0[\chi'(\omega)\cos\omega t + \chi''(\omega)\sin\omega t]}(-\omega x_0 \sin\omega t) = \frac{x_0^2}{2}\omega\chi''(\omega). \quad (7.127)$$

Let us calculate this function from Eqs. (108) and (123), just as we have done for the spectral density of fluctuations:

$$\begin{aligned} \chi''(\omega) &= \text{Im} \int_0^{+\infty} G(\tau) e^{i\omega\tau} d\tau = \frac{2}{\hbar} \sum_{n,n'} W_n |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \text{Im} \int_0^{+\infty} \frac{1}{2i} \left(\exp \left\{ i \frac{\tilde{E}\tau}{\hbar} \right\} - \text{c.c.} \right) e^{i\omega\tau} e^{-\varepsilon\tau} d\tau \\ &= \sum_{n,n'} W_n |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \text{Im} \left(\frac{1}{-\tilde{E} - \hbar\omega - i\hbar\varepsilon} - \frac{1}{\tilde{E} - \hbar\omega - i\hbar\varepsilon} \right) \\ &\equiv \sum_{n,n'} W_n |F_{nn'}|^2 \lim_{\varepsilon \rightarrow 0} \left(\frac{\hbar\varepsilon}{(\tilde{E} + \hbar\omega)^2 + (\hbar\varepsilon)^2} - \frac{\hbar\varepsilon}{(\tilde{E} - \hbar\omega)^2 + (\hbar\varepsilon)^2} \right). \end{aligned} \quad (7.128)$$

Making the transfer (118) from the double sum to the double integral, and then the integration variable transfer (120), we get

$$\begin{aligned} \chi''(\omega) &= \lim_{\varepsilon \rightarrow 0} \int d\tilde{E} \left[\int_{-\infty}^{+\infty} W \left(\tilde{E} + \frac{\tilde{E}}{2} \right) \rho \left(\tilde{E} + \frac{\tilde{E}}{2} \right) \rho \left(\tilde{E} - \frac{\tilde{E}}{2} \right) |F_{nn'}|^2 \frac{\hbar\varepsilon}{(\tilde{E} + \hbar\omega)^2 + (\hbar\varepsilon)^2} d\tilde{E} \right. \\ &\quad \left. - \int_{-\infty}^{+\infty} W \left(\tilde{E} + \frac{\tilde{E}}{2} \right) \rho \left(\tilde{E} + \frac{\tilde{E}}{2} \right) \rho \left(\tilde{E} - \frac{\tilde{E}}{2} \right) |F_{nn'}|^2 \frac{\hbar\varepsilon}{(\tilde{E} - \hbar\omega)^2 + (\hbar\varepsilon)^2} d\tilde{E} \right]. \end{aligned} \quad (7.129)$$

Now using the same argument about the smallness of parameter ε as above, we may take the spectral densities, the matrix elements of force, and the Gibbs probabilities out of the integrals, and work out the remaining integrals, getting a result very similar to Eq. (122):

$$\chi''(\omega) = \pi \int \rho_+ \rho_- [W_- |F_-|^2 - W_+ |F_+|^2] d\tilde{E}. \quad (7.130)$$

⁴² The sign minus in Eq. (127) is due to the fact that according to Eq. (90), F is the force exerted *on* our system (s) by the environment, so that the force exerted *by* our system on the environment is $-F$. With this sign clarification, the expression $\mathcal{P} = -F\dot{x} = -Fv$ for the instant power flow is evident if x is the usual Cartesian coordinate of a 1D particle. However, according to analytical mechanics (see, e.g., CM Chapters 2 and 10), it is also valid for any {generalized coordinate, generalized force} pair which forms the interaction Hamiltonian (90).

In order to relate these two results, it is sufficient to notice that according to Eq. (24), the Gibbs probabilities W_{\pm} are related by a coefficient depending on only the temperature T and observation frequency ω :

$$W_{\pm} \equiv W\left(\bar{E} + \frac{\tilde{E}_{\pm}}{2}\right) \equiv W\left(\bar{E} \pm \frac{\hbar\omega}{2}\right) = \frac{1}{Z} \exp\left\{-\frac{\bar{E} \pm \hbar\omega/2}{k_B T}\right\} = W(\bar{E}) \exp\left\{\mp \frac{\hbar\omega}{2k_B T}\right\}, \quad (7.131)$$

so that both the spectral density (122) and the dissipative part (130) of the generalized susceptibility may be expressed via the same integral over the environment energies:

$$S_F(\omega) = \hbar \cosh\left(\frac{\hbar\omega}{2k_B T}\right) \int \rho_+ \rho_- W(\bar{E}) [|F_+|^2 + |F_-|^2] d\bar{E}, \quad (7.132)$$

$$\chi''(\omega) = 2\pi \sinh\left(\frac{\hbar\omega}{2k_B T}\right) \int \rho_+ \rho_- W(\bar{E}) [|F_+|^2 + |F_-|^2] d\bar{E}, \quad (7.133)$$

and hence are universally related as

$$S_F(\omega) = \frac{\hbar}{2\pi} \chi''(\omega) \coth \frac{\hbar\omega}{2k_B T}. \quad (7.134)$$

Fluctuation-dissipation theorem

This is, finally, the much-celebrated Callen-Welton's fluctuation-dissipation theorem (FDT). It reveals a fundamental, intimate relationship between these two effects of the environment ("no dissipation without fluctuation") – hence the name. A curious feature of the FDT is that Eq. (134) includes the same function of temperature as the average energy (26) of a quantum oscillator of frequency ω , though, as the reader could witness, the notion of the oscillator was by no means used in its derivation. As will see in the next section, this fact leads to rather interesting consequences and even conceptual opportunities.

In the classical limit, $\hbar\omega \ll k_B T$, the FDT is reduced to

$$S_F(\omega) = \frac{\hbar}{2\pi} \chi''(\omega) \frac{2k_B T}{\hbar\omega} = \frac{k_B T}{\pi} \frac{\text{Im } \chi(\omega)}{\omega}. \quad (7.135)$$

In most systems of interest, the last fraction is close to a finite (positive) constant within a substantial range of relatively low frequencies. Indeed, expanding the right-hand side of Eq. (123) into the Taylor series in small ω , we get

$$\chi(\omega) = \chi(0) + i\omega\eta + \dots, \quad \text{with } \chi(0) = \int_0^\infty G(\tau) d\tau, \quad \text{and } \eta \equiv \int_0^\infty G(\tau) \tau d\tau. \quad (7.136)$$

Since the temporal Green's function G is real by definition, the Taylor expansion of $\chi''(\omega) \equiv \text{Im } \chi(\omega)$ at $\omega = 0$ starts with the linear term $i\omega\eta$, where η is a certain real coefficient, and unless $\eta = 0$, is dominated by this term at small ω . The physical sense of the constant η becomes clear if we consider an environment that provides a force described by a simple, well-known kinematic friction law

$$\langle \hat{F} \rangle = -\eta \dot{\hat{x}}, \quad \text{with } \eta \geq 0, \quad (7.137)$$

where η is usually called the *drag coefficient*. For the Fourier images of coordinate and force, this gives the relation $F_\omega = i\omega\eta x_\omega$, so that according to Eq. (124),

Ohmic
dissipation

$$\chi(\omega) = i\omega\eta, \quad \text{i.e. } \frac{\chi''(\omega)}{\omega} \equiv \frac{\text{Im } \chi(\omega)}{\omega} = \eta \geq 0. \quad (7.138)$$

With this approximation, and in the classical limit, the FDT (134) is reduced to the well-known *Nyquist formula*:⁴³

Nyquist
formula

$$S_F(\omega) = \frac{k_B T}{\pi} \eta, \quad \text{i.e. } \langle F_f^2 \rangle = 4k_B T \eta d\nu. \quad (7.139)$$

According to Eq. (112), if such a constant spectral density⁴⁴ persisted at all frequencies, it would correspond to a delta-correlated process $F(t)$, with

$$K_F(\tau) = 2\pi S_F(0)\delta(\tau) = 2k_B T \eta \delta(\tau) \quad (7.140)$$

- cf. Eqs. (82) and (83). Since in the classical limit the right-hand side of Eq. (109) is negligible, and the correlation function may be considered an even function of time, the symmetrized function under the integral in Eq. (113) may be rewritten just as $\langle F(\tau)F(0) \rangle$. In the limit of relatively low observation frequencies (in the sense that ω is much smaller than not only the quantum frontier $k_B T/\hbar$ but also the frequency scale of the function $\chi''(\omega)/\omega$), Eq. (138) may be used to recast Eq. (135) in the form⁴⁵

$$\eta \equiv \lim_{\omega \rightarrow 0} \frac{\chi''(\omega)}{\omega} = \frac{1}{k_B T} \int_0^\infty \langle F(\tau)F(0) \rangle d\tau. \quad (7.141)$$

To conclude this section, let me return for a minute to the questions formulated in our earlier discussion of dephasing in the two-level model. In that problem, the dephasing time scale is $T_2 = 1/2D_\phi$. Hence the classical approach to the dephasing, used in Sec. 3, is adequate if $\hbar D_\phi \ll k_B T$. Next, we may identify the operators \hat{f} and $\hat{\sigma}_z$ participating in Eq. (70) with, respectively, $(-\hat{F})$ and \hat{x} participating in the general Eq. (90). Then the comparison of Eqs. (82), (89), and (140) yields

$$\frac{1}{T_2} \equiv 2D_\phi = \frac{4k_B T}{\hbar^2} \eta, \quad (7.142)$$

Classical
dephasing

⁴³ Actually, the 1928 work by H. Nyquist was about the electronic noise in resistors, just discovered experimentally by his Bell Labs colleague John Bertrand Johnson. For an Ohmic resistor, as the dissipative “environment” of the electric circuit it is connected with, Eq. (137) is just the Ohm’s law, and may be recast as either $\langle V \rangle = -R(dQ/dt) = RI$, or $\langle I \rangle = -G(d\Phi/dt) = GV$. Thus for the voltage V across an open circuit, η corresponds to its resistance R , while for current I in a short circuit, to its conductance $G = 1/R$. In this case, the fluctuations described by Eq. (139) are referred to as the *Johnson-Nyquist noise*. (Because of this important application, any model leading to Eq. (138) is commonly referred to as the *Ohmic dissipation*, even if the physical nature of the variables x and F is quite different from voltage and current.)

⁴⁴ A random process whose spectral density may be reasonably approximated by a constant is frequently called the *white noise*, because it is a random mixture of all possible sinusoidal components with equal weights, reminding the spectral composition of the natural white light.

⁴⁵ Note that in some fields (especially in physical kinetics and chemical physics), this particular limit of the Nyquist formula is called the Green-Kubo (or just “Kubo”) formula. However, in the view of the FDT development history (described above), it is much more reasonable to associate these names with Eq. (109) – as it is done in most fields of physics.

so that, for the model described by Eq. (137) with a temperature-independent drag coefficient η , the rate of dephasing by a classical environment is proportional to its temperature.

7.5. The Heisenberg-Langevin approach

The fluctuation-dissipation theorem offers a very simple and efficient, though limited approach to the analysis of the system of interest (s in Fig. 1). It is to write its Heisenberg equations (4.199) of motion of the relevant operators, which would now include the environmental force operator, and explore these equations using the Fourier transform and the Wiener-Khinchin theorem (112)-(113). This approach to classical equations of motion is commonly associated with the name of Langevin,⁴⁶ so that its extension to dynamics of Heisenberg-picture operators is frequently referred to as the *Heisenberg-Langevin* (or “quantum Langevin”, or “Langevin-Lax”⁴⁷) *approach* to open system analysis.

Perhaps the best way to describe this method is to demonstrate how it works for the very important case of a 1D harmonic oscillator, so that the generalized coordinate x of Sec. 4 is just the oscillator’s coordinate. For the sake of simplicity, let us assume that the environment provides the simple Ohmic dissipation described by Eq. (137) – which is a very good approximation in many cases. As we already know from Chapter 5, the Heisenberg equations of motion for operators of coordinate and momentum of the oscillator, in the presence of an external force $F(t)$, are

$$\dot{\hat{x}} = \frac{\hat{p}}{m}, \quad \dot{\hat{p}} = -m\omega_0^2 \hat{x} + \hat{F}, \quad (7.143)$$

so that using Eqs. (92) and (137), we get

$$\dot{\hat{x}} = \frac{\hat{p}}{m}, \quad \dot{\hat{p}} = -m\omega_0^2 \hat{x} - \eta \dot{\hat{x}} + \hat{F}(t). \quad (7.144)$$

Combining Eqs. (144), we may write their system as a single differential equation

$$m\ddot{\hat{x}} + \eta \dot{\hat{x}} + m\omega_0^2 \hat{x} = \hat{F}(t), \quad (7.145)$$

which is similar to the well-known classical equation of motion of a damped oscillator under the effect of an external force. In the view of Eqs. (5.29) and (5.35), whose corollary the Ehrenfest theorem (5.36) is, this may look not surprising, but please note again that the approach discussed in the previous section justifies such quantitative description of the drag force in quantum mechanics – necessarily in parallel with the accompanying fluctuation force.

For the Fourier images of the operators, defined similarly to Eq. (115), Eq. (145) gives the following relation,

⁴⁶ A 1908 work by Paul Langevin was the first systematic development of Einstein’s ideas (1905) on the Brownian motion, using the random force language, as an alternative to Smoluchowski’s approach using the probability density language – see Sec. 6 below.

⁴⁷ Indeed, perhaps the largest credit for the extension of the Langevin approach to quantum systems belongs to Melvin J. Lax, whose work in the early 1960s was motivated mostly by quantum electronics applications – see, e.g., his monograph M. Lax, *Fluctuation and Coherent Phenomena in Classical and Quantum Physics*, Gordon and Breach, 1968, and references therein.

$$\hat{x}_\omega = \frac{F_\omega}{m(\omega_0^2 - \omega^2) - i\eta\omega}, \quad (7.146)$$

which should be also well known to the reader from the classical theory of forced oscillations.⁴⁸ However, since these Fourier components are still Heisenberg-picture operators, and their “values” for different ω generally do not commute, we have to tread carefully. The best way to proceed is to write a copy of Eq. (146) for frequency ($-\omega$), and then combine these equations to form a symmetrical combination similar to that used in Eq. (114). The result is

$$\frac{1}{2} \langle \hat{x}_\omega \hat{x}_{-\omega} + \hat{x}_{-\omega} \hat{x}_\omega \rangle = \frac{1}{|m(\omega_0^2 - \omega^2) - i\eta\omega|^2} \frac{1}{2} \langle \hat{F}_\omega \hat{F}_{-\omega} + \hat{F}_{-\omega} \hat{F}_\omega \rangle. \quad (7.147)$$

Since the spectral density definition similar to Eq. (114) is valid for any observable, in particular for x , Eq. (147) allows us to relate the symmetrized spectral densities of coordinate and force:

$$S_x(\omega) = \frac{S_F(\omega)}{|m(\omega_0^2 - \omega^2) - i\eta\omega|^2} \equiv \frac{S_F(\omega)}{m^2(\omega_0^2 - \omega^2)^2 + (\eta\omega)^2}. \quad (7.148)$$

Now using an analog of Eq. (116) for x , we can calculate the coordinate’s variance:

$$\langle x^2 \rangle = K_x(0) = \int_{-\infty}^{+\infty} S_x(\omega) d\omega = 2 \int_0^{+\infty} \frac{S_F(\omega) d\omega}{m^2(\omega_0^2 - \omega^2)^2 + (\eta\omega)^2}, \quad (7.149)$$

where now, in contrast to the notation used in Sec. 4, the sign $\langle \dots \rangle$ means averaging over the usual statistical ensemble of many systems of interest – in our current case, of many harmonic oscillators.

If the coupling to the environment is so weak that the drag coefficient η is small (in the sense that the oscillator’s dimensionless *Q-factor* is large, $Q \equiv m\omega_0/\eta \gg 1$), this integral is dominated by the resonance peak in a narrow vicinity, $|\omega - \omega_0| \equiv |\xi| \ll \omega_0$, of its resonance frequency, and we can take the relatively smooth function $S_F(\omega)$ out of the integral, thus reducing it to a table form:⁴⁹

$$\begin{aligned} \langle x^2 \rangle &\approx 2S_F(\omega_0) \int_0^{+\infty} \frac{d\omega}{m^2(\omega_0^2 - \omega^2)^2 + (\eta\omega)^2} \approx 2S_F(\omega_0) \int_{-\infty}^{+\infty} \frac{d\xi}{(2m\omega_0\xi)^2 + (\eta\omega_0)^2} \\ &\equiv 2S_F(\omega_0) \frac{1}{(\eta\omega_0)^2} \int_{-\infty}^{+\infty} \frac{d\xi}{(2m\xi/\eta)^2 + 1} = 2S_F(\omega_0) \frac{1}{(\eta\omega_0)^2} \frac{\pi\eta}{2m} = \frac{\pi S_F(\omega_0)}{\eta m \omega_0^2}. \end{aligned} \quad (7.150)$$

With the account of the FDT (134) and of Eq. (138), this gives⁵⁰

$$\langle x^2 \rangle = \frac{\pi}{\eta m \omega_0^2} \frac{\hbar}{2\pi} \eta \omega_0 \coth \frac{\hbar \omega_0}{2k_B T} \equiv \frac{\hbar}{2m\omega_0} \coth \frac{\hbar \omega_0}{2k_B T}. \quad (7.151)$$

⁴⁸ If necessary, see CM Sec. 5.1.

⁴⁹ See, e.g., MA Eq. (6.5a).

⁵⁰ Note that this calculation remains correct even if the dissipation’s dispersion law deviates from the Ohmic model (138), provided that the drag coefficient η is replaced with its effective value $\text{Im}\chi(\omega_0)/\omega_0$, because the effects of the environment are only felt, by the oscillator, at its oscillation frequency.

But this is exactly Eq. (48), which was derived in Sec. 2 from the Gibbs distribution, without any explicit account of the environment – though keeping it in mind by using the notion of the thermally-equilibrium ensemble.⁵¹

Notice that in the final form of Eq. (151) the coefficient η , which characterizes the oscillator-to-environment interaction strength, has canceled! Does this mean that in Sec. 4 we toiled in vain? By no means. First of all, the result (150), augmented by the FDT (134), has an important conceptual value. For example, let us consider the low-temperature limit $k_B T \ll \hbar\omega_0$ where Eq. (151) is reduced to

$$\langle x^2 \rangle = \frac{\hbar}{2m\omega_0} \equiv \frac{x_0^2}{2}. \quad (7.152)$$

Let us ask a naïve question: what exactly is the origin of this coordinate's uncertainty? From the point of view of the usual quantum mechanics of absolutely closed (Hamiltonian) systems, there is no doubt: this non-vanishing variance of the coordinate is the result of the final spatial extension of the ground-state wavefunction (2.275), reflecting Heisenberg's uncertainty relation – which in turn results from the fact that the operators of coordinate and momentum do not commute. However, from the point of view of the Heisenberg-Langevin equation (145), the variance (152) is an inalienable part of the oscillator's response to the fluctuation force $\tilde{F}(t)$ exerted by the environment at frequencies $\omega \approx \omega_0$. Though it is impossible to refute the former, absolutely legitimate point of view, in many applications it is easier to subscribe to the latter standpoint and treat the coordinate's uncertainty as the result of the so-called *quantum noise* of the environment, which, in equilibrium, obeys the FTD (134). This notion has received numerous confirmations in experiments that did not include *any* oscillators with their own frequencies ω_0 close to the noise measurement frequency ω .⁵²

The second advantage of the Heisenberg-Langevin approach is that it is possible to use Eq. (148) to calculate the (experimentally measurable!) distribution $S_x(\omega)$, i.e. decompose the fluctuations into their spectral components. This procedure is not restricted to the limit of small η (i.e. of large Q); for any damping, we may just plug the FDT (134) into Eq. (148). For example, let us have a look at the so-called *quantum diffusion*. A free 1D particle, moving in a viscous medium providing it with the Ohmic damping (137), may be considered as the particular case of a 1D harmonic oscillator (145), but with $\omega_0 = 0$, so that combining Eqs. (134) and (149), we get

$$\langle x^2 \rangle = 2 \int_0^{+\infty} \frac{S_F(\omega)d\omega}{(m\omega^2)^2 + (\eta\omega)^2} = 2\eta \int_0^{+\infty} \frac{1}{(m\omega^2)^2 + (\eta\omega)^2} \frac{\hbar\omega}{2\pi} \coth \frac{\hbar\omega}{2k_B T} d\omega. \quad (7.153)$$

This integral has two divergences. The first one, of the type $\int d\omega/\omega^2$ at the lower limit, is just a classical effect: according to Eq. (85), the particle's displacement variance grows with time, so it cannot have a finite time-independent value that Eq. (153) tries to calculate. However, we still can use that result to single out the quantum effects on diffusion – say, by comparing it with a similar but purely classical case. These effects are prominent at high frequencies, especially if the quantum noise overcomes the thermal noise before the dynamic cut-off, i.e. if

⁵¹ By the way, the simplest way to calculate $S_F(\omega)$, i.e. to derive the FDT, is to *require* that Eqs. (48) and (150) give the same result for an oscillator with any eigenfrequency ω . This is exactly the approach used by H. Nyquist (for the classical case) – see also SM Sec. 5.5.

⁵² See, for example, R. Koch *et al.*, *Phys. Lev. B* **26**, 74 (1982).

$$\frac{k_B T}{\hbar} \ll \frac{\eta}{m}. \quad (7.154)$$

In this case, there is a broad range of frequencies where the quantum noise gives a substantial contribution to the integral:

Quantum diffusion

$$\langle x^2 \rangle_Q \approx 2\eta \int_{k_B T / \hbar}^{\eta / m} \frac{1}{(\eta\omega)^2} \frac{\hbar\omega}{2\pi} d\omega \equiv \frac{\hbar}{\pi\eta} \int_{k_B T / \hbar}^{\eta / m} \frac{d\omega}{\omega} = \frac{\hbar}{\pi\eta} \ln \frac{\hbar\eta}{mk_B T} \sim \frac{\hbar}{\eta}. \quad (7.155)$$

Formally, this contribution diverges at either $m \rightarrow 0$ or $T \rightarrow 0$, but this logarithmic (i.e. extremely weak) divergence is readily quenched by almost any change of the environment model at very high frequencies, where the “Ohmic” approximation (136) becomes unrealistic.

The Heisenberg-Langevin approach is very powerful, because its straightforward generalizations enable analyses of fluctuations in virtually arbitrary linear systems, i.e. the systems described by linear differential (or integro-differential) equations of motion, including those with many degrees of freedom, and distributed systems (*continua*), and such systems prevail in many fields of physics. However, this approach also has its limitations. The main of them is that if the equations of motion of the Heisenberg operators are *not* linear, there is no linear relation, such as Eq. (146), between the Fourier images of the generalized forces and the generalized coordinates, and as the result, there is no simple relation, such as Eq. (148), between their spectral densities. In other words, if the Heisenberg equations of motion are nonlinear, there is no regular simple way to use them to calculate the statistical properties of the observables.

For example, let us return to the dephasing problem described by Eqs. (68)-(70), and assume that the deterministic and fluctuating parts of the effective force \dot{f} exerted by the environment, are characterized by relations similar, respectively, to Eqs. (124) and (134). Now writing the Heisenberg equations of motion for the two remaining spin operators, and using the commutation relations between them, we get

$$\dot{\hat{\sigma}}_x = \frac{1}{i\hbar} [\hat{\sigma}_x, \hat{H}] = \frac{1}{i\hbar} [\hat{\sigma}_x, (c_z + \hat{f}) \hat{\sigma}_z] = -\frac{2}{\hbar} \hat{\sigma}_y (c_z + \hat{f}) = -\frac{2}{\hbar} \hat{\sigma}_y (c_z + \eta \hat{\sigma}_z + \hat{f}), \quad (7.156)$$

and a similar equation for $\dot{\hat{\sigma}}_y$. Such nonlinear equations cannot be used to calculate the statistical properties of the Pauli operators in this system exactly – at least analytically.

For some calculations, this problem may be circumvented by *linearization*: if we are only interested in small fluctuations of the observables, their nonlinear Heisenberg equations of motion, such as Eq. (156), may be linearized with respect to small deviations of the operators about their (generally, time-dependent) deterministic “values”, and then the resulting linear equations for the operator variations may be solved either as has been demonstrated above, or (if the deterministic “values” evolve in time) using their Fourier expansions. Sometimes such approach gives relatively simple and important results,⁵³ but for many other problems, this approach is insufficient, leaving a lot of space for alternative methods.

⁵³ For example, the formula used for processing the experimental results by R. Koch *et al.* (mentioned above), had been derived in this way. (This derivation will be suggested to the reader as an exercise.)

7.6. Density matrix approach

The main alternative approach to the dynamics of open quantum systems, which is essentially a generalization of the one discussed in Sec. 2, is to extract the final results of interest from the dynamics of the density operator of our system s . Let us discuss this approach in detail.⁵⁴

We already know that the density matrix allows the calculation of the expectation value of any observable of the system s – see Eq. (5). However, our initial recipe (6) for the density matrix element calculation, which requires the knowledge of the exact state (2) of the whole Universe, is not too practicable, while the von Neumann equation (66) for the density matrix evolution is limited to cases in which probabilities W_j of the system states are fixed – thus excluding such important effects as the energy relaxation. However, such effects may be analyzed using a different assumption – that the system of interest interacts only with a *local environment* that is very close to its thermally-equilibrium state described, in the stationary-state basis, by a diagonal density matrix with the elements (24).

This calculation is facilitated by the following general observation. Let us number the basis states of the full local system (the system of our interest plus its local environment) by l , and use Eq. (5) to write

$$\langle A \rangle = \text{Tr}(\hat{A}\hat{w}_l) \equiv \sum_{l,l'} A_{ll'} w_{ll'} = \sum_{l,l'} \langle l | \hat{A} | l' \rangle \langle l' | \hat{w}_l | l \rangle, \quad (7.157)$$

where \hat{w}_l is the density operator of this local system. At a weak interaction between the system s and the local environment e , their states reside in different Hilbert spaces, so that we can write

$$|l\rangle = |s_j\rangle \otimes |e_k\rangle, \quad (7.158)$$

and if the observable A depends only on the coordinates of the system s of our interest, we may reduce Eq. (157) to the form similar to Eq. (5):

$$\begin{aligned} \langle A \rangle &= \sum_{j,j';k,k'} \langle e_k | \otimes \langle s_j | \hat{A} | s_{j'} \rangle \otimes | e_{k'} \rangle \langle e_{k'} | \otimes \langle s_{j'} | \hat{w}_l | s_j \rangle \otimes | e_k \rangle \\ &= \sum_{j,j'} A_{jj'} \left\langle s_{j'} \left(\sum_k \otimes \langle e_k | \hat{w}_l | e_k \rangle \otimes \right) \right| s_j \rangle = \text{Tr}_j(\hat{A}\hat{w}), \end{aligned} \quad (7.159)$$

where

$$\hat{w} \equiv \sum_k \langle e_k | \hat{w}_l | e_k \rangle = \text{Tr}_k \hat{w}_l, \quad (7.160)$$

showing how exactly the density operator \hat{w} of the system s may be calculated from \hat{w}_l .

Now comes the key physical assumption of this approach: since we may select the local environment e to be much larger than the system s of our interest, we may consider the composite system l as a Hamiltonian one, with time-independent probabilities of its stationary states, so that for the description of the evolution in time of *its* full density operator \hat{w}_l (again, in contrast to that, \hat{w} , of the system of our interest) we *may* use the von Neumann equation (66). Partitioning its right-hand side in accordance with Eq. (68), we get:

$$i\hbar \dot{\hat{w}}_l = [\hat{H}_s, \hat{w}_l] + [\hat{H}_e, \hat{w}_l] + [\hat{H}_{\text{int}}, \hat{w}_l]. \quad (7.161)$$

⁵⁴ As in Sec. 4, the reader not interested in the derivation of the basic equation (181) of the density matrix evolution may immediately jump to the discussion of this equation and its applications.

The next step is to use the perturbation theory to solve this equation in the lowest order in \hat{H}_{int} , which would yield, for the evolution of w , a non-vanishing contribution due to the interaction. For that, Eq. (161) is not very convenient, because its right-hand side contains two other terms, of a much larger scale than the interaction Hamiltonian. To mitigate this technical difficulty, the interaction picture that was discussed at the end of Sec. 4.6, is very natural. (It is not necessary though, and I will use this picture mostly as an exercise of its application – unfortunately, the only example I can afford in this course.)

As a reminder, in that picture (whose entities will be marked with index “I”, with the unmarked operators assumed to be in the Schrödinger picture), both the operators *and* the state vectors (and hence the density operator) depend on time. However, the time evolution of the operator of any observable A is described by an equation similar to Eq. (67), but with the *unperturbed* part of the Hamiltonian only – see Eq. (4.214). In model (68), this means

$$i\hbar\dot{\hat{A}}_I = [\hat{A}_I, \hat{H}_0]. \quad (7.162)$$

where the unperturbed Hamiltonian consists of two parts defined in different Hilbert spaces:

$$\hat{H}_0 \equiv \hat{H}_s + \hat{H}_e. \quad (7.163)$$

On the other hand, the state vector’s dynamics is governed by the interaction evolution operator \hat{u}_I that obeys Eqs. (4.215). Since this equation, using the interaction-picture Hamiltonian (4.216),

$$\hat{H}_I \equiv \hat{u}_0^\dagger \hat{H}_{\text{int}} \hat{u}_0, \quad (7.164)$$

is absolutely similar to the ordinary Schrödinger equation using the full Hamiltonian, we may repeat all arguments given at the beginning of Sec. 3 to prove that the dynamics of the density operator in the interaction picture of a Hamiltonian system is governed by the following analog of the von Neumann equation (66):

$$i\hbar\dot{\hat{w}}_I = [\hat{H}_I, \hat{w}_I], \quad (7.165)$$

where the index I is dropped for the notation simplicity. Since this equation is similar in structure (with the opposite sign) to the Heisenberg equation (67), we may use the solution Eq. (4.190) of the latter equation to write its analog:

$$\hat{w}_I(t) = \hat{u}_I(t, 0)\hat{w}_I(0)\hat{u}_I^\dagger(t, 0). \quad (7.166)$$

It is also straightforward to verify that in this picture, the expectation value of any observable A may be found from an expression similar to the basic Eq. (5):

$$\langle A \rangle = \text{Tr}(\hat{A}_I \hat{w}_I). \quad (7.167)$$

showing again that the interaction and Schrödinger pictures give the same final results.

In the most frequent case of factorable interaction (90),⁵⁵ Eq. (162) is simplified for both operators participating in that product – for each one in its own way. In particular, for $\hat{A} = \hat{x}$, it yields

⁵⁵ A similar analysis of a more general case, when the interaction with the environment has to be represented as a sum of products of the type (90), may be found, for example, in the monograph by K. Blum, *Density Matrix Theory and Applications*, 3rd ed., Springer, 2012.

$$i\hbar\dot{\hat{x}}_I = [\hat{x}_I, \hat{H}_0] = [\hat{x}_I, \hat{H}_s] + [\hat{x}_I, \hat{H}_e]. \quad (7.168)$$

Since the coordinate operator is defined in the Hilbert space of our system s , it commutes with the Hamiltonian of the environment, so that we finally get

$$i\hbar\dot{\hat{x}}_I = [\hat{x}_I, \hat{H}_s]. \quad (7.169)$$

On the other hand, if $\hat{A} = \hat{F}$, this operator is defined in the Hilbert space of the environment, and commutes with the Hamiltonian of the unperturbed system s . As a result, we get

$$i\hbar\dot{\hat{F}}_I = [\hat{F}_I, \hat{H}_e]. \quad (7.170)$$

This means that with our time-independent unperturbed Hamiltonians, \hat{H}_s and \hat{H}_e , the time evolution of the interaction-picture operators is rather simple. In particular, the analogy between Eq. (170) and Eq. (93) allows us to immediately write the following analog of Eq. (94):

$$\hat{F}_I(t) = \exp\left\{+\frac{i}{\hbar}\hat{H}_e t\right\} \hat{F}(0) \exp\left\{-\frac{i}{\hbar}\hat{H}_e t\right\}, \quad (7.171)$$

so that in the stationary-state basis n of the environment,

$$(\hat{F}_I)_{nn'}(t) = \exp\left\{+\frac{i}{\hbar}E_n t\right\} F_{nn'}(0) \exp\left\{-\frac{i}{\hbar}E_n t\right\} \equiv F_{nn'}(0) \exp\left\{-i\frac{E_n - E_{n'}}{\hbar} t\right\}, \quad (7.172)$$

and similarly (but in the basis of the stationary states of system s) for operator \hat{x} . As a result, the right-hand side of Eq. (164) may be also factored:

$$\begin{aligned} \hat{H}_I(t) &\equiv \hat{u}_0^\dagger(t, 0) \hat{H}_{\text{int}} \hat{u}_0(t, 0) = \exp\left\{+\frac{i}{\hbar}(\hat{H}_s + \hat{H}_e)t\right\} (-\hat{x}\hat{F}) \exp\left\{-\frac{i}{\hbar}(\hat{H}_s + \hat{H}_e)t\right\} \\ &= -\left(\exp\left\{+\frac{i}{\hbar}\hat{H}_s t\right\} \hat{x} \exp\left\{-\frac{i}{\hbar}\hat{H}_s t\right\} \right) \left(\exp\left\{+\frac{i}{\hbar}\hat{H}_e t\right\} \hat{F}(0) \exp\left\{-\frac{i}{\hbar}\hat{H}_e t\right\} \right) \equiv -\hat{x}_I(t)\hat{F}_I(t). \end{aligned} \quad (7.173)$$

So, the transfer to the interaction picture has taken some time, but now it enables a smooth ride.⁵⁶ Indeed, just as in Sec. 4, we may rewrite Eq. (165) in the integral form:

$$\hat{w}_I(t) = \frac{1}{i\hbar} \int_{-\infty}^t [\hat{H}_I(t'), \hat{w}_I(t')] dt'; \quad (7.174)$$

plugging this result into the right-hand side of Eq. (165), we get

$$\dot{\hat{w}}_I(t) = -\frac{1}{\hbar^2} \int_{-\infty}^t [\hat{H}_I(t), [\hat{H}_I(t'), \hat{w}_I(t')]] dt' = -\frac{1}{\hbar^2} \int_{-\infty}^t [\hat{x}(t)\hat{F}(t), [\hat{x}(t')\hat{F}(t'), \hat{w}_I(t')]] dt', \quad (7.175)$$

where, for the notation's brevity, from this point on I will strip the operators \hat{x} and \hat{F} of their index "I". (I hope their time dependence indicates the interaction picture clearly enough.)

⁵⁶ If we used either the Schrödinger or the Heisenberg picture instead, the forthcoming Eq. (175) would pick up a rather annoying multitude of fast-oscillating exponents, of different time arguments, on its right-hand side.

So far, this equation is exact (and cannot be solved analytically), but this is a good time to notice that even if we approximate the density operator on its right-hand side by its unperturbed, factorable “value” (corresponding to no interaction between the system s and its thermally-equilibrium environment e),⁵⁷

$$\hat{w}_I(t') \rightarrow \hat{w}(t')\hat{w}_e, \quad \text{with } \langle e_n | \hat{w}_e | e_{n'} \rangle = W_n \delta_{nn'}, \quad (7.176)$$

where e_n are the stationary states of the environment and W_n are the Gibbs probabilities (24), Eq. (175) still describes nontrivial time evolution of the density operator. This is exactly the first non-vanishing approximation (in the weak interaction) we have been looking for. Now using Eq. (160), we find the equation of evolution of the density operator of the system of our interest:

$$\dot{\hat{w}}(t) = -\frac{1}{\hbar^2} \int_{-\infty}^t \text{Tr}_n [\hat{x}(t)\hat{F}(t), [\hat{x}(t')\hat{F}(t'), \hat{w}(t')\hat{w}_e]] dt', \quad (7.177)$$

where the trace is over the stationary states of the environment. To spell out the right-hand side of Eq. (177), note again that the coordinate and force operators commute with each other (but not with themselves at different time moments!) and hence may be swapped at will, so that we may write

$$\begin{aligned} \text{Tr}_n [...] &= \hat{x}(t)\hat{x}(t')\hat{w}(t')\text{Tr}_n [\hat{F}(t)\hat{F}(t')\hat{w}_e] - \hat{x}(t)\hat{w}(t')\hat{x}(t')\text{Tr}_n [\hat{F}(t)\hat{w}_e\hat{F}(t')] \\ &\quad - \hat{x}(t')\hat{w}(t')\hat{x}(t)\text{Tr}_n [\hat{F}(t')\hat{w}_e\hat{F}(t)] + \hat{w}(t')\hat{x}(t')\hat{x}(t)\text{Tr}_n [\hat{w}_e\hat{F}(t')\hat{F}(t)] \\ &= \hat{x}(t)\hat{x}(t')\hat{w}(t') \sum_{n,n'} F_{nn'}(t)F_{n'n}(t')W_n - \hat{x}(t)\hat{w}(t')\hat{x}(t') \sum_{n,n'} F_{nn'}(t)W_{n'}F_{n'n}(t') \\ &\quad - \hat{x}(t')\hat{w}(t')\hat{x}(t) \sum_{n,n'} F_{nn'}(t')W_{n'}F_{n'n}(t) + \hat{w}(t')\hat{x}(t')\hat{x}(t) \sum_{n,n'} W_n F_{nn'}(t')F_{n'n}(t). \end{aligned} \quad (7.178)$$

Since the summation over both indices n and n' in this expression is over the same energy level set (of all stationary states of the environment), we may swap these indices in any of the sums. Doing this only in the terms including the factors $W_{n'}$, we turn them into W_n , so that this factor becomes common:

$$\begin{aligned} \text{Tr}_n [...] &= \sum_{n,n'} W_n [\hat{x}(t)\hat{x}(t')\hat{w}(t')F_{nn'}(t)F_{n'n}(t') - \hat{x}(t)\hat{w}(t')\hat{x}(t')F_{n'n}(t)F_{nn'}(t')] \\ &\quad - \hat{x}(t')\hat{w}\hat{x}(t)F_{n'n}(t')F_{nn'}(t) + \hat{w}\hat{x}(t')\hat{x}(t)F_{nn'}(t')F_{n'n}(t)]. \end{aligned} \quad (7.179)$$

Now using Eq. (172), we get

$$\begin{aligned} \text{Tr}_n [...] &= \sum_{n,n'} W_n |F_{nn'}|^2 \times \left[\begin{aligned} &\hat{x}(t)\hat{x}(t')\hat{w}(t')\exp\left\{+\frac{i\tilde{E}(t-t')}{\hbar}\right\} - \hat{x}(t)\hat{w}(t')\hat{x}(t')\exp\left\{-\frac{i\tilde{E}(t-t')}{\hbar}\right\} \\ &- \hat{x}(t')\hat{w}(t')\hat{x}(t)\exp\left\{+\frac{i\tilde{E}(t-t')}{\hbar}\right\} + \hat{w}(t')\hat{x}(t')\hat{x}(t)\exp\left\{-\frac{i\tilde{E}(t-t')}{\hbar}\right\} \end{aligned} \right] \\ &\equiv \sum_{n,n'} W_n |F_{nn'}|^2 \cos \frac{\tilde{E}(t-t')}{\hbar} [\hat{x}(t), [\hat{x}(t'), \hat{w}(t')]] + i \sum_{n,n'} W_n |F_{nn'}|^2 \sin \frac{\tilde{E}(t-t')}{\hbar} [\hat{x}(t), \{\hat{x}(t'), \hat{w}(t')\}]. \end{aligned} \quad (7.180)$$

Comparing the two double sums participating in this expression with Eqs. (108) and (111), we see that they are nothing else than, respectively, the symmetrized correlation function and the temporal Green’s

⁵⁷ For the notation simplicity, the fact that here (and in all following formulas) the density operator \hat{w} of the system s of our interest is taken in the interaction picture, is just implied.

function (multiplied by $\hbar/2$) of the time-difference argument $\tau = t - t' \geq 0$. As the result, Eq. (177) takes a compact form:

$$\dot{\hat{w}}(t) = -\frac{1}{\hbar^2} \int_{-\infty}^t K_F(t-t') [\hat{x}(t), [\hat{x}(t'), \hat{w}(t')]] dt' - \frac{i}{2\hbar} \int_{-\infty}^t G(t-t') [\hat{x}(t), \{\hat{x}(t'), \hat{w}(t')\}] dt'. \quad (7.181)$$

Density matrix:
time evolution

Let me hope that the readers (especially the ones who have braved through this derivation) enjoy this beautiful result as much as I do. It gives an equation for the time evolution of the density operator of the system of our interest (s), with the effects of its environment represented only by two real, c -number functions of τ : one (K_F) describing the fluctuation force exerted by the environment, and the other one (G) representing its ensemble-averaged environment's response to the system's evolution. And most spectacularly, these are exactly the same functions that participate in the alternative, Heisenberg-Langevin approach to the problem, and hence related to each other by the fluctuation-dissipation theorem (134).

After a short celebration, let us acknowledge that Eq. (181) is still an integro-differential equation, and needs to be solved together with Eq. (169) for the system coordinate's evolution. Such equations do not allow explicit analytical solutions, besides a few very simple (and not very interesting) cases. For most applications, further simplifications should be made. One of them is based on the fact (which was already discussed in Sec. 3) that both environmental functions participating in Eq. (181) tend to zero when their argument τ becomes much larger than the environment's correlation time τ_c , independent of the system-to-environment coupling strength. If the coupling is sufficiently weak, the time scales $T_{nn'}$ of the evolution of the density matrix elements, following from Eq. (181), are much longer than this correlation time, and also the characteristic time scale of the coordinate operator's evolution. In this limit, all arguments t' of the density operator, giving substantial contributions to the right-hand side of Eq. (181), are so close to t that it does not matter whether its argument is t' or just t . This simplification, $w(t') \approx w(t)$, is known as the *Markov approximation*.⁵⁸

However, this approximation alone is still insufficient for finding the general solution of Eq. (181). Substantial further progress is possible in two important cases. The most important of them is when the intrinsic Hamiltonian \hat{H}_s of the system s of our interest does not depend on time explicitly and has a *discrete* eigenenergy spectrum E_n ,⁵⁹ with well-separated levels:

$$|E_n - E_{n'}| \gg \frac{\hbar}{T_{nn'}}. \quad (7.182)$$

Let us see what does this condition yield for Eq. (181), rewritten for the matrix elements in the stationary state basis, in the Markov approximation:

⁵⁸ Named after Andrey Andreyevich Markov (1856-1922; in older Western literature, “Markoff”), a mathematician famous for his general theory of the so-called *Markov processes*, whose future development is completely determined by its present state, but not its pre-history.

⁵⁹ Here, rather reluctantly, I will use this standard notation, E_n , for the eigenenergies of our system of interest (s), in hope that the reader would not confuse these discrete energy levels with the quasi-continuous energy levels of its environment (e), participating in particular in Eqs. (108) and (111). As a reminder, by this stage of our calculations, the environment levels have disappeared from our formulas, leaving behind their functionals $K_F(\tau)$ and $G(\tau)$.

$$\dot{w}_{nn'} = -\frac{1}{\hbar^2} \int_{-\infty}^t K_F(t-t') [\hat{x}(t), [\hat{x}(t'), \hat{w}]]_{nn'} dt' - \frac{i}{2\hbar} \int_{-\infty}^t G(t-t') [\hat{x}(t), \{\hat{x}(t'), \hat{w}\}]_{nn'} dt'. \quad (7.183)$$

After spelling out the commutators, the right-hand side of this expression includes four operator products, which differ “only” by the operator order. Let us first have a look at one of these products,

$$[\hat{x}(t)\hat{x}(t')\hat{w}]_{nn'} \equiv \sum_{m,m'} x_{nm}(t)x_{mm'}(t')w_{m'n'}, \quad (7.184)$$

where the indices m and m' run over the same set of stationary states of the system s of our interest as the indices n and n' . According to Eq. (169) with a time-independent H_s , the matrix elements $x_{nn'}$ (in the stationary state basis) oscillate in time as $\exp\{i\omega_{nn'}t\}$, so that

$$[\hat{x}(t)\hat{x}(t')\hat{w}]_{nn'} = \sum_{m,m'} x_{nm}x_{mm'} \exp\{i(\omega_{nm}t + \omega_{mm'}t')\} w_{m'n'}, \quad (7.185)$$

where on the right-hand side, the coordinate matrix elements are in the Schrödinger picture, and the usual notation (6.85) is used for the quantum transition frequencies:

$$\hbar\omega_{nn'} \equiv E_n - E_{n'}. \quad (7.186)$$

According to the condition (182), frequencies $\omega_{nn'}$ with $n \neq n'$ are much higher than the speed of evolution of the density matrix elements (in the interaction picture!) – on both the left-hand and right-hand sides of Eq. (183). Hence, on the right-hand side of Eq. (183), we may keep only the terms that do not oscillate with these frequencies $\omega_{nn'}$, because rapidly-oscillating terms would give negligible contributions to the density matrix dynamics.⁶⁰ For that, in the double sum (185) we should save only the terms proportional to the difference $(t - t')$ because they will give (after the integration over t') a slowly changing contribution to the right-hand side.⁶¹ These terms should have $\omega_{nm} + \omega_{mm'} = 0$, i.e. $(E_n - E_m) + (E_m - E_{m'}) \equiv E_n - E_{m'} = 0$. For a non-degenerate energy spectrum, this requirement means $m' = n$; as a result, the double sum is reduced to a single one:

$$[\hat{x}(t)\hat{x}(t')\hat{w}]_{nn'} \approx w_{nn'} \sum_m x_{nm}x_{mn} \exp\{i\omega_{nm}(t-t')\} \equiv w_{nn'} \sum_m |x_{nm}|^2 \exp\{i\omega_{nm}(t-t')\}. \quad (7.187)$$

Another product, $[\hat{w}\hat{x}(t')\hat{x}(t)]_{nn'}$, which appears on the right-hand side of Eq. (183), may be simplified absolutely similarly, giving

$$[\hat{w}\hat{x}(t')\hat{x}(t)]_{nn'} \approx \sum_m |x_{n'm}|^2 \exp\{i\omega_{n'm}(t'-t)\} w_{nn'}. \quad (7.188)$$

These expressions hold whether n and n' are equal or not. The situation is different for two other products on the right-hand side of Eq. (183), with w sandwiched between $x(t)$ and $x(t')$. For example,

$$[\hat{x}(t)\hat{w}\hat{x}(t')]_{nn'} = \sum_{m,m'} x_{nm}(t)w_{mm'}x_{m'n'}(t') = \sum_{m,m'} x_{nm}w_{mm'}x_{m'n'} \exp\{i(\omega_{nm}t + \omega_{m'n'}t')\}. \quad (7.189)$$

⁶⁰ This is essentially the same rotating-wave approximation (RWA) as was used in Sec. 6.5.

⁶¹ As was already discussed in Sec. 4, the lower-limit substitution ($t' = -\infty$) in the integrals participating in Eq. (183) gives zero, due to the finite-time “memory” of the system, expressed by the decay of the correlation and response functions at large values of the time delay $\tau = t - t'$.

For this term, the same requirement of having a fast oscillating function of $(t - t')$ only, yields a different condition: $\omega_{nm} + \omega_{m'n'} = 0$, i.e.

$$(E_n - E_m) + (E_{m'} - E_{n'}) = 0. \quad (7.190)$$

Here the double sum's reduction is possible only if we make an additional assumption that all interlevel energy distances are unique, i.e. our system of interest has no equidistant levels (such as in the harmonic oscillator). For the diagonal elements ($n = n'$), the RWA requirement is reduced to $m = m'$, giving sums over all diagonal elements of the density matrix:

$$[\hat{x}(t)\hat{w}\hat{x}(t')]_{nn} = \sum_m |x_{nm}|^2 \exp\{i\omega_{nm}(t-t')\} w_{mm}. \quad (7.191)$$

(Another similar term, $[\hat{x}(t')\hat{w}\hat{x}(t)]_{nn}$, is just a complex conjugate of (191).) However, for off-diagonal matrix elements ($n \neq n'$), the situation is different: Eq. (190) may be satisfied only if $m = n$ and also $m' = n'$, so that the double sum is reduced to just one, non-oscillating term:

$$[\hat{x}(t)\hat{w}\hat{x}(t')]_{nn'} = x_{nn} w_{nn'} x_{n'n'}, \quad \text{for } n \neq n'. \quad (7.192)$$

The second similar term, $[\hat{x}(t')\hat{w}\hat{x}(t)]_{nn'}$, is exactly the same, so that in one of the integrals of Eq. (183), these terms add up, while in the second one, they cancel.

This is why the final equations of evolution look differently for diagonal and off-diagonal elements of the density matrix. For the former case ($n = n'$), Eq. (183) is reduced to the so-called *master equation*⁶² relating diagonal elements w_{nn} of the density matrix, i.e. the energy level occupancies W_n :⁶³

$$\begin{aligned} \dot{W}_n = \sum_{m \neq n} |x_{nm}|^2 \int_0^\infty & \left[-\frac{1}{\hbar^2} K_F(\tau)(W_n - W_m)(\exp\{i\omega_{nm}\tau\} + \exp\{-i\omega_{nm}\tau\}) \right. \\ & \left. - \frac{i}{2\hbar} G(\tau)(-W_n - W_m)(\exp\{i\omega_{nm}\tau\} - \exp\{-i\omega_{nm}\tau\}) \right] d\tau, \end{aligned} \quad (7.193)$$

where $\tau \equiv t - t'$. Changing the summation index notation from m to n' , we may rewrite the master equation in its canonical form

$$\boxed{\dot{W}_n = \sum_{n' \neq n} (\Gamma_{n' \rightarrow n} W_{n'} - \Gamma_{n \rightarrow n'} W_n)}, \quad (7.194) \quad \text{Master equation}$$

where the coefficients

$$\boxed{\Gamma_{n' \rightarrow n} \equiv |x_{nn'}|^2 \int_0^\infty \left[\frac{2}{\hbar^2} K_F(\tau) \cos \omega_{nn'} \tau - \frac{1}{\hbar} G(\tau) \sin \omega_{nn'} \tau \right] dt'}, \quad (7.195) \quad \text{Interlevel transition rates}$$

are called the *interlevel transition rates*.⁶⁴ Eq. (194) has a very clear physical meaning of the level occupancy dynamics (i.e. the balance of the probability flows ΓW) due to quantum transitions between

⁶² The master equations, first introduced to quantum mechanics in 1928 by W. Pauli, are sometimes called the “Pauli master equations”, or “kinetic equations”, or “rate equations”.

⁶³ As Eq. (193) shows, the term with $m = n$ would vanish and thus may be legitimately excluded from the sum.

⁶⁴ As Eq. (193) shows, the result for $\Gamma_{n \rightarrow n'}$ is described by Eq. (195) as well, provided that the indices n and n' are swapped in all components of its right-hand side, including the swap $\omega_{nn'} \rightarrow \omega_{n'n} = -\omega_{nn'}$.

the energy levels (see Fig. 7), in our current case caused by the interaction between the system of our interest and its environment.

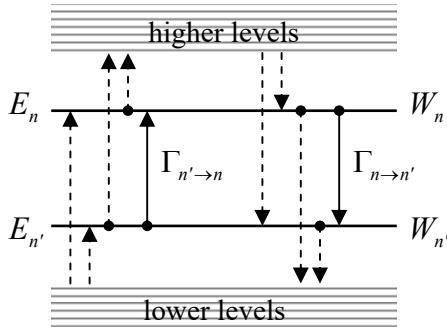

Fig. 7.7. Probability flows in a discrete-spectrum system. Solid arrows: the exchange between the two energy levels, n and n' , described by one term in the master equation (194); dashed arrows: other transitions to/from these two levels.

The Fourier transforms (113) and (123) enable us to express the two integrals in Eq. (195) via, respectively, the symmetrized spectral density $S_F(\omega)$ of environment force fluctuations and the imaginary part $\chi''(\omega)$ of the generalized susceptibility, both at frequency $\omega = \omega_{nn'}$. After that we may use the fluctuation-dissipation theorem (134) to exclude the former function, getting finally⁶⁵

Transition rates via $\chi''(\omega)$

$$\Gamma_{n' \rightarrow n} = \frac{1}{\hbar} |x_{nn'}|^2 \chi''(\omega_{nn'}) \left(\coth \frac{\hbar \omega_{nn'}}{2k_B T} - 1 \right) \equiv \frac{2}{\hbar} |x_{nn'}|^2 \frac{\chi''(\omega_{nn'})}{\exp\{(E_n - E_{n'})/k_B T\} - 1}. \quad (7.196)$$

Note that since the imaginary part χ'' of the generalized susceptibility is an odd function of frequency, Eq. (196) is in compliance with the Gibbs distribution for arbitrary temperature. Indeed, according to this equation, the ratio of the “up” and “down” rates for each pair of levels equals

$$\frac{\Gamma_{n' \rightarrow n}}{\Gamma_{n \rightarrow n'}} = \frac{\chi''(\omega_{nn'})}{\exp\{(E_n - E_{n'})/k_B T\} - 1} / \frac{\chi''(\omega_{n'n})}{\exp\{(E_{n'} - E_n)/k_B T\} - 1} \equiv \exp\left\{-\frac{E_n - E_{n'}}{k_B T}\right\}. \quad (7.197)$$

On the other hand, according to the Gibbs distribution (24), in thermal equilibrium the level populations should be in the same proportion. Hence, Eq. (196) complies with the so-called *detailed balance equation*,

$$W_n \Gamma_{n \rightarrow n'} = W_{n'} \Gamma_{n' \rightarrow n}, \quad (7.198)$$

valid in the equilibrium for each pair $\{n, n'\}$, so that all right-hand sides of all Eqs. (194), and hence the time derivatives of all W_n vanish – as they should. Thus, the stationary solution of the master equations indeed describes the thermal equilibrium correctly.

The system of master equations (194), frequently complemented by additional terms on their right-hand sides, describing interlevel transitions due to other factors (e.g., by an external ac force with a frequency close to one of $\omega_{nn'}$), is the key starting point for practical analyses of many quantum systems, notably including optical quantum amplifiers and generators (lasers). It is important to remember that

⁶⁵ It is straightforward (and highly recommended to the reader) to show that at low temperatures ($k_B T \ll |E_{n'} - E_n|$), Eq. (196) gives the same result as the Golden Rate formula (6.111), with $A = x$. (The low-temperature condition ensures that the initial occupancy of the excited level n is negligible, as was assumed at the derivation of Eq. (6.111).)

they are strictly valid only in the rotating-wave approximation, i.e. if Eq. (182) is well satisfied for all n and n' of substance.

For a particular but very important case of a two-level system (with, say, $E_1 > E_2$), the rate $\Gamma_{1 \rightarrow 2}$ may be interpreted (especially in the low-temperature limit $k_B T \ll \hbar\omega_{12} = E_1 - E_2$, when $\Gamma_{1 \rightarrow 2} \gg \Gamma_{2 \rightarrow 1}$) as the reciprocal characteristic time $1/T_1 \equiv \Gamma_{1 \rightarrow 2}$ of the *energy relaxation* process that brings the *diagonal* elements of the density matrix to their thermally-equilibrium values (24). For the Ohmic dissipation described by Eqs. (137)-(138), Eq. (196) yields

$$\frac{1}{T_1} \equiv \Gamma_{1 \rightarrow 2} = \frac{2}{\hbar^2} |x_{12}|^2 \eta \times \begin{cases} \hbar\omega_{12}, & \text{for } k_B T \ll \hbar\omega_{12}, \\ k_B T, & \text{for } \hbar\omega_{12} \ll k_B T. \end{cases} \quad (7.199)$$

Energy
relaxation
time

This relaxation time T_1 should not be confused with the characteristic time T_2 of the *off-diagonal* element decay, i.e. dephasing, which was already discussed in Sec. 3. In this context, let us see what do Eqs. (183) have to say about the dephasing rates. Taking into account our intermediate results (187)-(192), and merging the non-oscillating components (with $m = n$ and $m = n'$) of the sums Eq. (187) and (188) with the terms (192), which also do not oscillate in time, we get the following equation:⁶⁶

$$\dot{w}_{nn'} = - \left\{ \int_0^\infty \left[\frac{1}{\hbar^2} K_F(\tau) \left(\sum_{m \neq n} |x_{nm}|^2 \exp\{i\omega_{nm}\tau\} + \sum_{m \neq n'} |x_{n'm}|^2 \exp\{-i\omega_{n'm}\tau\} + (x_{nn} - x_{n'n'})^2 \right) \right. \right. \\ \left. \left. + \frac{i}{2\hbar} G(\tau) \left(\sum_{m \neq n} |x_{nm}|^2 \exp\{i\omega_{nm}\tau\} - \sum_{m \neq n'} |x_{n'm}|^2 \exp\{-i\omega_{n'm}\tau\} \right) \right] d\tau \right\} w_{nn'}, \text{ for } n \neq n'. \quad (7.200)$$

In contrast with Eq. (194), the right-hand side of this equation includes both a real and an imaginary part, and hence it may be represented as

$$\dot{w}_{nn'} = -(1/T_{nn'} + i\Delta_{nn'}) w_{nn'}, \quad (7.201)$$

where both factors $1/T_{nn'}$ and $\Delta_{nn'}$ are real. As Eq. (201) shows, the second term in the right-hand side of this equation causes slow oscillations of the matrix elements $w_{nn'}$, which, after returning to the Schrödinger picture, add just small corrections⁶⁷ to the unperturbed frequencies (186) of their oscillations, and are not important for most applications. More important is the first term, proportional to

$$\frac{1}{T_{nn'}} = \int_0^\infty \left[\frac{1}{\hbar^2} K_F(\tau) \left(\sum_{m \neq n} |x_{nm}|^2 \cos \omega_{nm}\tau + \sum_{m \neq n'} |x_{n'm}|^2 \cos \omega_{n'm}\tau + (x_{nn} - x_{n'n'})^2 \right) \right]$$

⁶⁶ Sometimes Eq. (200) (in any of its numerous alternative forms) is called the *Redfield equation*, after the 1965 work by A. Redfield. Note, however, that in the mid-1960s several other authors, notably including (in the alphabetical order) H. Haken, W. Lamb, M. Lax, W. Louisell, and M. Scully, also made major contributions to the very fast development of the density-matrix approach to open quantum systems.

⁶⁷ Such corrections are sometimes called *Lamb shifts*, due to their conceptual similarity to the genuine Lamb shift – the effect first observed experimentally in 1947 by Willis Lamb and Robert Rutherford: a minor difference between energy levels of the $2s$ and $2p$ states of hydrogen, due to the electric-dipole coupling of hydrogen atoms to the free-space electromagnetic environment. (These energies are equal not only in the non-relativistic theory described in Sec. 3.6 but also in the relativistic theory (see Secs. 6.3, 9.7), if the electromagnetic environment is ignored.) The explanation of the Lamb shift by H. Bethe, in the same 1947, essentially launched the whole field of quantum electrodynamics – to be briefly discussed in Chapter 9.

$$-\frac{1}{2\hbar}G(\tau)\left(\sum_{m \neq n}|x_{nm}|^2 \sin \omega_{nm}\tau + \sum_{m \neq n'}|x_{n'm}|^2 \sin \omega_{n'm}\tau\right)d\tau, \quad \text{for } n \neq n', \quad (7.202)$$

because it describes the effect completely absent without the environment coupling: exponential decay of the off-diagonal matrix elements, i.e. the dephasing. Comparing the first two terms of Eq. (202) with Eq. (195), we see that the dephasing rates may be described by a very simple formula:

Dephasing rate

$$\begin{aligned} \frac{1}{T_{nn'}} &= \frac{1}{2}\left(\sum_{m \neq n}\Gamma_{n \rightarrow m} + \sum_{m \neq n'}\Gamma_{n' \rightarrow m}\right) + \frac{\pi}{\hbar^2}(x_{nn} - x_{n'n'})^2 S_F(0) \\ &= \frac{1}{2}\left(\sum_{m \neq n}\Gamma_{n \rightarrow m} + \sum_{m \neq n'}\Gamma_{n' \rightarrow m}\right) + \frac{k_B T}{\hbar^2}\eta(x_{nn} - x_{n'n'})^2, \quad \text{for } n \neq n', \end{aligned} \quad (7.203)$$

where the low-frequency drag coefficient η is again defined as $\lim_{\omega \rightarrow 0}\chi''(\omega)/\omega$ – see Eq. (138).

This result shows that two effects yield independent contributions to the dephasing. The first of them may be interpreted as a result of “virtual” transitions of the system, from the levels n and n' of our interest, to other energy levels m ; according to Eq. (195), this contribution is proportional to the strength of coupling to the environment at relatively high frequencies ω_{nm} and $\omega_{n'm}$. (If the energy quanta $\hbar\omega$ of these frequencies are much larger than the thermal fluctuation scale $k_B T$, then only the lower levels, with $E_m < \max[E_n, E_{n'}]$ are important.) On the contrary, the second contribution is due to low-frequency, essentially classical fluctuations of the environment, and hence to the low-frequency dissipative susceptibility. In the Ohmic dissipation case, when the ratio $\eta \equiv \chi''(\omega)/\omega$ is frequency-independent, both contributions are of the same order, but their exact relation depends on the matrix elements $x_{nn'}$ of a particular system.

For example, returning for a minute to the two-level system discussed in Sec. 3, described by our current theory with the replacement $\hat{x} \rightarrow \hat{\sigma}_z$, the high-frequency contributions to dephasing vanish because of the absence of transitions between energy levels, while the low-frequency contribution yields

$$\frac{1}{T_2} \equiv \frac{1}{T_{12}} = \frac{k_B T}{\hbar^2}\eta(x_{nn} - x_{n'n'})^2 \rightarrow \frac{k_B T}{\hbar^2}\eta[(\sigma_z)_{11} - (\sigma_z)_{22}]^2 = \frac{4k_B T}{\hbar^2}\eta, \quad (7.204)$$

thus exactly reproducing the result (142) of the Heisenberg-Langevin approach.⁶⁸ Note also that the expression for T_2 is very close in structure to Eq. (199) for T_1 (in the high-temperature limit). However, for the simple interaction model (70) that was explored in Sec. 3, the off-diagonal elements of the operator $\hat{x} = \hat{\sigma}_z$ in the stationary-state z -basis vanish, so that $T_1 \rightarrow \infty$, while T_2 says finite. The physics of this result is very clear, for example, for the two-well implementation of the model (see Fig. 4 and its discussion): it is suitable for the case of a very high energy barrier between the wells, which inhibits tunneling, and hence any change of the well occupancies. However, T_1 may become finite, and comparable with T_2 , if tunneling between the wells is substantial.⁶⁹

⁶⁸ The first form of Eq. (203), as well as the analysis of Sec. 3, implies that low-frequency fluctuations of any other origin, not taken into account in own current analysis (say, an unintentional noise from experimental equipment), may also contribute to dephasing; such “technical fluctuations” are indeed a very serious challenge for the experimental implementation of coherent qubit systems – see Sec. 8.5 below.

⁶⁹ As was discussed in Sec. 5.1, the tunneling may be described by using, instead of Eq. (70), the full two-level Hamiltonian (5.3). Let me leave for the reader’s exercise to spell out the equations for the time evolution of the density matrix elements of this system, and of the expectation values of the Pauli operators, for this case.

Because of the reason explained above, the derivation of Eqs. (200)-(204) is not valid for systems with equidistant energy spectra – for example, the harmonic oscillator. For this particular, but very important system, with its simple matrix elements $x_{nn'}$ given by Eqs. (5.92), it is longish but straightforward to repeat the above calculations, starting from (183), to obtain an equation similar in structure to Eq. (200), but with two other terms, proportional to $w_{n\pm 1,n'\pm 1}$, on its right-hand side. Neglecting the minor Lamb-shift term, the equation reads

$$\dot{w}_{nn'} = -\delta \left\{ \begin{aligned} & [(n_e + 1)(n + n') + n_e(n + n' + 2)]w_{nn'} \\ & - 2(n_e + 1)[(n + 1)(n' + 1)]^{1/2} w_{n+1,n'+1} - 2n_e(nn')^{1/2} w_{n-1,n'-1} \end{aligned} \right\}. \quad (7.205)$$

Here δ is the effective damping coefficient,⁷⁰

$$\delta \equiv \frac{x_0^2}{2\hbar} \text{Im } \chi(\omega_0) \equiv \frac{\text{Im } \chi(\omega_0)}{2m\omega_0}, \quad (7.206)$$

equal to just $\eta/2m$ for the Ohmic dissipation, and n_e is the equilibrium number of oscillator's excitations, given by Eq. (26b), with the environment's temperature T . (I am using this new notation because in dynamics, the instant expectation value $\langle n \rangle$ may be time-dependent, and is generally different from its equilibrium value n_e .)

As a remark: the derivation of Eq. (205) might be started at a bit earlier point, from the Markov approximation applied to Eq. (181), expressing the coordinate operator via the creation-annihilation operators (5.65). This procedure gives the result in the operator (i.e. basis-independent) form:⁷¹

$$\dot{\hat{w}} = -\delta \left[(n_e + 1) \left(\left\{ \hat{a}^\dagger \hat{a}, \hat{w} \right\} - 2\hat{a}\hat{w}\hat{a}^\dagger \right) + n_e \left(\left\{ \hat{a}\hat{a}^\dagger, \hat{w} \right\} - 2\hat{a}^\dagger\hat{w}\hat{a} \right) \right]. \quad (7.207)$$

In the Fock state basis, this equation immediately reduces to Eq. (205); however, Eq. (207) may be more convenient for some applications.

Returning to Eq. (205), we see that it relates only the elements $w_{nn'}$ located at the same distance ($n - n'$) from the principal diagonal of the density matrix. This means, in particular, that the dynamics of the diagonal elements w_{nn} of the matrix, i.e. the Fock state probabilities W_n , is independent of the off-diagonal elements, and may be represented in the form (194), truncated to the transitions between the adjacent energy levels only ($n' = n \pm 1$):

⁷⁰ This coefficient participates prominently in the classical theory of damped oscillations (see, e.g., CM Sec. 5.1), in particular defining the oscillator's Q -factor as $Q \equiv \omega_0/2\delta$, and the decay time of the amplitude A and the energy E of free oscillations: $A(t) = A(0)\exp\{-\delta t\}$, $E(t) = E(0)\exp\{-2\delta t\}$.

⁷¹ Sometimes Eq. (207) is called the *Lindblad equation*, but I believe this terminology is inappropriate. It is true that its structure falls into a general category of equations, suggested by G. Lindblad in 1976 for the density operators in the Markov approximation, whose diagonalized form in the interaction picture is

$$\dot{\hat{w}} = \sum_j \gamma_j \left(2\hat{L}_j \hat{w} \hat{L}_j^\dagger - \left\{ \hat{L}_j \hat{L}_j^\dagger, \hat{w} \right\} \right).$$

However, Eq. (207) was derived much earlier (by L. Landau in 1927 for zero temperature, and by M. Lax in 1960 for an arbitrary temperature), and in contrast to the general Lindblad equation, spells out the participating operators \hat{L}_j and coefficients γ_j for a particular physical system – the harmonic oscillator.

$$\dot{W}_n = (\Gamma_{n+1 \rightarrow n} W_{n+1} - \Gamma_{n \rightarrow n+1} W_n) + (\Gamma_{n-1 \rightarrow n} W_{n-1} - \Gamma_{n \rightarrow n-1} W_n), \quad (7.208)$$

with the following rates:

$$\begin{aligned} \Gamma_{n+1 \rightarrow n} &= 2\delta(n+1)(n_e + 1), & \Gamma_{n \rightarrow n+1} &= 2\delta(n+1)n_e, \\ \Gamma_{n-1 \rightarrow n} &= 2\delta n n_e, & \Gamma_{n \rightarrow n-1} &= 2\delta n(n_e + 1). \end{aligned} \quad (7.209)$$

Since according to the definition of n_e , given by Eq. (26b),

$$n_e = \frac{1}{\exp\{\hbar\omega_0/k_B T\} - 1}, \quad \text{so that } n_e + 1 = \frac{\exp\{\hbar\omega_0/k_B T\}}{\exp\{\hbar\omega_0/k_B T\} - 1} = -\frac{1}{\exp\{-\hbar\omega_0/k_B T\} - 1}, \quad (7.210)$$

taking into account Eqs. (5.92), (186), (206), and the asymmetry of the function $\chi''(\omega)$, we see that these rates are again described by Eq. (196), even though the last formula was derived for non-equidistant energy spectra.

Hence the only substantial new feature of the master equation for the harmonic oscillator, is that the decay of the off-diagonal elements of its density matrix is scaled by the same parameter (2δ) as that of the decay of its diagonal elements, i.e. there is no radical difference between the dephasing and energy-relaxation times T_2 and T_1 . This fact may be interpreted as the result of the independence of the energy level distances, $\hbar\omega_0$, of the fluctuations $F(t)$ exerted on the oscillator by the environment, so that their low-frequency density, $S_F(0)$, does not contribute to the dephasing. (This fact formally follows also from Eq. (203) as well, taking into account that for the oscillator, $x_{nn} = x_{n'n'} = 0$.)

The simple equidistant structure of the oscillator's spectrum makes it possible to readily solve the system of Eqs. (208), with $n = 0, 1, 2, \dots$, for some important cases. In particular, if the initial state of the oscillator is a classical mixture, with no off-diagonal elements, its further relaxation proceeds as such a mixture: $w_{nn'}(t) = 0$ for all $n' \neq n$.⁷² In particular, it is straightforward to use Eq. (208) to verify that if the initial classical mixture obeys the Gibbs distribution (25), but with a temperature T_i different from that of the environment (T_e), then the relaxation process is reduced to a simple exponential transient of the effective temperature from T_i to T_e :

$$W_n(t) = \exp\left\{-n \frac{\hbar\omega_0}{k_B T_{\text{ef}}(t)}\right\} \left(1 - \exp\left\{-\frac{\hbar\omega_0}{k_B T_{\text{ef}}(t)}\right\}\right), \quad \text{with } T_{\text{ef}}(t) = T_i e^{-2\delta t} + T_e (1 - e^{-2\delta t}), \quad (7.211)$$

with the corresponding evolution of the expectation value of the full energy E – cf. Eq. (26b):

$$\langle E \rangle(t) = \frac{\hbar\omega_0}{2} + \hbar\omega_0 \langle n \rangle(t), \quad \langle n \rangle(t) = \frac{1}{\exp\{\hbar\omega_0/k_B T_{\text{ef}}(t)\} - 1} \xrightarrow{t \rightarrow \infty} n_e. \quad (7.212)$$

However, if the initial state of the oscillator is different (say, corresponds to some upper Fock state), the relaxation process, described by Eqs. (208)-(209), is more complex – see, e.g., Fig. 8. At low temperatures (Fig. 8a), it may be interpreted as a gradual “roll” of the probability distribution down the energy staircase, with a gradually decreasing velocity $dn/dt \propto n$. However, at substantial temperatures,

⁷² Note, however, that this is not true for many applications, in which a damped oscillator is also under the effect of an external time-dependent field, which may be described by additional, typically off-diagonal terms on the right-hand side of Eqs. (205).

with $k_B T \sim \hbar\omega_0$ (Fig. 8b), this “roll-down” is saturated when the level occupancies $W_n(t)$ approach their equilibrium values (25).⁷³

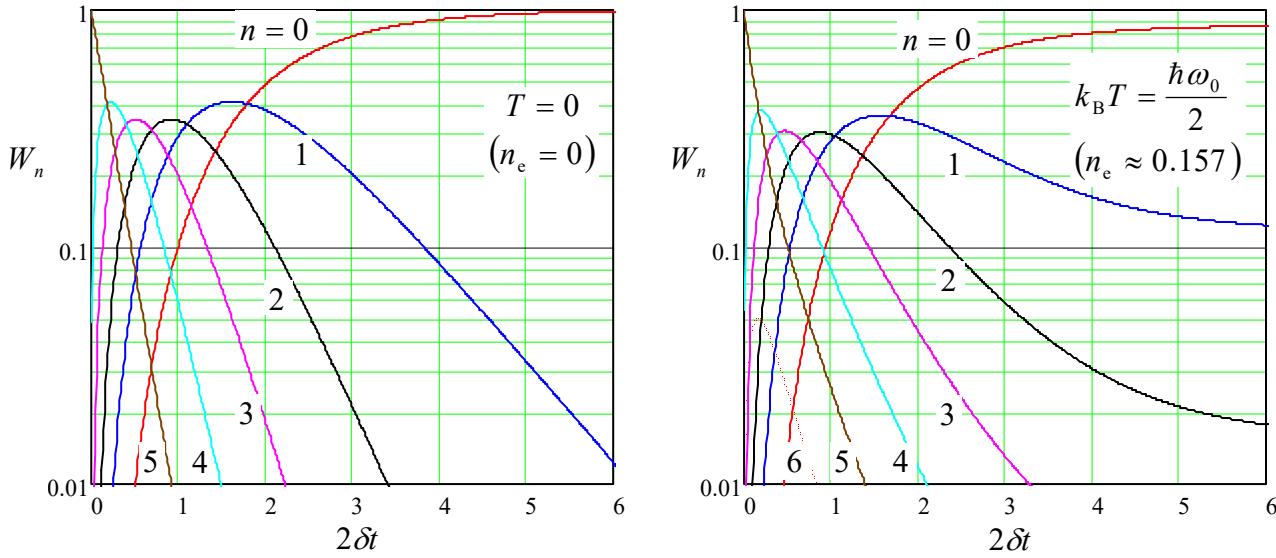

Fig. 7.8. Relaxation of a harmonic oscillator, initially in its 5th Fock state, at: (a) $T = 0$, and (b) $T > 0$. Note that in the latter case, even the energy levels with $n > 5$ get populated, due to their thermal excitation.

The analysis of this process may be simplified in the case when $W(n, t) \equiv W_n(t)$ is a smooth function of the energy level number n , limited to high levels: $n \gg 1$. In this limit, we may use the Taylor expansion of this function (written for the points $\Delta n = \pm 1$), truncated to three leading terms:

$$W_{n\pm 1}(t) \equiv W(n \pm 1, t) \approx W(n, t) \pm \frac{\partial W(n, t)}{\partial n} + \frac{1}{2} \frac{\partial^2 W(n, t)}{\partial n^2}. \quad (7.213)$$

Plugging this expression into Eqs. (208)-(209), we get for the function $W(n, t)$ a partial differential equation, which may be recast in the following form:

$$\frac{\partial W}{\partial t} = -\frac{\partial}{\partial n} [f(n)W] + \frac{\partial^2}{\partial n^2} [d(n)W], \quad \text{with } f(n) \equiv 2\delta(n_e - n), \quad d(n) \equiv 2\delta(n_e + \frac{1}{2})n. \quad (7.214)$$

Since at $n \gg 1$, the oscillator’s energy E is close to $\hbar\omega_0 n$, this *energy diffusion equation* (sometimes incorrectly called the Fokker-Planck equation – see below) essentially describes the time evolution of the continuous probability density $w(E, t)$, which may be defined as $w(E, t) \equiv W(E/\hbar\omega_0, t)/\hbar\omega_0$.⁷⁴

⁷³ The reader may like to have a look at the results of nice measurements of such functions $W_n(t)$ in microwave oscillators, performed using their coupling with Josephson-junction circuits: H. Wang *et al.*, *Phys. Rev. Lett.* **101**, 240401 (2008), and with Rydberg atoms: M. Brune *et al.*, *Phys. Rev. Lett.* **101**, 240402 (2008).

⁷⁴ In the classical limit $n_e \gg 1$, Eq. (214) is analytically solvable for any initial conditions – see, e.g., the paper by B. Zeldovich *et al.*, *Sov. Phys. JETP* **28**, 308 (1969), which also gives some more intricate solutions of Eqs. (208)-(209). Note, however, that the most important properties of the damped harmonic oscillator (including its relaxation dynamics) may be analyzed simpler by using the Heisenberg-Langevin approach discussed in the previous section.

This continuous approximation naturally reminds us of the need to discuss dissipative systems with a *continuous* spectrum. Unfortunately, for such systems the few (relatively :-) simple results that may be obtained from the basic Eq. (181), are essentially classical in nature and are discussed in detail in the SM part of this series. Here, I will give only a simple illustration. Let us consider a 1D particle that interacts weakly with a thermally-equilibrium environment, but otherwise is free to move along the x -axis. As we know from Chapters 2 and 5, in this case, the most convenient basis is that of the momentum eigenstates p . In the momentum representation, the density matrix is just the c -number function $w(p, p')$, defined by Eq. (54), which was already discussed in brief in Sec. 2. On the other hand, the coordinate operator, which participates in the right-hand side of Eq. (181), has the form given by the first of Eqs. (4.269),

$$\hat{x} = i\hbar \frac{\partial}{\partial p}, \quad (7.215)$$

dual to the coordinate-representation formula (4.268). As we already know, such operators are local – see, e.g., Eq. (4.244). Due to this locality, the whole right-hand side of Eq. (181) is local as well, and hence (within the framework of our perturbative treatment) the interaction with the environment affects only the diagonal values $w(p, p)$ of the density matrix, i.e. the momentum probability density $w(p)$.

Let us find the equation governing the evolution of this function in time in the Markov approximation, when the time scale of the density matrix evolution is much longer than the correlation time τ_c of the environment, i.e. the time scale of the functions $K_F(\tau)$ and $G(\tau)$. In this approximation, we may take the matrix elements out of the first integral of Eq. (181),

$$\begin{aligned} -\frac{1}{\hbar^2} \int_{-\infty}^t K_F(t-t') dt' [\hat{x}(t), [\hat{x}(t'), \hat{w}(t')]] &\approx -\frac{1}{\hbar^2} \int_0^\infty K_F(\tau) d\tau [\hat{x}, [\hat{x}, \hat{w}]] \\ &= -\frac{\pi}{\hbar^2} S_F(0) [\hat{x}, [\hat{x}, \hat{w}]] = -\frac{k_B T}{\hbar^2} \eta [\hat{x}, [\hat{x}, \hat{w}]], \end{aligned} \quad (7.216)$$

and calculate the last double commutator in the Schrödinger picture. This may be done either using an explicit expression for the matrix elements of the coordinate operator or in a simpler way – using the same trick as at the derivation of the Ehrenfest theorem in Sec. 5.2. Namely, expanding an arbitrary function $f(p)$ into the Taylor series in p ,

$$f(p) = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k f}{\partial p^k} p^k, \quad (7.217)$$

and using Eq. (215), we can prove the following simple commutation relation:

$$[\hat{x}, f] = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k f}{\partial p^k} [\hat{x}, p^k] = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^k f}{\partial p^k} (i\hbar k p^{k-1}) = i\hbar \sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^{k-1}}{\partial p^{k-1}} \left(\frac{\partial f}{\partial p} \right) p^{k-1} = i\hbar \frac{\partial f}{\partial p}. \quad (7.218)$$

Now applying this result sequentially, first to w and then to the resulting commutator, we get

$$[\hat{x}, [\hat{x}, w]] = \left[\hat{x}, i\hbar \frac{\partial w}{\partial p} \right] = i\hbar \frac{\partial}{\partial p} \left(i\hbar \frac{\partial w}{\partial p} \right) = -\hbar^2 \frac{\partial^2 w}{\partial p^2}. \quad (7.219)$$

It may look like the second integral in Eq. (181) might be simplified similarly. However, it vanishes at $p' \rightarrow p$, and $t' \rightarrow t$, so that to calculate the first non-vanishing contribution from that integral for $p = p'$, we have to take into account the small difference $\tau \equiv t - t' \sim \tau_c$ between the arguments of the

coordinate operators under that integral. This may be done using Eq. (169) with the free-particle's Hamiltonian consisting of the kinetic-energy contribution alone:

$$\hat{x}(t') - \hat{x}(t) \approx -\tau \dot{\hat{x}} = -\tau \frac{1}{i\hbar} [\hat{x}, \hat{H}_s] = -\tau \frac{1}{i\hbar} \left[\hat{x}, \frac{\hat{p}^2}{2m} \right] = -\tau \frac{\hat{p}}{m}, \quad (7.220)$$

where the exact argument of the operator on the right-hand side is already unimportant and may be taken for t . As a result, we may use the last of Eqs. (136) to reduce the second term on the right-hand side of Eq. (181) to

$$-\frac{i}{2\hbar} \int_{-\infty}^t G(t-t')[\hat{x}(t), \{\hat{x}(t'), \hat{w}(t')\}] dt' \approx \frac{i}{2\hbar} \int_0^\infty G(\tau) \tau d\tau \left[\hat{x}, \left\{ \frac{\hat{p}}{m}, \hat{w} \right\} \right] = \frac{\eta}{2i\hbar} \left[\hat{x}, \left\{ \frac{\hat{p}}{m}, \hat{w} \right\} \right]. \quad (7.221)$$

In the momentum representation, the momentum operator and the density matrix w are just c -numbers and commute, so that, applying Eq. (218) to the product pw , we get

$$\left[\hat{x}, \left\{ \frac{\hat{p}}{m}, \hat{w} \right\} \right] = \left[\hat{x}, 2 \frac{p}{m} w \right] = 2i\hbar \frac{\partial}{\partial p} \left(\frac{p}{m} w \right), \quad (7.222)$$

and may finally reduce the integro-differential equation Eq. (181) to a partial differential equation:

$$\frac{\partial w}{\partial t} = -\frac{\partial}{\partial p} (Fw) + \eta k_B T \frac{\partial^2 w}{\partial p^2}, \quad \text{with } F \equiv -\eta \frac{p}{m}. \quad (7.223)$$

Fokker –
Planck
equation:
free
1D particle

This is the 1D form of the famous *Fokker-Planck equation* describing the classical statistics of motion of a particle (in our particular case, of a free particle) in an environment providing a linear drag characterized by the coefficient η ; it belongs to the same drift-diffusion type as Eq. (214). The first, *drift* term on its right-hand side describes the particle's deceleration due to the drag force (137), $F = -\eta p/m = -\eta v$, provided by the environment. The second, *diffusion* term on the right-hand side of Eq. (223) describes the effect of fluctuations: the particle's momentum' random walk around its average (drift-affected, and hence time-dependent) value. The walk obeys the law similar to Eq. (85), but with the *momentum-space* diffusion coefficient

$$D_p = \eta k_B T. \quad (7.224)$$

This is the reciprocal-space version of the fundamental Einstein relation between the dissipation (friction) and fluctuations, in this classical limit represented by their thermal energy scale $k_B T$.⁷⁵

Just for the reader's reference, let me note that the Fokker-Planck equation (223) may be readily generalized to the 3D motion of a particle under the effect of an additional external force,⁷⁶ and in this

⁷⁵ Note that Eq. (224), as well as the original Einstein's relation between the diffusion coefficient D in the direct space and temperature, may be derived much simpler by other means – for example, from the Nyquist formula (139). These issues are discussed in detail in SM Chapter 5.

⁷⁶ Moreover, Eq. (223) may be generalized to the motion of a *quantum* particle in an additional periodic potential $U(\mathbf{r})$. In this case, due to the band structure of the energy spectrum (which was discussed in Secs. 2.7 and 3.4), the coupling to the environment produces not only a continuous drift-diffusion of the probability density in the space of the quasimomentum $\hbar\mathbf{q}$ but also quantum transitions between different energy bands at the same $\hbar\mathbf{q}$ – see, e.g., K. Likharev and A. Zorin, *J. Low Temp. Phys.* **59**, 347 (1985).

more general form is the basis for many important applications; however, due to its classical character, its discussion is also left for the SM part of this series.⁷⁷

To summarize our discussion of the two alternative approaches to the analysis of quantum systems interacting with a thermally-equilibrium environment, described in the last three sections, let me emphasize again that they give different descriptions of the same phenomena, and are characterized by the same two functions $G(\tau)$ and $K_F(\tau)$. Namely, in the Heisenberg-Langevin approach, we describe the system by operators that change (fluctuate) in time, even in the thermal equilibrium, while in the density-matrix approach, the system is described by non-fluctuating probability functions, such as $W_n(t)$ or $w(p, t)$, which are stationary in equilibrium. In the cases when a problem may be solved analytically to the end by both methods (for example, for a harmonic oscillator), they give identical results.

7.8. Exercise problems

7.1. Calculate the density matrix of a two-level system whose Hamiltonian is described, in a certain basis, by the following matrix:

$$H = \mathbf{c} \cdot \boldsymbol{\sigma} \equiv c_x \sigma_x + c_y \sigma_y + c_z \sigma_z,$$

where σ_k are the Pauli matrices and c_j are c -numbers, in thermodynamic equilibrium at temperature T .

7.2. In the usual z -basis, spell out the density matrix of a spin- $\frac{1}{2}$ with gyromagnetic ratio γ :

- (i) in the pure state with the spin definitely directed along the z -axis,
- (ii) in the pure state with the spin definitely directed along the x -axis,
- (iii) in thermal equilibrium at temperature T , in a magnetic field directed along the z -axis, and
- (iv) in thermal equilibrium at temperature T , in a magnetic field directed along the x -axis.

7.3. Calculate the Wigner function of a harmonic oscillator in:

- (i) in thermodynamic equilibrium at temperature T ,
- (ii) in the ground state, and
- (ii) in the Glauber state with dimensionless complex amplitude α .

Discuss the relation between the first of the results and the Gibbs distribution.

7.4. Calculate the Wigner function of a harmonic oscillator, with mass m and frequency ω_0 , in its first excited stationary state ($n = 1$).

7.5.* A harmonic oscillator is weakly coupled to an Ohmic environment.

- (i) Use the rotating-wave approximation to write the reduced equations of motion for the Heisenberg operators of the complex amplitude of oscillations.

⁷⁷ See SM Secs. 5.6-5.7. For a more detailed discussion of *quantum* effects in dissipative systems with continuous spectra see, e. g., either U. Weiss, *Quantum Dissipative Systems*, 2nd ed., World Scientific, 1999, or H.-P. Breuer and F. Petruccione, *The Theory of Open Quantum Systems*, Oxford U. Press, 2007.

(ii) Calculate the expectation values of the correlators of the fluctuation force operators participating in these equations, and express them via the average number $\langle n \rangle$ of thermally-induced excitations in equilibrium, given by the second of Eqs. (26b).

7.6. Calculate the average potential energy of long-range electrostatic interaction between two similar isotropic, 3D harmonic oscillators, each with the electric dipole moment $\mathbf{d} = q\mathbf{s}$, where \mathbf{s} is the oscillator's displacement from its equilibrium position, at arbitrary temperature T .

7.7. A semi-infinite string with mass μ per unit length is attached to a wall and stretched with a constant force (tension) \mathcal{T} . Calculate the spectral density of the transverse force exerted on the wall, in thermal equilibrium at temperature T .

7.8.* Calculate the low-frequency spectral density of small fluctuations of the voltage V across a Josephson junction, shunted with an Ohmic conductor, and biased with a dc external current $\bar{I} > I_c$.

Hint: You may use Eqs. (1.73)-(1.74) to describe the junction's dynamics, and assume that the shunting conductor remains in thermal equilibrium.

7.9. Prove that in the interaction picture of quantum dynamics, the expectation value of an arbitrary observable A may be indeed calculated using Eq. (167).

7.10. Show that the quantum-mechanical Golden Rule (6.149) and the master equation (196) give the same results for the rate of spontaneous quantum transitions $n' \rightarrow n$ in a system with a discrete energy spectrum, weakly coupled to a low-temperature heat bath (with $k_B T \ll \hbar\omega_{nn'}$).

Hint: You may start by establishing a relation between the function $\chi''(\omega_{nn'})$, which participates in Eq. (196), and the density of states ρ_n , which participates in the Golden Rule formula, using the particular case of sinusoidal classical oscillations in the system of interest.

7.11. For a harmonic oscillator with weak Ohmic dissipation, use Eqs. (208)-(209) to find the time evolution of the expectation value $\langle E \rangle$ of oscillator's energy for an arbitrary initial state, and compare the result with that following from the Heisenberg-Langevin approach.

7.12. Derive Eq. (219) in an alternative way, using an expression dual to Eq. (4.244).

7.13. A particle in a system of two coupled potential wells (see, e.g., Fig. 7.4 in the lecture notes) is weakly coupled to an Ohmic environment.

(i) Derive equations describing the time evolution of the density matrix elements.

(ii) Solve these equations in the low-temperature limit, when the energy level splitting is much larger than $k_B T$, to calculate the time evolution of the probability of finding the particle in one of the wells, after it had been placed there at $t = 0$.

7.14.* A spin- $\frac{1}{2}$ with gyromagnetic ratio γ is placed into the magnetic field $\mathcal{B}(t) = \mathcal{B}_0 + \tilde{\mathcal{B}}(t)$ with an arbitrary but relatively small time-dependent component, and is also weakly coupled to a dissipative environment. Derive differential equations describing the time evolution of the expectation values of spin's Cartesian components, at arbitrary temperature.

Chapter 8. Multiparticle Systems

This chapter provides a brief introduction to quantum mechanics of systems of similar particles, with special attention to the case when they are indistinguishable. For such systems, theory predicts (and experiment confirms) very specific effects even in the case of negligible explicit (“direct”) interactions between the particles. These effects notably include the Bose-Einstein condensation of bosons and the exchange interaction of fermions.

8.1. Distinguishable and indistinguishable particles

The importance of quantum systems of many similar particles is probably self-evident; just the very fact that most atoms include several/many electrons is sufficient to attract our attention. There are also important systems where the total number of electrons is much higher than in one atom; for example, a cubic centimeter of a typical metal houses $\sim 10^{23}$ conduction electrons that cannot be attributed to particular atoms, and have to be considered as common parts of the system as the whole. Though quantum mechanics offers virtually no exact analytical results for systems of substantially interacting particles,¹ it reveals very important new quantum effects even in the simplest cases when particles do not interact, and least explicitly (*directly*).

If non-interacting particles are either different from each other by their nature, or physically similar but still distinguishable because of other reasons, everything is simple – at least, conceptually. Then, as was already discussed in Sec. 6.7, a system of two particles, 1 and 2, each in a pure quantum state, may be described by a state vector which is a direct product,

$$|\alpha\rangle = |\beta\rangle_1 \otimes |\beta'\rangle_2, \quad (8.1a)$$

Distinguishable particles of single-particle vectors, describing their states β and β' defined in different Hilbert spaces. (Below, I will frequently use, for such direct product, the following convenient shorthand:

$$|\alpha\rangle = |\beta\beta'\rangle, \quad (8.1b)$$

in which the particle’s number is coded by the state symbol’s position.) Hence the *permuted state*

$$\hat{\mathcal{P}} |\beta\beta'\rangle = |\beta'\beta\rangle = |\beta'\rangle_1 \otimes |\beta\rangle_2, \quad (8.2)$$

where $\hat{\mathcal{P}}$ is the *permutation operator* defined by Eq. (2), is clearly different from the initial one.

This operator may be also used for states of systems of *identical particles*. In physics, the last term may be used to describe:

(i) the “really elementary” particles like electrons, which (at least at this stage of development of physics) are considered as structure-less entities, and hence are all identical;

¹ As was emphasized in Sec. 7.3, for such systems of similar particles the powerful methods discussed in the last chapter, based on the separation of the whole Universe into a “system of our interest” and its “environment”, typically do not work well – mostly because the quantum state of the “particle of interest” may be substantially correlated (in particular, entangled) with those of similar particles forming its “environment” – see below.

(ii) any objects (e.g., hadrons or mesons) that may be considered as a system of “more elementary” particles (e.g., quarks and gluons), but are placed in the same internal quantum state – most simply, though not necessarily, in the ground state.²

It is important to note that *identical* particles still may be *distinguishable* – say by their clear spatial separation. Such systems of similar but distinguishable particles (or subsystems) are broadly discussed nowadays in the context of quantum computing and encryption – see Sec. 5 below. This is why it is insufficient to use the term “identical particles” if we want to say that they are genuinely *indistinguishable*, so I below I will use the latter term, despite it being rather unpleasant grammatically.

It turns out that for a quantitative description of systems of indistinguishable particles we need to use, instead of direct products of the type (1), linear combinations of such products, for example of $|\beta\beta'\rangle$ and $|\beta'\beta\rangle$.³ To see this, let us discuss the properties of the permutation operator defined by Eq. (2). Consider an observable A , and a system of eigenstates of its operator:

$$\hat{A}|\alpha_j\rangle = A_j|\alpha_j\rangle. \quad (8.3)$$

If the particles are indistinguishable, the observable’s expectation value should not be affected by their permutation. Hence the operators \hat{A} and $\hat{\mathcal{P}}$ have to commute and share their eigenstates. This is why the eigenstates of the operator $\hat{\mathcal{P}}$ are so important: in particular, they include the eigenstates of the Hamiltonian, i.e. the stationary states of a system of indistinguishable particles.

Let us have a look at the action of the permutation operator squared, on an elementary ket-vector product:

$$\hat{\mathcal{P}}^2|\beta\beta'\rangle = \hat{\mathcal{P}}(\hat{\mathcal{P}}|\beta\beta'\rangle) = \hat{\mathcal{P}}|\beta'\beta\rangle = |\beta\beta'\rangle, \quad (8.4)$$

i.e. $\hat{\mathcal{P}}^2$ brings the state back to its original form. Since any pure state of a two-particle system may be represented as a linear combination of such products, this result does not depend on the state, and may be represented as the following operator relation:

$$\hat{\mathcal{P}}^2 = \hat{I}. \quad (8.5)$$

Now let us find the possible eigenvalues \mathcal{P}_j of the permutation operator. Acting by both sides of Eq. (5) on any of eigenstates $|\alpha_j\rangle$ of the permutation operator, we get a very simple equation for its eigenvalues:

$$\mathcal{P}_j^2 = 1, \quad (8.6)$$

² Note that from this point of view, even complex atoms or molecules, in the same internal quantum state, may be considered on the same footing as the “really elementary” particles. For example, the already mentioned recent spectacular interference experiments by R. Lopes *et al.*, which require particle identity, were carried out with couples of ⁴He atoms in the same internal quantum state.

³ A very legitimate question is why, in this situation, we need to introduce the particles’ numbers to start with. A partial answer is that in this approach, it is much simpler to derive (or guess) the system Hamiltonians from the correspondence principle – see, e.g., Eq. (27) below. Later in this chapter, we will discuss an alternative approach (the so-called “second quantization”), in which particle numbering is avoided. While that approach is more logical, writing adequate Hamiltonians (which, in particular, would avoid spurious self-interaction of the particles) within it is more challenging – see Sec. 3 below.

with two possible solutions:

$$\mathcal{P}_j = \pm 1. \quad (8.7)$$

Let us find the eigenstates of the permutation operator in the simplest case when each of the component particles can be only in one of two single-particle states – say, β and β' . Evidently, none of the simple products $|\beta\beta'\rangle$ and $|\beta'\beta\rangle$, taken alone, does qualify for the eigenstate – unless the states β and β' are identical. This is why let us try their linear combination

$$|\alpha_j\rangle = a|\beta\beta'\rangle + b|\beta'\beta\rangle, \quad (8.8)$$

so that

$$\hat{\mathcal{P}}|\alpha_j\rangle = \mathcal{P}_j|\alpha_j\rangle = a|\beta'\beta\rangle + b|\beta\beta'\rangle. \quad (8.9)$$

For the case $\mathcal{P}_j = +1$ we have to require the states (8) and (9) to be the same, so that $a = b$, giving the so-called *symmetric eigenstate*⁴

$$|\alpha_+\rangle = \frac{1}{\sqrt{2}}(|\beta\beta'\rangle + |\beta'\beta\rangle), \quad (8.10)$$

where the front coefficient guarantees the orthonormality of the two-particle state vectors, provided that the single-particle vectors are orthonormal. Similarly, for $\mathcal{P}_j = -1$ we get $a = -b$, i.e. an *antisymmetric eigenstate*

$$|\alpha_-\rangle = \frac{1}{\sqrt{2}}(|\beta\beta'\rangle - |\beta'\beta\rangle). \quad (8.11)$$

These are the simplest (two-particle, two-state) examples of *entangled states*, defined as multiparticle system states whose vectors cannot be factored into a direct product (1) of single-particle vectors.

So far, our math does not preclude either sign of \mathcal{P}_j , in particular the possibility that the sign would depend on the state (i.e. on the index j). Here, however, comes in a crucial fact: all indistinguishable particles fall into two groups:⁵

- (i) *bosons*, particles with integer spin s , for whose states $\mathcal{P}_j = +1$, and
- (ii) *fermions*, particles with half-integer spin, with $\mathcal{P}_j = -1$.

In the non-relativistic theory we are discussing now, this key fact should be considered as an experimental one. (The relativistic quantum theory, whose elements will be discussed in Chapter 9, offers proof that the half-integer-spin particles cannot be bosons and the integer-spin ones cannot be fermions.) However, our discussion of spin in Sec. 5.7 enables the following handwaving *interpretation* of the difference between these two particle species. In the free space, the permutation of particles 1 and 2 may be viewed as a result of their pair's common rotation by angle $\phi = \pm\pi$ about a properly selected z -

⁴ As in many situations we have met earlier, the kets given by Eqs. (10) and (11) may be multiplied by $\exp\{i\varphi\}$ with an arbitrary real phase φ . However, until we discuss coherent superpositions of various states α , there is no good motivation for taking the phase different from 0; that would only clutter the notation.

⁵ Sometimes this fact is described as having two different “statistics”: the *Bose-Einstein statistics* of bosons and *Fermi-Dirac statistics* of fermions, because their statistical distributions in thermal equilibrium are indeed different – see, e.g., SM Sec. 2.8. However, this difference is actually deeper: we are dealing with *two different quantum mechanics*.

axis. As we have seen in Sec. 5.7, at the rotation by this angle, the state vector $|\beta\rangle$ of a particle with a definite quantum number m_s acquires an extra factor $\exp\{\pm im_s\pi\}$. As we know, the quantum number m_s ranges from $-s$ to $+s$, in unit steps. As a result, for bosons, with integer s , m_s can take only integer values, so that $\exp\{\pm im_s\pi\} = \pm 1$, so that the product of two such factors in the state product $|\beta\beta'\rangle$ is equal to $+1$. On the contrary, for the fermions with their half-integer s , all m_s are half-integer as well, so that $\exp\{\pm im_s\pi\} = \pm i$ so that the product of two such factors in vector $|\beta\beta'\rangle$ is equal to $(\pm i)^2 = -1$.

The most impressive corollaries of Eqs. (10) and (11) are for the case when the partial states of the two particles are the same: $\beta = \beta'$. The corresponding Bose state α_+ , defined by Eq. (10), is possible; in particular, at sufficiently low temperatures, a set of non-interacting Bose particles condenses on the ground state – the so-called *Bose-Einstein condensate* (“BEC”).⁶ The most fascinating feature of the condensates is that their dynamics is governed by quantum mechanical laws, which may show up in the behavior of their observables with virtually no quantum uncertainties⁷ – see, e.g., Eqs. (1.73)-(1.74).

On the other hand, if we take $\beta = \beta'$ in Eq. (11), we see that state α_- becomes the null-state, i.e. *cannot exist* at all. This is the mathematical expression of the *Pauli exclusion principle*:⁸ two indistinguishable fermions cannot be placed into the same quantum state. (As will be discussed below, this is true for systems with more than two fermions as well.) Probably, the key importance of this principle is self-evident: if it was not valid for electrons (that are fermions), all electrons of each atom would condense on in their ground (1s-like) state, and all the usual chemistry (and biochemistry, and biology, including dear us!) would not exist. The Pauli principle makes fermions implicitly interacting even if they do not interact *directly*, i.e. in the usual sense of this word.

8.2. Singlets, triplets, and the exchange interaction

Now let us discuss possible approaches to quantitative analyses of identical particles, starting from a simple case of two spin-½ particles (say, electrons), whose explicit interaction with each other and the external world does not involve spin. The description of such a system may be based on factorable states with ket-vectors

$$|\alpha_-\rangle = |o_{12}\rangle \otimes |s_{12}\rangle, \quad (8.12)$$

with the orbital state vector $|o_{12}\rangle$ and the spin vector $|s_{12}\rangle$ belonging to different Hilbert spaces. It is frequently convenient to use the coordinate representation of such a state, sometimes called the *spinor*:

$\langle \mathbf{r}_1, \mathbf{r}_2 | \alpha_-\rangle = \langle \mathbf{r}_1, \mathbf{r}_2 | o_{12}\rangle \otimes |s_{12}\rangle \equiv \psi(\mathbf{r}_1, \mathbf{r}_2) |s_{12}\rangle.$

(8.13)
2-particle
spinor

Since the spin-½ particles are fermions, the particle permutation has to change the sign:

⁶ For a quantitative discussion of the Bose-Einstein condensation see, e.g., SM Sec. 3.4. Examples of such condensates include *superfluids* like helium, Cooper-pair condensates in superconductors, and BECs of weakly interacting atoms.

⁷ For example, for a coherent condensate of $N \gg 1$ particles, Heisenberg's uncertainty relation takes the form $\delta x \delta p = \delta x \delta(Nmv) \geq \hbar/2$, so that its coordinate x and velocity v may be measured simultaneously with much higher precision than those of a single particle.

⁸ It was first formulated for electrons by Wolfgang Pauli in 1925, on the background of less general rules suggested by Gilbert Lewis (1916), Irving Langmuir (1919), Niels Bohr (1922), and Edmund Stoner (1924) for the explanation of experimental spectroscopic data.

$$\hat{\mathcal{P}}\psi(\mathbf{r}_1, \mathbf{r}_2)|s_{12}\rangle \equiv \psi(\mathbf{r}_2, \mathbf{r}_1)|s_{21}\rangle = -\psi(\mathbf{r}_1, \mathbf{r}_2)|s_{12}\rangle, \quad (8.14)$$

of either the orbital factor or the spin factor.

In particular, in the case of symmetric orbital factor,

$$\psi(\mathbf{r}_2, \mathbf{r}_1) = \psi(\mathbf{r}_1, \mathbf{r}_2), \quad (8.15)$$

the spin factor has to obey the relation

$$|s_{21}\rangle = -|s_{12}\rangle. \quad (8.16)$$

Let us use the ordinary z -basis (where z , in the absence of an external magnetic field, is an arbitrary spatial axis) for both spins. In this basis, the ket-vector of any two spins- $\frac{1}{2}$ may be represented as a linear combination of the following four basis vectors:

$$|\uparrow\uparrow\rangle, |\downarrow\downarrow\rangle, |\uparrow\downarrow\rangle, \text{ and } |\downarrow\uparrow\rangle. \quad (8.17)$$

The first two kets evidently do not satisfy Eq. (16), and cannot participate in the state. Applying to the remaining kets the same argumentation as has resulted in Eq. (11), we get

Singlet state

$$|s_{12}\rangle = |s_-\rangle \equiv \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle). \quad (8.18)$$

Such an orbital-symmetric and spin-antisymmetric state is called the *singlet*.

The origin of this term becomes clear from the analysis of the opposite (orbital-antisymmetric and spin-symmetric) case:

$$\psi(\mathbf{r}_2, \mathbf{r}_1) = -\psi(\mathbf{r}_1, \mathbf{r}_2), \quad |s_{12}\rangle = |s_+\rangle. \quad (8.19)$$

For the composition of such a symmetric spin state, the first two kets of Eq. (17) are completely acceptable (with arbitrary weights), and so is an entangled spin state that is the symmetric combination of the two last kets, similar to Eq. (10):

$$|s_+\rangle \equiv \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle), \quad (8.20)$$

so that the general spin state is a *triplet*:

Triplet state

$$|s_{12}\rangle = c_+|\uparrow\uparrow\rangle + c_-|\downarrow\downarrow\rangle + c_0\frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle). \quad (8.21)$$

Note that any such state (with any values of the coefficients c satisfying the normalization condition), corresponds to the same orbital wavefunction and hence the same energy. However, each of these three states has a specific value of the z -component of the net spin – evidently equal to, respectively, $+\hbar$, $-\hbar$, and 0. Because of this, even a small external magnetic field lifts their degeneracy, splitting the energy level in three; hence the term “triplet”.

In the particular case when the particles do not interact at all, for example

$$\hat{H} = \hat{h}_1 + \hat{h}_2, \quad \hat{h}_k = \frac{\hat{p}_k^2}{2m} + \hat{u}(\mathbf{r}_k), \quad \text{with } k = 1, 2, \quad (8.22)$$

the two-particle Schrödinger equation for the symmetrical orbital wavefunction (15) is obviously satisfied by the direct products,

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = \psi_n(\mathbf{r}_1)\psi_{n'}(\mathbf{r}_2), \quad (8.23)$$

of single-particle eigenfunctions, with arbitrary sets n, n' of quantum numbers. For the particular but very important case $n = n'$, this means that the eigenenergy of the (only acceptable) singlet state,

$$\frac{1}{\sqrt{2}}(\lvert \uparrow \downarrow \rangle - \lvert \downarrow \uparrow \rangle)\psi_n(\mathbf{r}_1)\psi_n(\mathbf{r}_2), \quad (8.24)$$

is just $2\varepsilon_n$, where ε_n is the single-particle energy level.⁹ In particular, for the ground state of the system, such singlet spin state gives the lowest energy $E_g = 2\varepsilon_g$, while any triplet spin state (19) would require one of the particles to be in a different orbital state, i.e. in a state of higher energy, so that the total energy of the system would be also higher.

Now moving to the systems in which two indistinguishable spin- $\frac{1}{2}$ particles do interact, let us consider, as their simplest but important¹⁰ example, the lower energy states of a neutral atom¹¹ of helium – more exactly, ${}^4\text{He}$. Such an atom consists of a nucleus with two protons and two neutrons, with the total electric charge $q = +2e$, and two electrons “rotating” about the nucleus. Neglecting the small relativistic effects that were discussed in Sec. 6.3, the Hamiltonian describing the electron motion may be expressed as

$$\hat{H} = \hat{h}_1 + \hat{h}_2 + \hat{U}_{\text{int}}, \quad \hat{h}_k = \frac{\hat{p}_k^2}{2m} - \frac{2e^2}{4\pi\varepsilon_0 r_k}, \quad \hat{U}_{\text{int}} = \frac{e^2}{4\pi\varepsilon_0 |\mathbf{r}_1 - \mathbf{r}_2|}. \quad (8.25)$$

As with most problems of multiparticle quantum mechanics, the eigenvalue/eigenstate problem for this Hamiltonian does not have an exact analytical solution, so let us carry out its approximate analysis considering the electron-electron interaction U_{int} as a perturbation. As was discussed in Chapter 6, we have to start with the “0th-order” approximation in which the perturbation is ignored, so that the Hamiltonian is reduced to the sum (22). In this approximation, the ground state of the atom is the singlet (24), with the orbital factor

$$\psi_g(\mathbf{r}_1, \mathbf{r}_2) = \psi_{100}(\mathbf{r}_1)\psi_{100}(\mathbf{r}_2), \quad (8.26)$$

and energy $2\varepsilon_g$. Here each factor $\psi_{100}(\mathbf{r})$ is the single-particle wavefunction of the ground (1s) state of the hydrogen-like atom with $Z = 2$, with quantum numbers $n = 1, l = 0$, and $m = 0$ – hence the wavefunctions’ indices. According to Eqs. (3.174) and (3.208),

$$\psi_{100}(\mathbf{r}) = Y_0^0(\theta, \varphi)\mathcal{R}_{1,0}(r) = \frac{1}{\sqrt{4\pi}} \frac{2}{r_0^{3/2}} e^{-r/r_0}, \quad \text{with } r_0 = \frac{r_B}{Z} = \frac{r_B}{2}, \quad (8.27)$$

and according to Eqs. (3.191) and (3.201), in this approximation the total ground state energy is

⁹ In this chapter, I try to use lower-case letters for all *single-particle* observables (in particular, ε for their energies), in order to distinguish them as clearly as possible from the *system’s* observables (including the total energy E of the system), which are typeset in capital letters.

¹⁰ Indeed, helium makes up more than 20% of all “ordinary” matter of our Universe.

¹¹ Note that the positive ion He^{+1} of this atom, with just one electron, is fully described by the hydrogen-like atom theory with $Z = 2$, whose ground-state energy, according to Eq. (3.191), is $-Z^2 E_H/2 = -2E_H \approx -55.4 \text{ eV}$.

$$E_g^{(0)} = 2\epsilon_g^{(0)} = 2 \left(-\frac{\epsilon_0}{2n^2} \right)_{n=1, Z=2} = 2 \left(-\frac{Z^2 E_H}{2} \right)_{Z=2} = -4E_H \approx -109 \text{ eV}. \quad (8.28)$$

This is still somewhat far (though not terribly far!) from the experimental value $E_g \approx -78.8 \text{ eV}$ – see the bottom level in Fig. 1a.

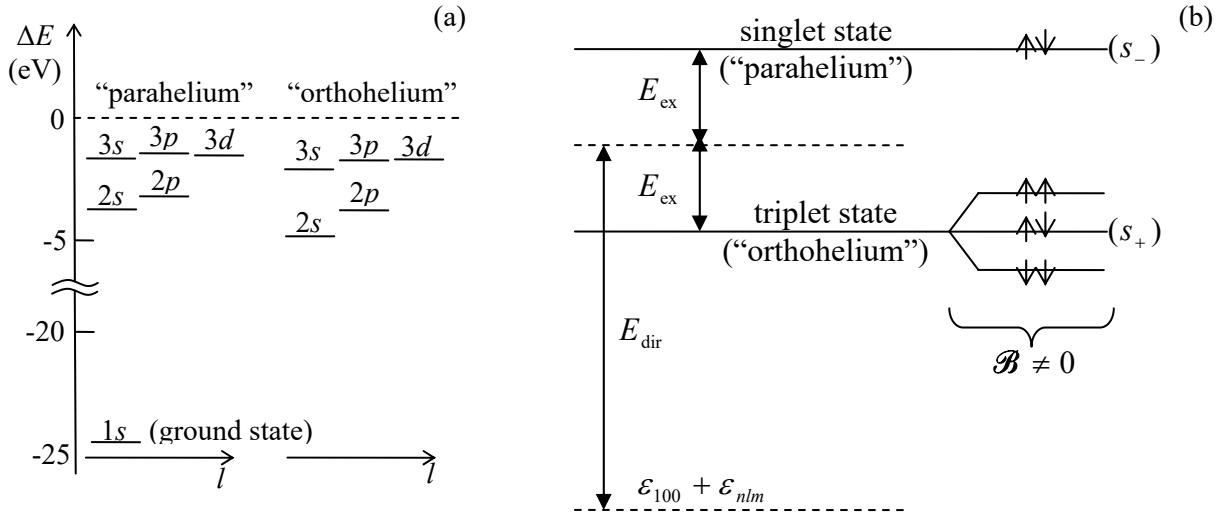

Fig. 8.1. The lower energy levels of a helium atom: (a) experimental data and (b) a schematic structure of an excited state in the first order of the perturbation theory. On panel (a), all energies are referred to that ($-2E_H \approx -55.4 \text{ eV}$) of the ground state of the positive ion He^{+1} , so that their magnitudes are the (readily measurable) energies of the atom's single ionization starting from the corresponding state of the neutral atom. Note that the “spin direction” nomenclature on panel (b) is rather crude: it does not reflect the difference between the entangled states s_+ and s_- .

Making a minor (but very useful) detour from our main topic, let us note that we can get a much better agreement with experiment by calculating the electron interaction energy in the 1st order of the perturbation theory. Indeed, in application to our system, Eq. (6.14) reads

$$E_g^{(1)} = \langle g | \hat{U}_{\text{int}} | g \rangle = \int d^3 r_1 \int d^3 r_2 \psi_g^*(\mathbf{r}_1, \mathbf{r}_2) U_{\text{int}}(\mathbf{r}_1, \mathbf{r}_2) \psi_g(\mathbf{r}_1, \mathbf{r}_2). \quad (8.29)$$

Plugging in Eqs. (25)-(27), we get

$$E_g^{(1)} = \left(\frac{1}{4\pi} \frac{4}{r_0^3} \right)^2 \int d^3 r_1 \int d^3 r_2 \frac{e^2}{4\pi\epsilon_0 |\mathbf{r}_1 - \mathbf{r}_2|} \exp \left\{ -\frac{2(r_1 + r_2)}{r_0} \right\}. \quad (8.30)$$

As may be readily evaluated analytically (this exercise is left for the reader), this expression equals $(5/4)E_H$, so that the corrected ground state energy,

$$E_g \approx E_g^{(0)} + E_g^{(1)} = (-4 + 5/4)E_H = -74.8 \text{ eV}, \quad (8.31)$$

is much closer to experiment.

There is still room here for a ready improvement, using the variational method discussed in Sec. 2.9. For our particular case of the ${}^4\text{He}$ atom, we may try to use, as the trial state, the orbital wavefunction given by Eqs. (26)-(27), but with the atomic number Z considered as an adjustable

parameter $Z_{\text{ef}} < Z = 2$ rather than a fixed number. The physics behind this approach is that the electric charge density $\rho(\mathbf{r}) = -e|\psi(\mathbf{r})|^2$ of each electron forms a negatively charged “cloud” that reduces the effective charge of the nucleus, as seen by the other electron, to $Z_{\text{ef}}e$, with some $Z_{\text{ef}} < 2$. As a result, the single-particle wavefunction spreads further in space (with the scale $r_0 = r_B/Z_{\text{ef}} > r_B/Z$), while keeping its functional form (27) nearly intact. Since the kinetic energy T in the system’s Hamiltonian (25) is proportional to $r_0^{-2} \propto Z_{\text{ef}}^{-2}$, while the potential energy is proportional to $r_0^{-1} \propto Z_{\text{ef}}^{-1}$, we can write

$$E_g(Z_{\text{ef}}) = \left(\frac{Z_{\text{ef}}}{2}\right)^2 \langle T_g \rangle_{Z=2} + \frac{Z_{\text{ef}}}{2} \langle U_g \rangle_{Z=2}. \quad (8.32)$$

Now we can use the fact that according to Eq. (3.212), for any stationary state of a hydrogen-like atom (just as for the classical circular motion in the Coulomb potential), $\langle U \rangle = 2E$, and hence $\langle T \rangle = E - \langle U \rangle = -E$. Using Eq. (30), and adding the correction (31) to the potential energy, we get

$$E_g(Z_{\text{ef}}) = \left[4\left(\frac{Z_{\text{ef}}}{2}\right)^2 + \left(-8 + \frac{5}{4}\right) \frac{Z_{\text{ef}}}{2} \right] E_H. \quad (8.33)$$

This expression allows an elementary calculation of the optimal value of Z_{ef} , and the corresponding minimum of the function $E_g(Z_{\text{ef}})$:

$$(Z_{\text{ef}})_{\text{opt}} = 2\left(1 - \frac{5}{32}\right) = 1.6875, \quad (E_g)_{\text{min}} \approx -2.85E_H \approx -77.5 \text{ eV}. \quad (8.34)$$

Given the trial state’s crudeness, this number is in surprisingly good agreement with the experimental value cited above, with a difference of the order of 1%.

Now let us return to the main topic of this section – the effects of particle (in this case, electron) indistinguishability. As we have just seen, the ground-level energy of the helium atom is not affected directly by this fact, but the situation is different for its excited states – even the lowest ones. The reasonably good precision of the perturbation theory, which we have seen for the ground state, tells us that we can base our analysis of wavefunctions (ψ_e) of the lowest excited state orbitals, on products like $\psi_{100}(\mathbf{r}_k)\psi_{nlm}(\mathbf{r}_{k'})$, with $n > 1$. To satisfy the fermion permutation rule, $\mathcal{P}_j = -1$, we have to take the orbital factor of the state in either the symmetric or the antisymmetric form:

$$\psi_e(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{\sqrt{2}} [\psi_{100}(\mathbf{r}_1)\psi_{nlm}(\mathbf{r}_2) \pm \psi_{nlm}(\mathbf{r}_1)\psi_{100}(\mathbf{r}_2)], \quad (8.35)$$

Orthohelium
and
parahelium:
orbital
wavefunctions

with the proper total permutation asymmetry provided by the corresponding spin factor (18) or (21), so that the upper/lower sign in Eq. (35) corresponds to the singlet/triplet spin state. Let us calculate the expectation values of the total energy of the system in the first order of the perturbation theory. Plugging Eq. (35) into the 0th-order expression

$$\langle E_e \rangle^{(0)} = \int d^3r_1 \int d^3r_2 \psi_e^*(\mathbf{r}_1, \mathbf{r}_2) (\hat{h}_1 + \hat{h}_2) \psi_e(\mathbf{r}_1, \mathbf{r}_2), \quad (8.36)$$

we get two groups of similar terms that differ only by the particle index. We can merge the terms of each pair by changing the notation as $(\mathbf{r}_1 \rightarrow \mathbf{r}, \mathbf{r}_2 \rightarrow \mathbf{r}')$ in one of them, and $(\mathbf{r}_1 \rightarrow \mathbf{r}', \mathbf{r}_2 \rightarrow \mathbf{r})$ in the counterpart term. Using Eq. (25), and the mutual orthogonality of the wavefunctions $\psi_{100}(\mathbf{r})$ and $\psi_{nlm}(\mathbf{r})$, we get the following result:

$$\langle E_e \rangle^{(0)} = \int \psi_{100}^*(\mathbf{r}) \left(-\frac{\hbar^2 \nabla_r^2}{2m} - \frac{2e^2}{4\pi\epsilon_0 r} \right) \psi_{100}(\mathbf{r}) d^3r + \int \psi_{nlm}^*(\mathbf{r}') \left(-\frac{\hbar^2 \nabla_{r'}^2}{2m} - \frac{2e^2}{4\pi\epsilon_0 r'} \right) \psi_{nlm}(\mathbf{r}') d^3r' \quad (8.37)$$

$\equiv \epsilon_{100} + \epsilon_{nlm}, \quad \text{with } n > 1.$

It may be interpreted as the sum of eigenenergies of two separate single particles, one in the ground state 100, and another in the excited state nlm – although actually the electron states are entangled. Thus, in the 0th order of the perturbation theory, the electron entanglement does not affect their energy.

However, the potential energy of the system also includes the interaction term U_{int} , which does not allow such separation. Indeed, in the 1st approximation of the perturbation theory, the total energy E_e of the system may be expressed as $\epsilon_{100} + \epsilon_{nlm} + E_{\text{int}}^{(1)}$, with

$$E_{\text{int}}^{(1)} = \langle U_{\text{int}} \rangle = \int d^3r_1 \int d^3r_2 \psi_e^*(\mathbf{r}_1, \mathbf{r}_2) U_{\text{int}}(\mathbf{r}_1, \mathbf{r}_2) \psi_e(\mathbf{r}_1, \mathbf{r}_2), \quad (8.38)$$

Plugging Eq. (35) into this result, using the symmetry of the function U_{int} with respect to the particle number permutation, and the same particle coordinate re-numbering as above, we get

$$E_{\text{int}}^{(1)} = E_{\text{dir}} \pm E_{\text{ex}}, \quad (8.39)$$

with the following, deceptively similar expressions for the two components of this sum/difference:

Direct
interaction
energy

Exchange
interaction
energy

$$E_{\text{dir}} \equiv \int d^3r \int d^3r' \psi_{100}^*(\mathbf{r}) \psi_{nlm}^*(\mathbf{r}') U_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_{100}(\mathbf{r}) \psi_{nlm}(\mathbf{r}'), \quad (8.40)$$

$$E_{\text{ex}} \equiv \int d^3r \int d^3r' \psi_{100}^*(\mathbf{r}) \psi_{nlm}^*(\mathbf{r}') U_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_{nlm}(\mathbf{r}) \psi_{100}(\mathbf{r}'). \quad (8.41)$$

Since the single-particle orbitals can be always made real, both components are positive – or at least non-negative. However, their physics and magnitude are different. The integral (40), called the *direct interaction energy*, allows a simple semi-classical interpretation as the Coulomb energy of interacting electrons, each distributed in space with the electric charge density $\rho(\mathbf{r}) = -e\psi^*(\mathbf{r})\psi(\mathbf{r})$:¹²

$$E_{\text{dir}} = \int d^3r \int d^3r' \frac{\rho_{100}(\mathbf{r})\rho_{nlm}(\mathbf{r}')}{4\pi\epsilon_0 |\mathbf{r} - \mathbf{r}'|} \equiv \int \rho_{100}(\mathbf{r})\phi_{nlm}(\mathbf{r}) d^3r \equiv \int \rho_{nlm}(\mathbf{r})\phi_{100}(\mathbf{r}) d^3r, \quad (8.42)$$

where $\phi(\mathbf{r})$ are the electrostatic potentials created by the electron “charge clouds”:¹³

$$\phi_{100}(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int d^3r' \frac{\rho_{100}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}, \quad \phi_{nlm}(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int d^3r' \frac{\rho_{nlm}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}. \quad (8.43)$$

However, the integral (41), called the *exchange interaction energy*, evades a classical interpretation, and (as it is clear from its derivation) is the direct corollary of electrons’ indistinguishability. The magnitude of E_{ex} is also very much different from E_{dir} because the function under the integral (41) disappears in the regions where the single-particle wavefunctions $\psi_{100}(\mathbf{r})$ and $\psi_{nlm}(\mathbf{r})$ do not overlap. This is in full agreement with the discussion in Sec. 1: if two particles are identical but well separated, i.e. their wavefunctions do not overlap, the exchange interaction disappears,

¹² See, e.g., EM Sec. 1.3, in particular Eq. (1.54).

¹³ Note that the result for E_{dir} correctly reflects the basic fact that a charged particle does not interact with itself, even if its wavefunction is quantum-mechanically spread over a finite space volume. Unfortunately, this is not true for some popular approximate theories of multiparticle systems – see Sec. 4 below.

i.e. measurable effects of particle indistinguishability vanish. (In contrast, the integral (40) decreases with the growing electron separation only slowly, due to the long-range Coulomb interaction.)

Figure 1b shows the structure of an excited energy level, with certain quantum numbers $n > 1$, l , and m , given by Eqs. (39)-(41). The upper, so-called *parahelium*¹⁴ level, with the energy

$$E_{\text{para}} = (\varepsilon_{100} + \varepsilon_{nlm}) + E_{\text{dir}} + E_{\text{ex}} > \varepsilon_{100} + \varepsilon_{nlm}, \quad (8.44)$$

corresponds to the symmetric orbital state and hence to the singlet spin state (18), while the lower, *orthohelium* level, with

$$E_{\text{orth}} = (\varepsilon_{100} + \varepsilon_{nlm}) + E_{\text{dir}} - E_{\text{ex}} < E_{\text{para}}, \quad (8.45)$$

corresponds to the degenerate triplet spin state (21).

This degeneracy may be lifted by an external magnetic field, whose effect on the electron spins¹⁵ is described by the following evident generalization of the Pauli Hamiltonian (4.163),

$$\hat{H}_{\text{field}} = -\gamma \hat{\mathbf{s}}_1 \cdot \mathcal{B} - \gamma \hat{\mathbf{s}}_2 \cdot \mathcal{B} \equiv -\gamma \hat{\mathbf{S}} \cdot \mathcal{B}, \quad \text{with } \gamma = \gamma_e \equiv -\frac{e}{m_e} \equiv -2 \frac{\mu_B}{\hbar}, \quad (8.46)$$

where

$$\hat{\mathbf{S}} \equiv \hat{\mathbf{s}}_1 + \hat{\mathbf{s}}_2, \quad (8.47)$$

is the operator of the (vector) sum of the system of two spins.¹⁶ To analyze this effect, we need first to make one more detour, to address the general issue of *spin addition*. The main rule¹⁷ here is that in a full analogy with the net spin of a single particle, defined by Eq. (5.170), the net spin operator (47) of *any* system of two spins, and its component \hat{S}_z along the (arbitrarily selected) z -axis, obey the same commutation relations (5.168) as the component operators, and hence have the properties similar to those expressed by Eqs. (5.169) and (5.175):

$$\hat{S}^2 |S, M_S\rangle = \hbar^2 S(S+1) |S, M_S\rangle, \quad \hat{S}_z |S, M_S\rangle = \hbar M_S |S, M_S\rangle, \quad \text{with } -S \leq M_S \leq +S, \quad (8.48)$$

where the ket vectors correspond to the coupled basis of joint eigenstates of the operators of S^2 and S_z (but not necessarily all component operators – see again the Venn shown in Fig. 5.12 and its discussion, with the replacements \mathbf{S} , $\mathbf{L} \rightarrow \mathbf{s}_{1,2}$ and $\mathbf{J} \rightarrow \mathbf{S}$). Repeating the discussion of Sec. 5.7 with these replacements, we see that in both coupled and uncoupled bases, the net magnetic number M_S is simply expressed via those of the components

¹⁴ This terminology reflects the historic fact that the observation of two different hydrogen-like spectra, corresponding to the opposite signs in Eq. (39), was first taken as evidence for two different species of ${}^4\text{He}$, which were called, respectively, the “orthohelium” and the “parahelium”.

¹⁵ As we know from Sec. 6.4, the field also affects the orbital motion of the electrons, so that the simple analysis based on Eq. (46) is strictly valid only for the s excited state ($l = 0$, and hence $m = 0$). However, the orbital effects of a weak magnetic field do not affect the triplet level splitting we are analyzing now.

¹⁶ Note that similarly to Eqs. (22) and (25), here the uppercase notation of the component spins is replaced with their lowercase notation, to avoid any possibility of their confusion with the total spin of the system.

¹⁷ Since we already know that the spin of a particle is physically nothing more than a (specific) part of its angular momentum, the similarity of the properties (48) of the sum (47) of spins of different particles to those of the sum (5.170) of different spin components of the same particle is very natural, but still has to be considered as a new fact – confirmed by a vast body of experimental data.

$$M_S = (m_s)_1 + (m_s)_2. \quad (8.49)$$

However, the net spin quantum number S (in contrast to the Nature-given spins $s_{1,2}$ of its elementary components) is not universally definite, and we may immediately say only that it has to obey the following analog of the relation $|l - s| \leq j \leq (l + s)$ discussed in Sec. 5.7:

$$|s_1 - s_2| \leq S \leq s_1 + s_2. \quad (8.50)$$

What exactly S is (within these limits), depends on the spin state of the system.

For the simplest case of two spin- $\frac{1}{2}$ components, each with $s = \frac{1}{2}$ and $m_s = \pm\frac{1}{2}$, Eq. (49) gives three possible values of M_S , equal to 0 and ± 1 , while Eq. (50) limits the possible values of S to just either 0 or 1. Using the last of Eqs. (48), we see that the possible combinations of the quantum numbers are

$$\begin{cases} S = 0, \\ M_S = 0, \end{cases} \quad \text{and} \quad \begin{cases} S = 1, \\ M_S = 0, \pm 1. \end{cases} \quad (8.51)$$

It is virtually evident that the singlet spin state s_- belongs to the first class, while the simple (separable) triplet states $\uparrow\uparrow$ and $\downarrow\downarrow$ belong to the second class, with $M_S = +1$ and $M_S = -1$, respectively. However, for the entangled triplet state s_+ , evidently with $M_S = 0$, the value of S is less obvious. Perhaps the easiest way to recover it¹⁸ to use the “rectangular diagram”, similar to that shown in Fig. 5.14, but redrawn for our case of two spins, i.e., with the replacements $m_l \rightarrow (m_s)_1 = \pm\frac{1}{2}$, $m_s \rightarrow (m_s)_2 = \pm\frac{1}{2}$ – see Fig. 2.

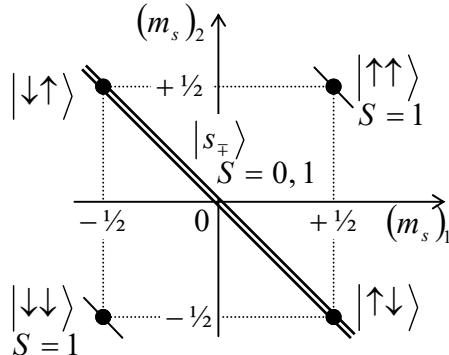

Fig. 8.2. The “rectangular diagram” showing the relation between the uncoupled-representation states (dots) and the coupled-representation states (straight lines) of a system of two spins- $\frac{1}{2}$ – cf. Fig. 5.14.

Just as at the addition of various angular momenta of a single particle, the top-right and bottom-left corners of this diagram correspond to the factorable triplet states $\uparrow\uparrow$ and $\downarrow\downarrow$, which participate in both the uncoupled-representation and coupled-representation bases, and have the largest value of S , i.e. 1. However, the entangled states s_+ , which are linear combinations of the uncoupled-representation states $\uparrow\downarrow$ and $\downarrow\uparrow$, cannot have the same value of S , so that for the triplet state s_+ , S has to take the value different from that (0) of the singlet state, i.e. 1. With that, the first of Eqs. (48) gives the following expectation values for the square of the net spin operator:

$$\langle S^2 \rangle = \begin{cases} 2\hbar^2, & \text{for each triplet state,} \\ 0, & \text{for the singlet state.} \end{cases} \quad (8.52)$$

¹⁸ Another, a bit longer but perhaps a more prudent way is to directly calculate the expectation values of \hat{S}^2 for the states s_+ , and then find S by comparing the results with the first of Eqs. (48); it is highly recommended to the reader as a useful exercise.

Note that for the entangled triplet state s_+ , whose ket-vector (20) is a linear superposition of two kets of states with *opposite* spins, this result is highly counter-intuitive, and shows how careful we should be interpreting entangled quantum states. (As will be discussed in Chapter 10, the entanglement brings even more surprises for quantum measurements.)

Now we may return to the particular issue of the magnetic field effect on the triplet state of the ${}^4\text{He}$ atom. Directing the z -axis along the field, we may reduce Eq. (46) to

$$\hat{H}_{\text{field}} = -\gamma_e \hat{S}_z \mathcal{B} \equiv 2\mu_B \mathcal{B} \frac{\hat{S}_z}{\hbar}. \quad (8.53)$$

Since all three triplet states (21) are eigenstates, in particular, of the operator \hat{S}_z , and hence of the Hamiltonian (53), we may use the second of Eqs. (48) to calculate their energy change simply as

$$\Delta E_{\text{field}} = 2\mu_B \mathcal{B} M_S = 2\mu_B \mathcal{B} \times \begin{cases} +1, & \text{for the factorable triplet state } \uparrow\uparrow, \\ 0, & \text{for the entangled triplet state } s_+, \\ -1, & \text{for the factorable triplet state } \downarrow\downarrow. \end{cases} \quad (8.54)$$

This splitting of the “orthohelium” level is schematically shown in Fig. 1b.¹⁹

8.3. Multiparticle systems

Leaving several other problems on two-particle systems for the reader’s exercise, let me proceed to the discussion of systems with $N > 2$ indistinguishable particles, whose list notably includes atoms, molecules, and condensed-matter systems. In this case, Eq. (7) for fermions is generalized as

$$\hat{\mathcal{P}}_{kk'} |\alpha_- \rangle = -|\alpha_- \rangle, \quad \text{for all } k, k' = 1, 2, \dots, N, \quad (8.55)$$

where the operator $\hat{\mathcal{P}}_{kk'}$ permutes particles with numbers k and k' . As a result, for systems with non-directly-interacting fermions, the Pauli principle forbids any state in which *any* two particles have similar single-particle wavefunctions. Nevertheless, it permits two fermions to have similar *orbital* wavefunctions, provided that their spins are in the singlet state (18), because this satisfies the permutation requirement (55). This fact is of paramount importance for the ground state of the systems whose Hamiltonians do not depend on spin because it allows the fermions to be in their orbital single-particle ground states, with two electrons of the spin singlet sharing the same orbital state. Hence, for the limited (but very important!) goal of finding ground-state energies of multi-fermion systems with negligible direct interaction, we may ignore the actual singlet spin structure, and reduce the Pauli

¹⁹ It is interesting that another very important two-electron system, the hydrogen (H_2) molecule, which was briefly discussed in Sec. 2.6, also has two similarly named forms, *parahydrogen* and *orthohydrogen*. However, their difference is due to two possible (respectively, singlet and triplet) states of the system of two spins of the two hydrogen nuclei – protons, which are also spin- $1/2$ particles. The resulting energy of the parahydrogen is lower than that of the orthohydrogen by only ~ 45 meV per molecule – the difference comparable with $k_B T$ at room temperature (~ 26 meV). As a result, at the ambient conditions, the equilibrium ratio of these two *spin isomers* is close to 3:1. Curiously, the theoretical prediction of this minor effect by W. Heisenberg (together with F. Hund) in 1927 was cited in his 1932 Nobel Prize award as the most noteworthy application of quantum theory.

exclusion principle to the simple picture of single-particle orbital energy levels, each “occupied with two fermions”.

As a very simple example, let us find the ground energy of five fermions, confined in a hard-wall, cubic-shaped 3D volume of side a , ignoring their direct interaction. From Sec. 1.7, we know the single-particle energy spectrum of the system:

$$\varepsilon_{n_x, n_y, n_z} = \varepsilon_0 (n_x^2 + n_y^2 + n_z^2), \quad \text{with } \varepsilon_0 \equiv \frac{\pi^2 \hbar^2}{2ma^2}, \quad \text{and } n_x, n_y, n_z = 1, 2, \dots \quad (8.56)$$

so that the lowest-energy states are:

- one ground state with $\{n_x, n_y, n_z\} = \{1, 1, 1\}$, and energy $\varepsilon_{111} = (1^2 + 1^2 + 1^2) \varepsilon_0 = 3 \varepsilon_0$, and
- three excited states, with $\{n_x, n_y, n_z\}$ equal to either $\{2, 1, 1\}$, or $\{1, 2, 1\}$, or $\{1, 1, 2\}$, with equal energies $\varepsilon_{211} = \varepsilon_{121} = \varepsilon_{112} = (2^2 + 1^2 + 1^2) \varepsilon_0 = 6 \varepsilon_0$.

According to the above simple formulation of the Pauli principle, each of these orbital energy levels can accommodate up to two fermions. Hence the lowest-energy (ground) state of the five-fermion system is achieved by placing two of them on the ground level $\varepsilon_{111} = 3 \varepsilon_0$, and the remaining three particles, in any of the degenerate “excited” states of energy $6 \varepsilon_0$, so that the ground-state energy of the system is

$$E_g = 2 \times 3 \varepsilon_0 + 3 \times 6 \varepsilon_0 \equiv 24 \varepsilon_0 \equiv \frac{12 \pi^2 \hbar^2}{ma^2}. \quad (8.57)$$

Moreover, in many cases, relatively weak interaction between fermions does not blow up such a simple quantum state classification scheme qualitatively, and the Pauli principle allows tracing the order of single-particle state filling. This is exactly the simple approach that has been used in our discussion of atoms in Sec. 3.7. Unfortunately, it does not allow for a more specific characterization of the ground states of most atoms, in particular the evaluation of the corresponding values of the quantum numbers S , L , and J that characterize the net angular momenta of the atom, and hence its response to an external magnetic field. These numbers are defined by relations similar to Eqs. (48), each for the corresponding vector operator of the net angular momenta:

$$\hat{\mathbf{S}} \equiv \sum_{k=1}^N \hat{\mathbf{s}}_k, \quad \hat{\mathbf{L}} \equiv \sum_{k=1}^N \hat{\mathbf{l}}_k, \quad \hat{\mathbf{J}} \equiv \sum_{k=1}^N \hat{\mathbf{j}}_k; \quad (8.58)$$

note that these definitions are consistent with Eq. (5.170) applied both to the angular momenta \mathbf{s}_k , \mathbf{l}_k , and \mathbf{j}_k of each particle, and to the full vectors \mathbf{S} , \mathbf{L} , and \mathbf{J} . When the numbers S , L , and J for a state are known, they are traditionally recorded in the form of the so-called *Russell-Saunders symbols*:²⁰

$$^{2S+1}\mathcal{L}_J, \quad (8.59)$$

where S and J are the corresponding values of these quantum numbers, while \mathcal{L} is a capital *letter*, encoding the quantum number L – via the same spectroscopic notation as for single particles (see Sec. 3.6): $\mathcal{L} = S$ for $L = 0$, $\mathcal{L} = P$ for $L = 1$, $\mathcal{L} = D$ for $L = 2$, etc. (The reason why the front superscript of the Russel-Saunders symbol lists $2S + 1$ rather than just S , is that according to the last of Eqs. (48), it

²⁰ Named after H. Russell and F. Saunders, whose pioneering (circa 1925) processing of experimental spectral-line data has established the very idea of vector addition of the electron spins, described by the first of Eqs. (58).

shows the number of possible values of the quantum number M_S , which characterizes the state's spin degeneracy, and is called its *multiplicity*.)

For example, for the simplest, hydrogen atom ($Z = 1$), with its single electron in the ground $1s$ state, $L = l = 0$, $S = s = \frac{1}{2}$, and $J = S = \frac{1}{2}$, so that its Russell-Saunders symbol is $2S_{1/2}$. Next, the discussion of the helium atom ($Z = 2$) in the previous section has shown that in its ground state $L = 0$ (because of the $1s$ orbital state of both electrons), and $S = 0$ (because of the singlet spin state), so that the total angular momentum also vanishes: $J = 0$. As a result, the Russell-Saunders symbol is 1S_0 . The structure of the next atom, lithium ($Z = 3$) is also easy to predict, because, as was discussed in Sec. 3.7, its ground-state electron configuration is $1s^22s^1$, i.e. includes two electrons in the “helium shell”, i.e. on the $1s$ orbitals (now we know that they are actually in a singlet spin state), and one electron in the $2s$ state, of higher energy, also with zero orbital momentum, $l = 0$. As a result, the total L in this state is evidently equal to 0, and S is equal to $\frac{1}{2}$, so that $J = \frac{1}{2}$, meaning that the Russell-Saunders symbol of lithium is $^2P_{1/2}$. Even in the next atom, beryllium ($Z = 4$), with the ground state configuration $1s^22s^2$, the symbol is readily predictable, because none of its electrons has non-zero orbital momentum, giving $L = 0$. Also, each electron pair is in the singlet spin state, i.e. we have $S = 0$, so that $J = 0$ – the quantum number set described by the Russell-Saunders symbol 1S_0 – just as for helium.

However, for the next, boron atom ($Z = 5$), with its ground-state electron configuration $1s^22s^22p^1$ (see, e.g., Fig. 3.24), there is no obvious way to predict the result. Indeed, this atom has two pairs of electrons, with opposite spins, on its two lowest s -orbitals, giving zero contributions to the net S , L , and J . Hence these total quantum numbers may be only contributed by the last, fifth electron with $s = \frac{1}{2}$ and $l = 1$, giving $S = \frac{1}{2}$, $L = 1$. As was discussed in Sec. 5.7 for the single-particle case, the vector addition of the angular momenta \mathbf{S} and \mathbf{L} enables two values of the quantum number J : either $L + S = \frac{3}{2}$ or $L - S = \frac{1}{2}$. Experiment shows that the difference between the energies of these two states is very small (~ 2 meV), so that at room temperature (with $k_B T \approx 26$ meV) they are both occupied, with the genuine ground state having $J = \frac{1}{2}$, so that its Russell-Saunders symbol is $^2P_{1/2}$.

Such energy differences, which become larger for heavier atoms, are determined both by the Coulomb and spin-orbit²¹ interactions between the electrons. Their quantitative analysis is rather involved (see below), but the results tend to follow simple phenomenological *Hund rules*, with the following hierarchy:

Rule 1. For a given electron configuration, the ground state has the *largest* possible S , and hence the largest multiplicity $2S + 1$.

Rule 2. For a given S , the ground state has the *largest* possible L .

Rule 3. For given S and L , J has its *smallest* possible value, $|L - S|$, if the given sub-shell $\{n, l\}$ is filled not more than by half, while in the opposite case, J has its *largest* possible value, $L + S$.

Let us see how these rules work for the boron atom we have just discussed. For it, the Hund Rules 1 and 2 are satisfied automatically, while the sub-shell $\{n = 2, l = 1\}$, which can house up to $2(2l + 1) = 6$ electrons, is filled with just one $2p$ electron, i.e. by less than a half of the maximum value. As a result, the Hund Rule 3 predicts the ground state's value $J = \frac{1}{2}$, in agreement with experiment.

²¹ In light atoms, the spin-orbit interaction is so weak that it may be reasonably well described as an interaction of the total momenta \mathbf{L} and \mathbf{S} of the system – the so-called LS (or “Russell-Saunders”) coupling. On the other hand, in very heavy atoms, the interaction is effectively between the net momenta $\mathbf{j}_k = \mathbf{l}_k + \mathbf{s}_k$ of the individual electrons – the so-called jj coupling. This is the reason why in such atoms the Hund rule 3 may be violated.

Generally, for lighter atoms, the Hund rules are well obeyed. However, the lower down the Hund rule hierarchy, the less “powerful” the rules are, i.e. the more often they are violated in heavier atoms.

Now let us discuss possible approaches to a quantitative theory of multiparticle systems – not only atoms. As was discussed in Sec. 1, if fermions do not interact directly, the stationary states of the system have to be the antisymmetric eigenstates of the permutation operator, i.e. satisfy Eq. (55). To understand how such states may be formed from the single-electron ones, let us return for a minute to the case of two electrons, and rewrite Eq. (11) in the following compact form:

$$|\alpha_-\rangle \equiv \frac{1}{\sqrt{2}}(|\beta\rangle \otimes |\beta'\rangle - |\beta'\rangle \otimes |\beta\rangle) = \frac{1}{\sqrt{2}} \begin{vmatrix} |\beta\rangle & |\beta'\rangle \\ |\beta'\rangle & |\beta\rangle \end{vmatrix} \begin{array}{l} \text{state 1} \\ \downarrow \end{array} \begin{array}{l} \text{state 2} \\ \downarrow \end{array} \quad (8.60a)$$

← particle number 1,
← particle number 2,

where the direct product signs are just implied. In this way, the Pauli principle is mapped on the well-known property of matrix determinants: if any of two columns of a matrix coincide, its determinant vanishes. This *Slater determinant* approach²² may be readily generalized to N fermions occupying any N (not necessarily the lowest-energy) single-particle states $\beta, \beta', \beta'', \dots$, etc:

Slater determinant

$$|\alpha_-\rangle = \frac{1}{(N!)^{1/2}} \left| \begin{array}{cccc} |\beta\rangle & |\beta'\rangle & |\beta''\rangle & \dots \\ |\beta\rangle & |\beta'\rangle & |\beta''\rangle & \dots \\ |\beta\rangle & |\beta'\rangle & |\beta''\rangle & \dots \\ \dots & \dots & \dots & \dots \end{array} \right|_{\overbrace{N}}^{\text{state list} \rightarrow \text{particle list}} \quad (8.60b)$$

The Slater determinant form is extremely nice and compact – in comparison with direct writing of a sum of $N!$ products, each of N ket factors. However, there are two major problems with using it for practical calculations:

(i) For the calculation of any bra-ket product (say, within the perturbation theory) we still need to spell out each bra- and ket-vector as a sum of component terms. Even for a limited number of electrons (say $N \sim 10^2$ in a typical atom), the number $N! \sim 10^{160}$ of terms in such a sum is impractically large for any analytical or numerical calculation.

(ii) In the case of interacting fermions, the Slater determinant does not describe the eigenvectors of the system; rather the stationary state is a *superposition* of such basis functions, i.e. of the Slater determinants – each for a specific selection of N states from the full set of single-particle states – that is generally larger than N .

For atoms and simple molecules, whose filled-shell electrons may be excluded from an explicit analysis (by describing their effects, approximately, with effective *pseudo-potentials*), the effective number N may be reduced to a smaller number N_{ef} of the order of 10, so that $N_{\text{ef}}! < 10^6$, and the Slater determinants may be used for numerical calculations – for example, in the Hartree-Fock theory – see the next section. However, for condensed-matter systems, such as metals and semiconductors, with the

²² It was suggested in 1929 by John C. Slater.

number of free electrons is of the order of 10^{23} per cm³, this approach is generally unacceptable, though with some smart tricks (such as using the crystal's periodicity) it may be still used for some approximate (also mostly numerical) calculations.

These challenges make the development of a more general theory that would not use particle numbers (which are superficial for indistinguishable particles to start with) a must for getting any final analytical results for multiparticle systems. The most effective formalism for this purpose, which avoids particle numbering at all, is called the *second quantization*.²³ Actually, we have already discussed a particular version of this formalism, for the case of the 1D harmonic oscillator, in Sec. 5.4. As a reminder, after the definition (5.65) of the “creation” and “annihilation” operators via those of the particle’s coordinate and momentum, we have derived their key properties (5.89),

$$\hat{a}|n\rangle = n^{1/2}|n-1\rangle, \quad \hat{a}^\dagger|n\rangle = (n+1)^{1/2}|n+1\rangle, \quad (8.61)$$

where n are the stationary (Fock) states of the oscillator. This property allows an interpretation of the operators’ actions as the creation/annihilation of a single *excitation* with the energy $\hbar\omega_0$ – thus justifying the operator names. In the next chapter, we will show that such excitation of an electromagnetic field mode may be interpreted as a massless *boson* with $s = 1$, called the *photon*.

In order to generalize this approach to *arbitrary bosons*, not appealing to a specific system, we may use relations similar to Eq. (61) to *define* the creation and annihilation operators. The definitions look simple in the language of the so-called *Dirac states*, described by ket-vectors

$$|N_1, N_2, \dots, N_j, \dots\rangle, \quad (8.62)$$

Dirac state

where N_j is the state *occupancy*, i.e. the number of bosons in the single-particle state j . Let me emphasize that here the indices $1, 2, \dots, j, \dots$ number single-particle *states* (including their spin parts) rather than *particles*. Thus the very notion of an individual particle’s number is completely (and for indistinguishable particles, very relevantly) absent from this formalism. Generally, the set of single-particle states participating in the Dirac state may be selected arbitrarily, provided that it is full and orthonormal in the sense

$$\langle N'_1, N'_2, \dots, N'_{j'}, \dots | N_1, N_2, \dots, N_j, \dots \rangle = \delta_{N_1 N'_1} \delta_{N_2 N'_2} \dots \delta_{N_j N'_{j'}}, \quad (8.63)$$

though for systems of non- (or weakly) interacting bosons, using the stationary states of individual particles in the system under analysis is almost always the best choice.

Now we can define the *particle annihilation operator* as follows:

$$\hat{a}_j |N_1, N_2, \dots, N_j, \dots\rangle \equiv N_j^{1/2} |N_1, N_2, \dots, N_j - 1, \dots\rangle. \quad (8.64)$$

Boson annihilation operator

Note that the pre-ket coefficient, similar to that in the first of Eqs. (61), guarantees that any attempt to annihilate a particle in an initially unpopulated state gives the non-existing (“null”) state:

$$\hat{a}_j |N_1, N_2, \dots, 0_j, \dots\rangle = 0, \quad (8.65)$$

²³ It was invented (first for photons and then for arbitrary bosons) by P. Dirac in 1927, and then modified in 1928 for fermions by E. Wigner and P. Jordan. Note that the term “second quantization” is rather misleading for the non-relativistic applications we are discussing here, but finds certain justification in the quantum field theory.

where the symbol 0_j means zero occupancy of the j^{th} state. According to Eq. (63), an equivalent way to write Eq. (64) is

$$\langle N'_1, N'_2, \dots, N'_j, \dots | \hat{a}_j | N_1, N_2, \dots, N_j, \dots \rangle = N_j^{1/2} \delta_{N_1 N'_1} \delta_{N_2 N'_2} \dots \delta_{N_j N'_j} \dots \quad (8.66)$$

According to the general Eq. (4.65), the matrix element of the Hermitian conjugate operator \hat{a}_j^\dagger is

$$\begin{aligned} \langle N'_1, N'_2, \dots, N'_j, \dots | \hat{a}_j^\dagger | N_1, N_2, \dots, N_j, \dots \rangle &= \langle N_1, N_2, \dots, N_j, \dots | \hat{a}_j | N'_1, N'_2, \dots, N'_j, \dots \rangle^* \\ &= \langle N_1, N_2, \dots, N_j, \dots | (N'_j)^{1/2} | N'_1, N'_2, \dots, N'_j - 1, \dots \rangle = (N'_j)^{1/2} \delta_{N_1 N'_1} \delta_{N_2 N'_2} \dots \delta_{N_j N'_j - 1} \dots \\ &= (N_j + 1)^{1/2} \delta_{N_1 N'_1} \delta_{N_2 N'_2} \dots \delta_{N_j + 1, N'_j}, \end{aligned} \quad (8.67)$$

meaning that

Boson
creation
operator

$$\hat{a}_j^\dagger | N_1, N_2, \dots, N_j, \dots \rangle = (N_j + 1)^{1/2} | N_1, N_2, \dots, N_j + 1, \dots \rangle, \quad (8.68)$$

in total compliance with the second of Eqs. (61). In particular, this *particle creation operator* allows the description of the generation of a single particle from the *vacuum* (not null!) state $|0, 0, \dots\rangle$:

$$\hat{a}_j^\dagger | 0, 0, \dots, 0_j, \dots, 0 \rangle = | 0, 0, \dots, 1_j, \dots, 0 \rangle, \quad (8.69)$$

and hence a product of such operators may create, from the vacuum, a multiparticle state with an arbitrary set of occupancies:²⁴

$$\underbrace{\hat{a}_1^\dagger \hat{a}_1^\dagger \dots \hat{a}_1^\dagger}_{N_1 \text{ times}} \underbrace{\hat{a}_2^\dagger \hat{a}_2^\dagger \dots \hat{a}_2^\dagger}_{N_2 \text{ times}} \dots | 0, 0, \dots \rangle = (N_1! N_2! \dots)^{1/2} | N_1, N_2, \dots \rangle. \quad (8.70)$$

Next, combining Eqs. (64) and (68), we get

$$\hat{a}_j^\dagger \hat{a}_j | N_1, N_2, \dots, N_j, \dots \rangle = N_j | N_1, N_2, \dots, N_j, \dots \rangle, \quad (8.71)$$

so that, just as for the particular case of harmonic oscillator excitations, the operator

$$\hat{N}_j \equiv \hat{a}_j^\dagger \hat{a}_j \quad (8.72)$$

“counts” the number of particles in the j^{th} single-particle state, while preserving the whole multiparticle state. Acting on a state by the creation-annihilation operators in the reverse order, we get

$$\hat{a}_j \hat{a}_j^\dagger | N_1, N_2, \dots, N_j, \dots \rangle = (N_j + 1) | N_1, N_2, \dots, N_j, \dots \rangle. \quad (8.73)$$

Eqs. (71) and (73) show that for *any* state of a multiparticle system (which may be represented as a linear superposition of Dirac states with all possible sets of numbers N_j), we may write

$$\hat{a}_j \hat{a}_j^\dagger - \hat{a}_j^\dagger \hat{a}_j \equiv [\hat{a}_j, \hat{a}_j^\dagger] = \hat{I}, \quad (8.74)$$

²⁴ The resulting Dirac state is *not* an eigenstate of every multiparticle Hamiltonian. However, we will see below that for a set of non-interacting particles it *is* a stationary state, so that the full set of such states may be used as a good basis in perturbation theories of systems of weakly interacting particles.

again in agreement with what we had for the 1D oscillator – cf. Eq. (5.68). According to Eqs. (63), (64), and (68), the creation and annihilation operators corresponding to different single-particle states do commute, so that Eq. (74) may be generalized as

$$\left[\hat{a}_j, \hat{a}_{j'}^\dagger \right] = \hat{I} \delta_{jj'}, \quad (8.75)$$

while the similar operators commute, regardless of which states do they act upon:

$$\left[\hat{a}_j^\dagger, \hat{a}_{j'}^\dagger \right] = \left[\hat{a}_j, \hat{a}_{j'} \right] = \hat{0}. \quad (8.76)$$

Bosonic operators:
commutation relations

As was mentioned earlier, a major challenge in the Dirac approach is to rewrite the Hamiltonian of a multiparticle system, that naturally carries particle numbers k (see, e.g., Eq. (22) for $k = 1, 2$), in the second quantization language, in which there are no these numbers. Let us start with *single-particle* components of such Hamiltonians, i.e. operators of the type

$$\hat{F} = \sum_{k=1}^N \hat{f}_k. \quad (8.77)$$

Single-particle operator

where all N operators \hat{f}_k are similar, besides that each of them acts on one specific (k^{th}) particle, and N is the total number of particles in the system, which is evidently equal to the sum of single-particle state occupancies:

$$N = \sum_j N_j. \quad (8.78)$$

The most important examples of such operators are the kinetic energy of N similar single particles, and their potential energy in an external field:

$$\hat{T} = \sum_{k=1}^N \frac{\hat{p}_k^2}{2m}, \quad \hat{U} = \sum_{k=1}^N \hat{u}(\mathbf{r}_k). \quad (8.79)$$

For bosons, instead of the Slater determinant (60), we have to write a similar expression, but without the sign alternation at permutations:

$$\left| N_1, \dots, N_j, \dots \right\rangle = \left(\frac{N_1! \dots N_j! \dots}{N!} \right)^{1/2} \sum_P \left| \underbrace{\dots \beta \beta' \beta'' \dots}_{N \text{ operands}} \right\rangle, \quad (8.80)$$

sometimes called the *permanent*. Note again that the left-hand side of this relation is written in the Dirac notation (that does not use particle numbering), while on its right-hand side, just in relations of Secs. 1 and 2, the particle numbers are coded with the positions of the single-particle states inside the state vectors, and the summation is over all different permutations of the states in the ket – cf. Eq. (10). (According to the basic combinatorics,²⁵ there are $N!/(N_1! \dots N_j! \dots)$ such permutations, so that the front coefficient in Eq. (80) ensures the normalization of the Dirac state, provided that the single-particle states β, β', \dots are normalized.) Let us use Eq. (80) to spell out the following matrix element for a system with $(N-1)$ particles:

²⁵ See, e.g., MA Eq. (2.3).

$$\begin{aligned} & \langle \dots N_j, \dots N_{j'} - 1, \dots | \hat{F} | \dots N_j - 1, \dots N_{j'}, \dots \rangle \\ &= \frac{N_1! \dots (N_j - 1)! \dots (N_{j'} - 1)! \dots}{(N - 1)!} (N_j N_{j'})^{1/2} \sum_{P(N-1)} \sum_{P(N-1)} \langle \dots \beta \beta' \beta'' \dots | \sum_{k=1}^{N-1} \hat{f}_k | \dots \beta \beta' \beta'' \dots \rangle, \end{aligned} \quad (8.81)$$

where all non-specified occupation numbers in the corresponding positions of the bra- and ket-vectors are equal to each other. Each single-particle operator \hat{f}_k participating in the operator sum, acts on the bra- and ket-vectors of states only in one (k^{th}) position, giving the following result, independent of the position number:

$$\langle \beta_j |_{\text{in } k^{\text{th}} \text{ position}} \hat{f}_k | \beta_{j'} \rangle_{\text{in } k^{\text{th}} \text{ position}} = \langle \beta_j | \hat{f} | \beta_{j'} \rangle \equiv f_{jj'}. \quad (8.82)$$

Since in both permutation sets participating in Eq. (81), with $(N - 1)$ state vectors each, all positions are equivalent, we can fix the position (say, take the first one) and replace the sum over k with the multiplication by of the bracket by $(N - 1)$. The fraction of permutations with the necessary bra-vector (with number j) in that position is $N_j/(N - 1)$, while that with the necessary ket-vector (with number j') in the same position is $N_{j'}/(N - 1)$. As the result, the permutation sum in Eq. (81) reduces to

$$(N - 1) \frac{N_j}{N - 1} \frac{N_{j'}}{N - 1} f_{jj'} \sum_{P(N-2)} \sum_{P(N-2)} \langle \dots \beta \beta' \beta'' \dots | \dots \beta \beta' \beta'' \dots \rangle, \quad (8.83)$$

where our specific position k is now excluded from both the bra- and ket-vector permutations. Each of these permutations now includes only $(N_j - 1)$ states j and $(N_{j'} - 1)$ states j' , so that, using the state orthonormality, we finally arrive at a very simple result:

$$\begin{aligned} & \langle \dots N_j, \dots N_{j'} - 1, \dots | \hat{F} | \dots N_j - 1, \dots N_{j'}, \dots \rangle \\ &= \frac{N_1! \dots (N_j - 1)! \dots (N_{j'} - 1)! \dots}{(N - 1)!} (N_j N_{j'})^{1/2} (N - 1) \frac{N_j}{N - 1} \frac{N_{j'}}{N - 1} f_{jj'} \frac{(N - 2)!}{N_1! \dots (N_j - 1)! \dots (N_{j'} - 1)! \dots} \\ & \equiv (N_j N_{j'})^{1/2} f_{jj'}. \end{aligned} \quad (8.84)$$

On the other hand, let us calculate matrix elements of the following operator:

$$\sum_{j,j'} f_{jj'} \hat{a}_j^\dagger \hat{a}_{j'} . \quad (8.85)$$

A direct application of Eqs. (64) and (68) shows that the only non-vanishing of the elements are

$$\langle \dots N_j, \dots N_{j'} - 1, \dots | f_{jj'} \hat{a}_j^\dagger \hat{a}_{j'} | \dots N_j - 1, \dots, N_{j'}, \dots \rangle = (N_j N_{j'})^{1/2} f_{jj'} . \quad (8.86)$$

But this is exactly the last form of Eq. (84), so that in the basis of Dirac states, the operator (77) may be represented as

$$\hat{F} = \sum_{j,j'} f_{jj'} \hat{a}_j^\dagger \hat{a}_{j'} . \quad (8.87)$$

This beautifully simple relation is the key formula of the second quantization theory, and is essentially the Dirac-language analog of Eq. (4.59) of the single-particle quantum mechanics. Each term of the sum (87) may be described by a very simple mnemonic rule: for each pair of single-particle states

j and j' , annihilate a particle in the state j' , create one in the state j , and weigh the result with the corresponding single-particle matrix element. One of the corollaries of Eq. (87) is that the expectation value of an operator whose eigenstates coincide with the Dirac states is

$$\langle F \rangle \equiv \langle \dots N_j, \dots | \hat{F} | \dots N_j, \dots \rangle = \sum_j f_{jj} N_j, \quad (8.88)$$

with an evident physical interpretation as the sum of single-particle expectation values over all states, weighed by the occupancy of each state.

Proceeding to *fermions*, which have to obey the Pauli principle, we immediately notice that any occupation number N_j may only take two values, 0 or 1. To account for that, and also make the key relation (87) valid for fermions as well, the creation-annihilation operators are defined by the following relations:

$$\hat{a}_j |N_1, N_2, \dots, 0_j, \dots\rangle = 0, \quad \hat{a}_j |N_1, N_2, \dots, 1_j, \dots\rangle = (-1)^{\Sigma(1, j-1)} |N_1, N_2, \dots, 0_j, \dots\rangle, \quad (8.89)$$

$$\hat{a}_j^\dagger |N_1, N_2, \dots, 0_j, \dots\rangle = (-1)^{\Sigma(1, j-1)} |N_1, N_2, \dots, 1_j, \dots\rangle, \quad \hat{a}_j^\dagger |N_1, N_2, \dots, 1_j, \dots\rangle = 0, \quad (8.90)$$

Fermion
creation-
annihilation
operators

where the symbol $\Sigma(J, J')$ means the sum of all occupancy numbers in the states with numbers from J to J' , including the border points:

$$\Sigma(J, J') \equiv \sum_{j=J}^{J'} N_j, \quad (8.91)$$

so that the sum participating in Eqs. (89)-(90) is the total occupancy of all states with the numbers below j . (The states are supposed to be numbered in a fixed albeit arbitrary order.) As a result, these relations may be conveniently summarized in the following verbal form: if an operator replaces the j^{th} state's occupancy with the opposite one (either 1 with 0, or vice versa), it also changes the sign before the result if (and only if) the total number of particles in the states with $j' < j$ is odd.

Let us use this (perhaps somewhat counter-intuitive) sign alternation rule to spell out the ket-vector $|11\rangle$ of a completely filled two-state system, formed from the vacuum state $|00\rangle$ in two different ways. If we start by creating a fermion in the state 1, we get

$$\hat{a}_1^\dagger |0, 0\rangle = (-1)^0 |1, 0\rangle \equiv |1, 0\rangle, \quad \hat{a}_2^\dagger \hat{a}_1^\dagger |0, 0\rangle = \hat{a}_2^\dagger |1, 0\rangle = (-1)^1 |1, 1\rangle \equiv -|1, 1\rangle, \quad (8.92a)$$

while if the operator order is different, the result is

$$\hat{a}_2^\dagger |0, 0\rangle = (-1)^0 |0, 1\rangle \equiv |0, 1\rangle, \quad \hat{a}_1^\dagger \hat{a}_2^\dagger |0, 0\rangle = \hat{a}_1^\dagger |0, 1\rangle = (-1)^0 |1, 1\rangle \equiv |1, 1\rangle, \quad (8.92b)$$

so that

$$(\hat{a}_1^\dagger \hat{a}_2^\dagger + \hat{a}_2^\dagger \hat{a}_1^\dagger) |0, 0\rangle = 0. \quad (8.93)$$

Since the action of any of these operator products on any initial state rather than the vacuum one also gives the null ket, we may write the following operator equality:

$$\hat{a}_1^\dagger \hat{a}_2^\dagger + \hat{a}_2^\dagger \hat{a}_1^\dagger \equiv \left\{ \hat{a}_1^\dagger, \hat{a}_2^\dagger \right\} = \hat{0}. \quad (8.94)$$

It is straightforward to check that this result is valid for Dirac vectors of an arbitrary length, and does not depend on the occupancy of other states, so that we may generalize it as

$$\left\{ \hat{a}_j^\dagger, \hat{a}_{j'}^\dagger \right\} = \left\{ \hat{a}_j, \hat{a}_{j'} \right\} = \hat{0}; \quad (8.95)$$

Fermionic operators:
commutation relations

these equalities hold for $j = j'$ as well. On the other hand, an absolutely similar calculation shows that the mixed creation-annihilation commutators do depend on whether the states are different or not:²⁶

$$\left\{ \hat{a}_j, \hat{a}_{j'}^\dagger \right\} = \hat{I} \delta_{jj'}. \quad (8.96)$$

These equations look very much like Eqs. (75)-(76) for bosons, “only” with the replacement of commutators with anticommutators. Since the core laws of quantum mechanics, including the operator compatibility (Sec. 4.5) and the Heisenberg equation (4.199) of operator evolution in time, involve commutators rather than anticommutators, one might think that all the behavior of bosonic and fermionic multiparticle systems should be dramatically different. However, the difference is not as big as one could expect; indeed, a straightforward check shows that the sign factors in Eqs. (89)-(90) just compensate those in the Slater determinant, and thus make the key relation (87) valid for the fermions as well. (Indeed, this is the very goal of the introduction of these factors.)

To illustrate this fact on the simplest example, let us examine what does the second quantization formalism say about the dynamics of non-interacting particles in the system whose single-particle properties we have discussed repeatedly, namely two nearly-similar potential wells, coupled by tunneling through the separating potential barrier – see, e.g., Figs. 2.21 or 7.4. If the coupling is so small that the states localized in the wells are only weakly perturbed, then in the basis of these states, the single-particle Hamiltonian of the system may be represented by the 2×2 matrix (5.3). With the energy reference selected at the middle between the energies of unperturbed states, the coefficient b vanishes, this matrix is reduced to

$$h = \mathbf{c} \cdot \boldsymbol{\sigma} \equiv \begin{pmatrix} c_z & c_- \\ c_+ & -c_z \end{pmatrix}, \quad \text{with } c_\pm \equiv c_x \pm i c_y, \quad (8.97)$$

and its eigenvalues to

$$\varepsilon_\pm = \pm c, \quad \text{with } c \equiv |\mathbf{c}| \equiv (c_x^2 + c_y^2 + c_z^2)^{1/2}. \quad (8.98)$$

Now following the recipe (87), we can use Eq. (97) to represent the Hamiltonian of the whole system of particles in terms of the creation-annihilation operators:

$$\hat{H} = c_z \hat{a}_1^\dagger \hat{a}_1 + c_- \hat{a}_1^\dagger \hat{a}_2 + c_+ \hat{a}_2^\dagger \hat{a}_1 - c_z \hat{a}_2^\dagger \hat{a}_2, \quad (8.99)$$

where $\hat{a}_{1,2}^\dagger$ and $\hat{a}_{1,2}$ are the operators of creation and annihilation of a particle in the corresponding *potential well*. (Again, in the second quantization approach the *particles* are not numbered at all!) As Eq. (72) shows, the first and the last terms of the right-hand side of Eq. (99) describe the particle energies $\varepsilon_{1,2} = \pm c_z$ in uncoupled wells,

$$c_z \hat{a}_1^\dagger \hat{a}_1 = c_z \hat{N}_1 \equiv \varepsilon_1 \hat{N}_1, \quad -c_z \hat{a}_2^\dagger \hat{a}_2 = -c_z \hat{N}_2 \equiv \varepsilon_2 \hat{N}_2, \quad (8.100)$$

²⁶ A by-product of this calculation is proof that the operator defined by Eq. (72) counts the number of particles N_j (now equal to either 1 or 0), just as it does for bosons.

while the sum of the middle two terms is the second-quantization description of tunneling between the wells.

Now we can use the general Eq. (4.199) of the Heisenberg picture to spell out the equations of motion of the creation-annihilation operators. For example,

$$i\hbar\dot{\hat{a}}_1 = [\hat{a}_1, \hat{H}] = c_z \left[\hat{a}_1, \hat{a}_1^\dagger \hat{a}_1 \right] + c_- \left[\hat{a}_1, \hat{a}_1^\dagger \hat{a}_2 \right] + c_+ \left[\hat{a}_1, \hat{a}_2^\dagger \hat{a}_1 \right] - c_z \left[\hat{a}_1, \hat{a}_2^\dagger \hat{a}_2 \right]. \quad (8.101)$$

Since the Bose and Fermi operators satisfy different commutation relations, one could expect the right-hand side of this equation to be different for bosons and fermions. However, it is not so. Indeed, all commutators on the right-hand side of Eq. (101) have the following form:

$$\left[\hat{a}_j, \hat{a}_{j'}^\dagger \hat{a}_{j''} \right] \equiv \hat{a}_j \hat{a}_{j'}^\dagger \hat{a}_{j''} - \hat{a}_{j'}^\dagger \hat{a}_{j''} \hat{a}_j. \quad (8.102)$$

As Eqs. (74) and (94) show, the first pair product of operators on the right-hand side may be recast as

$$\hat{a}_j \hat{a}_{j'}^\dagger = \hat{I} \delta_{jj'} \pm \hat{a}_{j'}^\dagger \hat{a}_j, \quad (8.103)$$

where the upper sign pertains to bosons and the lower one to fermions, while according to Eqs. (76) and (95), the very last pair product in Eq. (102) is

$$\hat{a}_{j''} \hat{a}_j = \pm \hat{a}_j \hat{a}_{j''}, \quad (8.104)$$

with the same sign convention. Plugging these expressions into Eq. (102), we see that regardless of the particle type, there is a universal (and generally very useful) commutation relation

$$\left[\hat{a}_j, \hat{a}_{j'}^\dagger \hat{a}_{j''} \right] = \hat{a}_{j''} \delta_{jj'}, \quad (8.105)$$

valid for both bosons and fermions. As a result, the Heisenberg equation of motion for the operator \hat{a}_1 , and the equation for \hat{a}_2 (which may be obtained absolutely similarly), are also universal:²⁷

$$\begin{aligned} i\hbar\dot{\hat{a}}_1 &= c_z \hat{a}_1 + c_- \hat{a}_2, \\ i\hbar\dot{\hat{a}}_2 &= c_+ \hat{a}_1 - c_z \hat{a}_2. \end{aligned} \quad (8.106)$$

This is a system of two coupled, linear differential equations, which is similar to the equations for the c -number probability amplitudes of single-particle wavefunctions of a two-level system – see, e.g., Eq. (2.201) and the model solution of Problem 4.25. Their general solution is a linear superposition

$$\hat{a}_{1,2}(t) = \sum_{\pm} \hat{\alpha}_{1,2}^{(\pm)} \exp\{\lambda_{\pm} t\}. \quad (8.107)$$

As usual, to find the exponents λ_{\pm} , it is sufficient to plug in a particular solution $\hat{a}_{1,2}(t) = \hat{\alpha}_{1,2} \exp\{\lambda t\}$ into Eq. (106) and require that the determinant of the resulting homogeneous, linear system for the “coefficients” (actually, time-independent operators) $\hat{\alpha}_{1,2}$ equals zero. This gives us the following characteristic equation

²⁷ Equations of motion for the creation operators $\hat{a}_{1,2}^\dagger$ are just the Hermitian-conjugates of Eqs. (106), and do not add any new information about the system’s dynamics.

$$\begin{vmatrix} c_z - i\hbar\lambda & c_- \\ c_+ & -c_z - i\hbar\lambda \end{vmatrix} = 0, \quad (8.108)$$

with two roots $\lambda_{\pm} = \pm i\Omega/2$, where $\Omega \equiv 2c/\hbar$ – cf. Eq. (5.20). Now plugging each of the roots, one by one, into the system of equations for $\hat{\alpha}_{1,2}$, we can find these operators, and hence the general solution of system (98) for arbitrary initial conditions.

Let us consider the simple case $c_y = c_z = 0$ (meaning in particular that the wells are exactly aligned, see Fig. 2.21), so that $\hbar\Omega/2 \equiv c = c_x$; then the solution of Eq. (106) is

$$\hat{a}_1(t) = \hat{a}_1(0) \cos \frac{\Omega t}{2} - i\hat{a}_2(0) \sin \frac{\Omega t}{2}, \quad \hat{a}_2(t) = -i\hat{a}_1(0) \sin \frac{\Omega t}{2} + \hat{a}_2(0) \cos \frac{\Omega t}{2}. \quad (8.109)$$

Multiplying the first of these relations by its Hermitian conjugate, and ensemble-averaging the result, we get

$$\langle N_1 \rangle \equiv \left\langle \hat{a}_1^\dagger(t) \hat{a}_1(t) \right\rangle = \left\langle \hat{a}_1^\dagger(0) \hat{a}_1(0) \right\rangle \cos^2 \frac{\Omega t}{2} + \left\langle \hat{a}_2^\dagger(0) \hat{a}_2(0) \right\rangle \sin^2 \frac{\Omega t}{2} - i \left\langle \hat{a}_1^\dagger(0) \hat{a}_2(0) + \hat{a}_2^\dagger(0) \hat{a}_1(0) \right\rangle \sin \frac{\Omega t}{2} \cos \frac{\Omega t}{2}. \quad (8.110)$$

Quantum oscillations:
second quantization form

Let the initial state of the system be a single Dirac state, i.e. have a definite number of particles in each well; in this case, only the two first terms on the right-hand side of Eq. (110) are different from zero, giving:²⁸

$$\langle N_1 \rangle = N_1(0) \cos^2 \frac{\Omega t}{2} + N_2(0) \sin^2 \frac{\Omega t}{2}. \quad (8.111)$$

For one particle, initially placed in either well, this gives us our old result (2.181) describing the usual quantum oscillations of the particle between two wells with the frequency Ω . However, Eq. (111) is valid for *any* set of initial occupancies; let us use this fact. For example, starting from two particles, with initially one particle in each well, we get $\langle N_1 \rangle = 1$, regardless of time. So, the occupancies do not oscillate, and no experiment may detect the quantum oscillations, though their frequency Ω is still formally present in the time evolution equations. This fact may be interpreted as the simultaneous quantum oscillations of two particles between the wells, exactly in anti-phase. For bosons, we can go on to even larger occupancies by preparing the system, for example, in the state with $N_1(0) = N$, $N_2(0) = 0$. The result (111) says that in this case, we see that the quantum oscillation amplitude increases N -fold; this is a particular manifestation of the general fact that bosons can be (and evolve in time) in the same quantum state. On the other hand, for fermions we cannot increase the initial occupancies beyond 1, so that the largest oscillation amplitude we can get is if we initially fill just one well.

The Dirac approach may be readily generalized to more complex systems. For example, Eq. (99) implies that an arbitrary system of potential wells with weak tunneling coupling between the adjacent wells may be described by the Hamiltonian

$$\hat{H} = \sum_j \varepsilon_j a_j^\dagger \hat{a}_j + \sum_{\{j,j'\}} \delta_{jj'} a_j^\dagger \hat{a}_{j'} + \text{h.c.}, \quad (8.112)$$

²⁸ For the second well's occupancy, the result is complementary, $N_2(t) = N_1(0)\sin^2\Omega t + N_2(0)\cos^2\Omega t$, giving in particular a good sanity check: $N_1(t) + N_2(t) = N_1(0) + N_2(0) = \text{const.}$

where the symbol $\{j, j'\}$ means that the second sum is restricted to pairs of next-neighbor wells – see, e.g., Eq. (2.203) and its discussion. Note that this Hamiltonian is still a quadratic form of the creation-annihilation operators, so the Heisenberg-picture equations of motion of these operators are still linear, and its exact solutions, though possibly cumbersome, may be studied in detail. Due to this fact, the Hamiltonian (112) is widely used for the study of some phenomena, for example, the very interesting *Anderson localization* effects, in which a random distribution of the localized-site energies ε_j prevents tunneling particles, within a certain energy range, from spreading to unlimited distances.²⁹

8.4. Perturbative approaches

The situation becomes much more difficult if we need to account for direct interactions between the particles. Let us assume that the interaction may be reduced to that between their pairs (as it is the case at their Coulomb interaction and most other interactions³⁰), so that it may be described by the following “pair-interaction” Hamiltonian

$$\hat{U}_{\text{int}} = \frac{1}{2} \sum_{\substack{k,k'=1 \\ k \neq k'}}^N \hat{u}_{\text{int}}(\mathbf{r}_k, \mathbf{r}_{k'}), \quad (8.113)$$

with the front factor of $1/2$ compensating the double-counting of each particle pair. The translation of this operator to the second-quantization form may be done absolutely similarly to the derivation of Eq. (87), and gives a similar (though naturally more involved) result

$$\hat{U}_{\text{int}} = \frac{1}{2} \sum_{j,j',l,l'} u_{jj'll'} \hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_l \hat{a}_{l'}, \quad (8.114)$$

Pair-interaction Hamiltonian: two forms

where the two-particle matrix elements are defined similarly to Eq. (82):

$$u_{jj'll'} \equiv \langle \beta_j \beta_{j'} | \hat{u}_{\text{int}} | \beta_l \beta_{l'} \rangle. \quad (8.115)$$

The only new feature of Eq. (114) is a specific order of the indices of the creation operators. Note the mnemonic rule of writing this expression, similar to that for Eq. (87): each term corresponds to moving a pair of particles from states l and l' to states j' and j (in this order!) factored with the corresponding two-particle matrix element (115).

However, with the account of such term, the resulting Heisenberg equations of the time evolution of the creation/annihilation operators are nonlinear, so that solving them and calculating observables from the results is usually impossible, at least analytically. The only case when some general results may be obtained is the *weak interaction* limit. In this case, the unperturbed Hamiltonian contains only single-particle terms such as (79), and we can always (at least conceptually :-) find such a basis of orthonormal single-particle states β_j in which that Hamiltonian is diagonal in the Dirac representation:

²⁹ For a review of the 1D version of this problem, see, e.g., J. Pendry, *Adv. Phys.* **43**, 461 (1994).

³⁰ A simple but important example from the condensed matter theory is the so-called *Hubbard model*, in which particle repulsion limits their number on each of localized sites to either 0, or 1, or 2, with negligible interaction of the particles on different sites – though the next-neighbor sites are still connected by tunneling – as in Eq. (112).

$$\hat{H}^{(0)} = \sum_j \varepsilon_j^{(0)} \hat{a}_j^\dagger \hat{a}_j . \quad (8.116)$$

Now we can use Eq. (6.14), in this basis, to calculate the interaction energy as a first-order perturbation:

$$\begin{aligned} E_{\text{int}}^{(1)} &= \langle N_1, N_2, \dots | \hat{U}_{\text{int}} | N_1, N_2, \dots \rangle = \frac{1}{2} \langle N_1, N_2, \dots | \sum_{j,j',l,l'} u_{jj'll'} \hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_l \hat{a}_l | N_1, N_2, \dots \rangle \\ &\equiv \frac{1}{2} \sum_{j,j',l,l'} u_{jj'll'} \langle N_1, N_2, \dots | \hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_l \hat{a}_l | N_1, N_2, \dots \rangle. \end{aligned} \quad (8.117)$$

Since, according to Eq. (63), the Dirac states with different occupancies are orthogonal, the last long bracket is different from zero only for three particular subsets of its indices:

(i) $j \neq j'$, $l = j$, and $l' = j'$. In this case, the four-operator product in Eq. (117) is equal to $\hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_{j'} \hat{a}_j$, and applying the commutation rules twice, we can bring it to the so-called *normal ordering*, with each creation operator standing to the right of the corresponding annihilation operator, thus forming the particle number operator (72):

$$\hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_{j'} \hat{a}_j = \pm \hat{a}_j^\dagger \hat{a}_j^\dagger \hat{a}_j \hat{a}_{j'} = \pm \hat{a}_j^\dagger (\pm \hat{a}_j \hat{a}_{j'}^\dagger) \hat{a}_{j'} = \hat{a}_j^\dagger \hat{a}_j \hat{a}_{j'}^\dagger \hat{a}_{j'} = \hat{N}_j \hat{N}_{j'}, \quad (8.118)$$

with a similar sign of the final result for bosons and fermions.

(ii) $j \neq j'$, $l = j'$, and $l' = j$. In this case, the four-operator product is equal to $\hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_j \hat{a}_{j'}$, and bringing it to the form $\hat{N}_j \hat{N}_{j'}$ requires only one commutation:

$$\hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_j \hat{a}_{j'} = \hat{a}_j^\dagger (\pm \hat{a}_j \hat{a}_{j'}^\dagger) \hat{a}_{j'} = \pm \hat{a}_j^\dagger \hat{a}_j \hat{a}_{j'}^\dagger \hat{a}_{j'} = \pm \hat{N}_j \hat{N}_{j'}, \quad (8.119)$$

with the upper sign for bosons and the lower sign for fermions.

(iii) All indices are equal to each other, giving $\hat{a}_j^\dagger \hat{a}_{j'}^\dagger \hat{a}_l \hat{a}_l = \hat{a}_j^\dagger \hat{a}_j^\dagger \hat{a}_j \hat{a}_j$. For fermions, such an operator (that “tries” to create or to kill two particles in a row, in the same state) immediately gives the null-vector. In the case of bosons, we may use Eq. (74) to commute the internal pair of operators, getting

$$\hat{a}_j^\dagger \hat{a}_j^\dagger \hat{a}_j \hat{a}_j = \hat{a}_j^\dagger (\hat{a}_j \hat{a}_j^\dagger - \hat{I}) \hat{a}_j = \hat{N}_j (\hat{N}_j - \hat{I}). \quad (8.120)$$

Note, however, that this expression formally covers the fermion case as well (always giving zero). As a result, Eq. (117) may be rewritten in the following universal form:

$$E_{\text{int}}^{(1)} = \frac{1}{2} \sum_{\substack{j,j' \\ j \neq j'}} N_j N_{j'} (u_{jj'jj'} \pm u_{jj'jj}) + \frac{1}{2} \sum_j N_j (N_j - 1) u_{jjjj}. \quad (8.121)$$

Particle interaction:
1st-order
energy
correction

The corollaries of this important result are very different for bosons and fermions. In the former case, the last term usually dominates, because the matrix elements (115) are typically the largest when all basis functions coincide. Note that this term allows a very simple interpretation: the number of the diagonal matrix elements it sums up for each state (j) is just the number of interacting particle pairs residing in that state.

In contrast, for fermions the last term is zero, and the interaction energy is proportional to the difference of the two terms inside the first parentheses. To spell them out, let us consider the case when there is no direct spin-orbit interaction. Then the vectors $|\beta_j\rangle$ of the single-particle state basis may be represented as direct products $|o_j\rangle \otimes |m_j\rangle$ of their orbital and spin-orientation parts. (Here, for the brevity of notation, I am using m instead of m_s .) For spin- $\frac{1}{2}$ particles, including electrons, m_j may equal only either $+\frac{1}{2}$ or $-\frac{1}{2}$; in this case the spin part of the first matrix element, proportional to $u_{jj'jj'}$, equals

$$\langle m| \otimes \langle m' | m \rangle \otimes | m' \rangle, \quad (8.122)$$

where, as in the general Eq. (115), the position of a particular state vector in each direct product is encoding the particle's number. Since the spins of different particles are defined in different Hilbert spaces, we may move their state vectors around to get

$$\langle m| \otimes \langle m' | m \rangle \otimes | m' \rangle = (\langle m | m \rangle)_1 \times (\langle m' | m' \rangle)_2 = 1, \quad (8.123)$$

for any pair of j and j' . On the other hand, the second matrix element, $u_{jj'jj'}$, is factored by

$$\langle m| \otimes \langle m' | m' \rangle \otimes | m \rangle = (\langle m | m' \rangle)_1 \times (\langle m' | m \rangle)_2 = \delta_{mm'}. \quad (8.124)$$

In this case, it is convenient to rewrite Eq. (121) in the coordinate representation, using single-particle wavefunctions called *spin-orbitals*

$$\psi_j(\mathbf{r}) \equiv \langle \mathbf{r} | \beta_j \rangle = (\langle \mathbf{r} | o \rangle \otimes | m \rangle)_j. \quad (8.125)$$
Spin-orbital

They differ from the spatial parts of the usual orbital wavefunctions of the type (4.233) only in that their index j should be understood as the set of the orbital-state and the spin-orientation indices.³¹ Also, due to the Pauli-principle restriction of numbers N_j to either 0 or 1, Eq. (121) may be also rewritten without the explicit occupancy numbers, with the understanding that the summation is extended only over the pairs of occupied states. As a result, it becomes

$$E_{\text{int}}^{(1)} = \frac{1}{2} \sum_{\substack{j,j' \\ j \neq j'}} \int d^3 r \int d^3 r' \left[\psi_j^*(\mathbf{r}) \psi_{j'}^*(\mathbf{r}') u_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_j(\mathbf{r}) \psi_{j'}(\mathbf{r}') - \psi_j^*(\mathbf{r}) \psi_{j'}^*(\mathbf{r}') u_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_{j'}(\mathbf{r}) \psi_j(\mathbf{r}') \right]. \quad (8.126)$$
Energy correction due to fermion interaction

In particular, for a system of two electrons, we may limit the summation to just two states ($j, j' = 1, 2$). As a result, we return to Eqs. (39)-(41), with the bottom (minus) sign in Eq. (39), corresponding to the triplet spin states. Hence, Eq. (126) may be considered as the generalization of the direct and exchange interaction balance picture to an arbitrary number of orbitals and an arbitrary total number N of electrons. Note, however, that this formula cannot correctly describe the energy of the singlet spin states, corresponding to the plus sign in Eq. (39), and also of the entangled triplet states.³² The reason is

³¹ The spin-orbitals (125) are also close to spinors (13), besides that the former definition takes into account that the spin s of a single particle is fixed, so that the spin-orbital may be indexed by the spin's orientation $m \equiv m_s$ only. Also, if an orbital index is used, it should be clearly distinguished from j , i.e. the set of the orbital and spin indices. This is why I believe that the frequently met notation of spin-orbitals as $\psi_{j,s}(\mathbf{r})$ may lead to confusion.

³² Indeed, due to the condition $j' \neq j$, and Eq. (124), the calculated negative exchange interaction is limited to electron state pairs with the same spin direction – such as the factorable triplet states ($\uparrow\uparrow$ and $\downarrow\downarrow$) of a two-electron system, in which the contribution of E_{ex} , given by Eq. (41), to the total energy is also negative.

that the description of entangled spin states, given in particular by Eqs. (18) and (20), requires linear *superpositions* of different Dirac states. (A proof of this fact is left for the reader's exercise.)

Now comes a very important fact: the *approximate* result (126), added to the sum of unperturbed energies $\varepsilon_j^{(0)}$, equals the sum of *exact* eigenenergies of the so-called *Hartree-Fock equation*:³³

Hartree-Fock equation

$$\left(-\frac{\hbar^2}{2m} \nabla^2 + u(\mathbf{r}) \right) \psi_j(\mathbf{r}) + \sum_{j' \neq j} \int \left[\psi_{j'}^*(\mathbf{r}') u_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_j(\mathbf{r}) \psi_{j'}(\mathbf{r}') - \psi_{j'}^*(\mathbf{r}') u_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_{j'}(\mathbf{r}) \psi_j(\mathbf{r}) \right] d^3 r' = \varepsilon_j \psi_j(\mathbf{r}), \quad (8.127)$$

where $u(\mathbf{r})$ is the external-field potential acting on each particle separately – see the second of Eqs. (79). An advantage of this equation in comparison with Eq. (126) is that it allows the (approximate) calculation of not only the energy spectrum of the system, but also the corresponding spin-orbitals, taking into account their electron-electron interaction. Of course, Eq. (127) is an *integro-differential* rather than just a differential equation. There are, however, efficient methods of numerical solution of such equations, typically based on iterative methods. One more important practical trick is the exclusion of the filled internal electron shells (see Sec. 3.7) from the explicit calculations, because the shell states are virtually unperturbed by the valence electron effects involved in typical atomic phenomena and chemical reactions. In this approach, the Coulomb field of the shells, described by fixed, pre-calculated, and tabulated *pseudo-potentials*, is added to that of the nuclei. This approach dramatically cuts the computing resources necessary for systems of relatively heavy atoms, enabling a pretty accurate simulation of electronic and chemical properties of rather complex molecules, with thousands of electrons.³⁴ As a result, the Hartree-Fock approximation has become the de-facto baseline of all so-called *ab-initio* (“first-principle”) calculations in the very important field of quantum chemistry.³⁵

In departures from this baseline, there are two opposite trends. For larger accuracy (and typically smaller systems), several “post-Hartree-Fock methods”, notably including the *configuration interaction* method,³⁶ that are more complex but may provide higher accuracy, have been developed.

There is also a strong opposite trend of extending such *ab initio* (“first-principle”) methods to larger systems while sacrificing some of the results’ accuracy and reliability. The ultimate limit of this trend is applicable when the single-particle wavefunction overlaps are small and hence the exchange interaction is negligible. In this limit, the last term in the square brackets in Eq. (127) may be ignored, and the multiplier $\psi_j(\mathbf{r})$ taken out of the integral, which is thus reduced to a differential equation – formally just the Schrödinger equation for a single particle in the following self-consistent effective potential:

³³ This equation was suggested in 1929 by Douglas Hartree for the direct interaction and extended to the exchange interaction by Vladimir Fock in 1930. To verify its compliance with Eq. (126), it is sufficient to multiply all terms of Eq. (127) by $\psi_j^*(\mathbf{r})$, integrate them over all \mathbf{r} -space (so that the right-hand side would give ε_j), and then sum these single-particle energies over all occupied states j .

³⁴ For condensed-matter systems, this and other computational methods are applied to single elementary spatial cells, with a limited number of electrons in them, using cyclic boundary conditions.

³⁵ See, e.g., A. Szabo and N. Ostlund, *Modern Quantum Chemistry*, Revised ed., Dover, 1996.

³⁶ That method, in particular, allows the calculation of proper linear superpositions of the Dirac states (such as the entangled states for $N = 2$, discussed above) which are missing in the generic Hartree-Fock approach – see, e.g., the just-cited monograph by Szabo and Ostlund.

$$u_{\text{ef}}(\mathbf{r}) = u(\mathbf{r}) + u_{\text{dir}}(\mathbf{r}), \quad u_{\text{dir}}(\mathbf{r}) = \sum_{j' \neq j} \int \psi_{j'}^*(\mathbf{r}') u_{\text{int}}(\mathbf{r}, \mathbf{r}') \psi_{j'}(\mathbf{r}') d^3 r'. \quad (8.128)$$

Hartree approximation

This is the so-called *Hartree approximation* – that gives reasonable results for some systems,³⁷ especially those with low electron density.

However, in dense electron systems (such as typical atoms, molecules, and condensed matter) the exchange interaction, described by the second term in the square brackets of Eqs. (126)-(127), may be as high as $\sim 30\%$ of the direct interaction, and frequently cannot be ignored. The tendency of taking this interaction in the simplest possible form is currently dominated by the *Density Functional Theory*,³⁸ universally known by its acronym DFT. In this approach, the equation solved for each eigenfunction $\psi_j(\mathbf{r})$ is a differential, Schrödinger-like *Kohn-Sham equation*

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + u(\mathbf{r}) + u_{\text{dir}}^{\text{KS}}(\mathbf{r}) + u_{\text{xc}}(\mathbf{r}) \right] \psi_j(\mathbf{r}) = \varepsilon_j \psi_j(\mathbf{r}), \quad (8.129)$$

Kohn-Sham equation

where

$$u_{\text{dir}}^{\text{KS}}(\mathbf{r}) = -e\phi(\mathbf{r}), \quad \phi(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \int d^3 r' \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}, \quad \rho(\mathbf{r}) = -en(\mathbf{r}), \quad (8.130)$$

and $n(\mathbf{r})$ is the total electron density in a particular point, calculated as

$$n(\mathbf{r}) \equiv \sum_j \psi_j^*(\mathbf{r}) \psi_j(\mathbf{r}). \quad (8.131)$$

The most important feature of the Kohn-Sham Hamiltonian is the simplified description of the exchange and correlation effects by the effective *exchange-correlation potential* $u_{\text{xc}}(\mathbf{r})$. This potential is calculated in various approximations, most of them valid only in the limit when the number of electrons in the system is very high. The simplest of them (proposed by Kohn *et al.* in the 1960s) is the *Local Density Approximation* (LDA) in which the effective exchange potential at each point is a function only of the electron density n at the same point \mathbf{r} , taken from the theory of a *uniform* gas of free electrons.³⁹ However, for many tasks of quantum chemistry, the accuracy given by the LDA is insufficient, because inside molecules the density n typically changes very fast. As a result, DFT has become widely accepted in that field only after the introduction, in the 1980s, of more accurate, though more cumbersome models for $u_{\text{xc}}(\mathbf{r})$, notably the so-called *Generalized Gradient Approximations* (GGAs). Due to its relative simplicity, DFT enables the calculation, with the same computing resources and reasonable precision, some properties of much larger systems than the methods based on the Hartree-Fock theory. As the result, it has become a very popular tool of ab initio calculations. This popularity is enhanced by the availability of several advanced DFT software packages, some of them in the public domain.

³⁷ An extreme example of the Hartree approximation is the *Thomas-Fermi model* of heavy atoms (with $Z \gg 1$), in which atomic electrons, at each distance r from the nucleus, are treated as an ideal, uniform Fermi gas, with a certain density $n(r)$ corresponding to the local value $u_{\text{ef}}(r)$, but a global value of their highest full single-particle energy, $\varepsilon = 0$, to ensure the equilibrium. (The analysis of this model is left for the reader's exercise.)

³⁸ It had been developed by Walter Kohn and his associates (notably Pierre Hohenberg) in 1965-66, and eventually (in 1998) was marked with a Nobel Prize in Chemistry for W. Kohn.

³⁹ Just for the reader's reference: for a uniform, degenerate Fermi-gas of electrons (with the Fermi energy $\varepsilon_F \gg k_B T$), the most important, exchange part u_x of u_{xc} may be calculated analytically: $u_x = -(3/4\pi) e^2 k_F / 4\pi\varepsilon_0$, where the Fermi momentum $k_F = (2m_e\varepsilon_F)^{1/2}/\hbar$ is defined by the electron density: $n = 2(4\pi/3)k_F^3/(2\pi)^3 \equiv k_F^3/3\pi^2$.

Please note, however, that despite this undisputable success, this approach has its problems. From my personal point of view, the most offensive of them is the implicit assumption of the unphysical Coulomb interaction of an electron with itself (by dropping, on the way from Eq. (128) to Eq. (130), the condition $j' \neq j$ at the calculation of $u_{\text{dir}}^{\text{KS}}$). As a result, for a reasonable description of some effects, the available DFT packages are either inapplicable at all or require substantial artificial tinkering.⁴⁰

Unfortunately, because of lack of time/space, for details I have to refer the interested reader to specialized literature.⁴¹

8.5. Quantum computation and cryptography

Now I have to review the emerging fields of *quantum computation* and *encryption*. (Since these fields are much related, they are often referred to under the common title of “quantum information science”, though this term is somewhat misleading, de-emphasizing physical aspects of the topic.) These fields are currently the subject of intensive research and development efforts, which has already brought, besides an enormous body of hype, some results of general importance. My coverage, by necessity short, will focus on these results, referring the reader interested in details to special literature.⁴² Because of the very active stage of the fields, I will also provide quite a few references to recent publications, making the style of this section closer to a brief literature review than to a textbook’s section.

Presently, most work on quantum computation and encryption is based on systems of spatially separated (and hence *distinguishable*) two-level systems – in this context, universally called *qubits*.⁴³ Due to this distinguishability, the issues that were the focus of the first sections of this chapter, including the second quantization approach, are irrelevant here. On the other hand, systems of qubits have some interesting properties that have not been discussed in this course yet.

First of all, a system of $N \gg 1$ qubits may contain much more information than the same number of N classical bits. Indeed, according to the discussions in Chapter 4 and Sec. 5.1, an arbitrary pure state of a single qubit may be represented by its ket vector (4.37) – see also Eq. (5.1):

$$|\alpha\rangle_{N=1} = \alpha_1|u_1\rangle + \alpha_2|u_2\rangle, \quad (8.132)$$

where $\{u_j\}$ is any orthonormal two-state basis. It is natural and common to employ, as u_j , the eigenstates a_j of the observable A that is eventually measured in the particular physical implementation of the qubit – say, a certain Cartesian component of spin-½. It is also common to write the kets of these base states as $|0\rangle$ and $|1\rangle$, so that Eq. (132) takes the form

⁴⁰ As just a few examples, see N. Simonian *et al.*, *J. Appl. Phys.* **113**, 044504 (2013); M. Medvedev *et al.*, *Science* **355**, 49 (2017); A. Hutama *et al.*, *J. Phys. Chem. C* **121**, 14888 (2017).

⁴¹ See, e.g., either the monograph by R. Parr and W. Yang, *Density-Functional Theory of Atoms and Molecules*, Oxford U. Press, 1994, or the later textbook J. A. Steckel and D. Sholl, *Density Functional Theory: Practical Introduction*, Wiley, 2009. For a popular review and references to more recent work in this still-developing field, see A. Zangwill, *Phys. Today* **68**, 34 (July 2015).

⁴² Despite the recent flood of new books on the field, one of its first surveys, by M. Nielsen and I. Chuang, *Quantum Computation and Quantum Information*, Cambridge U. Press, 2000, is perhaps still the best one.

⁴³ In some texts, the term qubit (or “Qbit”, or “Q-bit”) is used instead for the *information contents* of a two-level system – very much like the classical bit of information (in this context, frequently called “Cbit” or “C-bit”) describes the information contents of a classical bistable system – see, e.g., SM Sec. 2.2.

$$|\alpha\rangle_{N=1} = a_0|0\rangle + a_1|1\rangle \equiv \sum_{j=0,1} a_j |j\rangle. \quad (8.133)$$

Single qubit state's representation

(Here, and in the balance of this section, the letter j is used to denote an integer equal to either 0 or 1.) According to this relation, any state α of a qubit is completely defined by two complex c -numbers a_j , i.e. by 4 real numbers. Moreover, due to the normalization condition $|a_0|^2 + |a_1|^2 = 1$, we need just 3 independent real numbers – say, the Bloch sphere coordinates θ and φ (see Fig. 5.3), plus the common phase γ , which becomes important only when we consider coherent states of a several-qubit system.

This is a good time to note that a qubit is very much different from any classical bistable system used to store single bits of information – such as two possible voltage states of the usual SRAM cell (essentially, a positive-feedback loop of two transistor-based inverters). Namely, the stationary states of a classical bistable system, due to its nonlinearity, are stable with respect to small perturbations, so that they may be very robust to unintentional interaction with their environment. In contrast, the qubit's state may be disturbed (i.e. its representation point on the Bloch sphere shifted) by even minor perturbations, because it does not have such an internal state stabilization mechanism.⁴⁴ Due to this reason, qubit-based systems are rather vulnerable to environment-induced drifts, including the dephasing and relaxation discussed in the previous chapter, creating major experimental challenges – see below.

Now, if we have a system of 2 qubits, the vectors of its arbitrary pure state may be represented as a sum of $2^2 = 4$ terms,⁴⁵

$$|\alpha\rangle_{N=2} = a_{00}|00\rangle + a_{01}|01\rangle + a_{10}|10\rangle + a_{11}|11\rangle \equiv \sum_{j_1, j_2=0,1} a_{j_1 j_2} |j_1 j_2\rangle, \quad (8.134)$$

Two-qubit state's representation

with four complex coefficients, i.e. eight real numbers, subject to just one normalization condition, which follows from the requirement $\langle\alpha|\alpha\rangle = 1$:

$$\sum_{j_1, j_2=0,1} \left| a_{j_1 j_2} \right|^2 = 1. \quad (8.135)$$

The evident generalization of Eqs. (133)-(134) to an arbitrary pure state of an N -qubit system is a sum of 2^N terms:

$$|\alpha\rangle_N = \sum_{j_1, j_2, \dots, j_N=0,1} a_{j_1 j_2 \dots j_N} |j_1 j_2 \dots j_N\rangle, \quad (8.136)$$

including all possible combinations of 0s and 1s for indices j , so that the state is fully described by 2^N complex numbers, i.e. $2 \cdot 2^N \equiv 2^{N+1}$ real numbers, with only one constraint, similar to Eq. (135), imposed by the normalization condition. Let me emphasize that this exponential growth of the information contents would not be possible without the qubit state entanglement. Indeed, in the particular case when qubit states are not entangled, i.e. are factorable:

⁴⁴ In this aspect as well, the information processing systems based on qubits are closer to classical analog computers (which were popular once, but nowadays are used for a few special applications only) rather than classical digital ones.

⁴⁵ Here and in most instances below I use the same shorthand notation as was used at the beginning of this chapter – cf. Eq. (1b). In this short form, qubit's number is coded by the order of its state index inside a full ket-vector, while in the long form, such as in Eq. (137), it is coded by the order of its single-qubit vector in a full direct product.

$$|\alpha\rangle_N = |\alpha_1\rangle|\alpha_2\rangle\cdots|\alpha_N\rangle, \quad (8.137)$$

where each $|\alpha_n\rangle$ is described by an equality similar to Eq. (133) with its individual expansion coefficients, the system state description requires only $3N - 1$ real numbers – e.g., N sets $\{\theta, \varphi, \gamma\}$ less one common phase.

However, it would be wrong to project this exponential growth of information contents directly on the capabilities of quantum computation, because this process has to include the output information readout, i.e. qubit state measurements. Due to the fundamental intrinsic uncertainty of quantum systems, the measurement of a single qubit even in a pure state (133) generally may give either of two results, with probabilities $W_0 = |a_0|^2$ and $W_1 = |a_1|^2$. To comply with the general notion of computation, any quantum computer has to provide certain (or virtually certain) results, and hence the probabilities W_j have to be very close to either 0 or 1, so that before the measurement, each measured qubit has to be in a basis state – either 0 or 1. This means that the computational system with N output qubits, just before the final readout, has to be in one of the factorable states

$$|\alpha\rangle_N = |j_1\rangle|j_2\rangle\cdots|j_N\rangle \equiv |j_1 j_2 \dots j_N\rangle, \quad (8.138)$$

which is a very small subset even of the set of all unentangled states (137), and whose maximum information contents is just N classical bits.

Now the reader may start thinking that this constraint strips quantum computations of any advantages over their classical counterparts, but such a view is also superficial. To show that, let us consider the scheme of the most actively explored type of quantum computation, shown in Fig. 3.⁴⁶

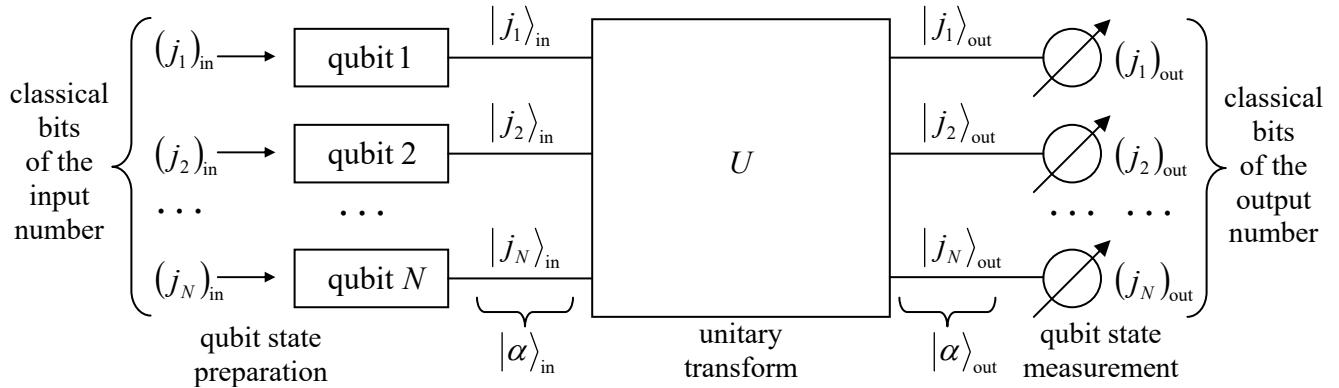

Fig. 8.3. The baseline scheme of quantum computation.

Here each horizontal line (sometimes called a “wire”⁴⁷) corresponds to a single qubit, tracing its time evolution in the same direction as at the usual time function plots: from left to right. This means

⁴⁶ Numerous modifications of this “baseline” scheme have been suggested, for example with the number of output qubits different from that of input qubits, etc. Some other options are discussed at the end of this section.

⁴⁷ The notion of “wires” stems from the similarity between such quantum schemes and the drawings describing classical computation circuits – see, e.g., Fig. 4a below. In the classical case, the lines may be indeed understood as physical wires connecting physical devices: logic gates and/or memory cells. In this context, note that classical computer components also have non-zero time delays, so that even in this case the left-to-right device ordering is useful to indicate the timing of (and frequently the causal relation between) the signals.

that the left column $|\alpha\rangle_{\text{in}}$ of ket-vectors describes the initial state of the qubits,⁴⁸ while the right column $|\alpha\rangle_{\text{out}}$ describes their final (but pre-measurement) state. The box labeled U represents the qubit evolution in time due to their specially arranged interactions between each other and/or external drive “forces”. Besides these forces, during this evolution the system is supposed to be ideally isolated from the dephasing and energy-dissipating environment, so that the process may be described by a unitary operator defined in the 2^N -dimensional Hilbert space of N qubits:

$$|\alpha\rangle_{\text{out}} = \hat{U}|\alpha\rangle_{\text{in}}. \quad (8.139)$$

With the condition that the input and output states have the simple form (138), this equality reads

$$|(j_1)_{\text{out}}(j_2)_{\text{out}}\dots(j_N)_{\text{out}}\rangle = \hat{U}|(j_1)_{\text{in}}(j_2)_{\text{in}}\dots(j_N)_{\text{in}}\rangle. \quad (8.140)$$

The art of quantum computer design consists of selecting such unitary operators \hat{U} that would:

- satisfy Eq. (140),
- be physically implementable, and
- enable substantial performance advantages of the quantum computation over its classical counterparts with similar functionality, at least for some digital functions (algorithms).

I will have time/space to demonstrate the possibility of such advantages on just one, perhaps the simplest example – the so-called *Deutsch problem*,⁴⁹ on the way discussing several common notions and issues of this field. Let us consider the family of single-bit classical Boolean functions $j_{\text{out}} = f(j_{\text{in}})$. Since both j are Boolean variables, i.e. may take only values 0 and 1, there are evidently only 4 such functions – see the first four columns of the following table:

f	$f(0)$	$f(1)$	class	F	$f(1)-f(0)$
f_1	0	0	constant	0	0
f_2	0	1	balanced	1	1
f_3	1	0	balanced	1	-1
f_4	1	1	constant	0	0

(8.141)

Of them, the functions f_1 and f_4 , whose values are independent of their arguments, are called *constants*, while the functions f_2 (called “YES” or “IDENTITY”) and f_3 (“NOT” or “INVERSION”) are called *balanced*. The Deutsch problem is to determine the class of a single-bit function, implemented in a “black box”, as being either constant or balanced, using just one experiment.

⁴⁸ As was discussed in Chapter 7, the preparation of a pure state (133) is (conceptually :-) straightforward. Placing a qubit into a weak contact with an environment of temperature $T \ll \Delta/k_B$, where Δ is the difference between energies of the eigenstates 0 and 1, we may achieve its relaxation into the lowest-energy state. Then, if the qubit must be set into a different pure state, it may be driven there by the application of a pulse of a proper external classical “force”. For example, if an actual spin-½ is used as the qubit, a pulse of a magnetic field, with proper direction and duration, may be applied to arrange its precession to the required Bloch sphere point – see Fig. 5.3c. However, in most physical implementations of qubits, a more practicable way for that step is to use a proper part of the Rabi oscillation period – see Sec. 6.5.

⁴⁹ It is named after David Elieser Deutsch, whose 1985 paper (motivated by an inspirational but not very specific publication by Richard Feynman in 1982) launched the whole field of quantum computation.

Classically, this is clearly impossible, and the simplest way to perform the function's classification involves two similar black boxes f – see Fig. 4a.⁵⁰ It also uses the so-called *exclusive-OR* (XOR for short) *gate* whose output is described by the following function F of its two Boolean arguments j_1 and j_2 :⁵¹

$$F(j_1, j_2) = j_1 \oplus j_2 \equiv \begin{cases} 0, & \text{if } j_1 = j_2, \\ 1, & \text{if } j_1 \neq j_2. \end{cases} \quad (8.142)$$

In the particular circuit shown in Fig. 4a, the gate produces the following output:

$$F = f(0) \oplus f(1), \quad (8.143)$$

which is equal to 1 if $f(0) \neq f(1)$, i.e. if the function f is balanced, and to 0 in the opposite case – see column F in the table of Eq. (141).

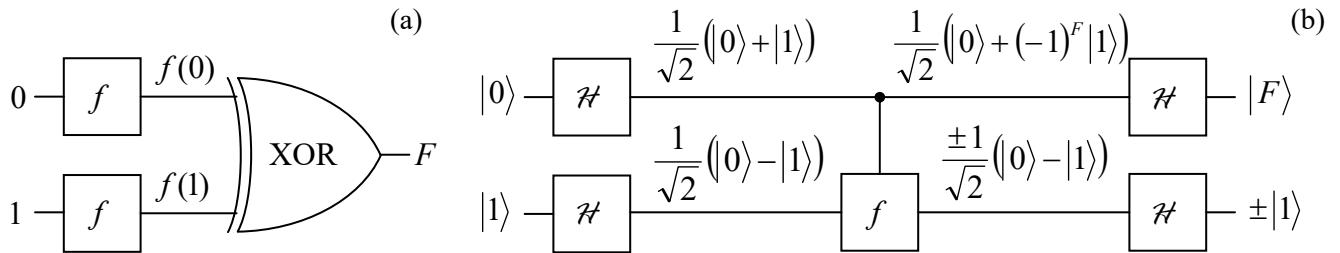

Fig. 8.4. The simplest (a) classical and (b) quantum ways to classify a single-bit Boolean function f .

On the other hand, as will be shown below, any of four functions f may be implemented quantum-mechanically, for example (Fig. 5a) as a unitary transform of two input qubits, acting as follows on each basis component $|j_1 j_2\rangle \equiv |j_1\rangle |j_2\rangle$ of the general input state (134):

$$\hat{f}|j_1\rangle |j_2\rangle = |j_1\rangle |j_2 \oplus f(j_1)\rangle, \quad (8.144)$$

where f is the corresponding classical Boolean function – see the table in Eq. (141).

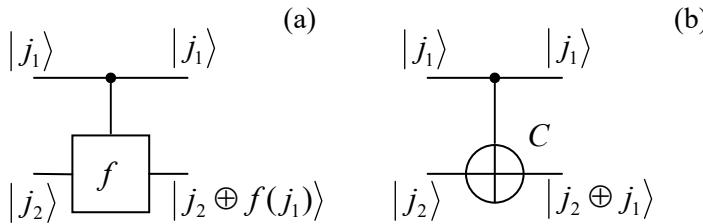

Fig. 8.5. Two-qubit quantum gates: (a) a two-qubit function f and (b) its particular case C (CNOT), and their actions on a basis state.

In the particular case when f in Eq. (144) is just the YES function: $f(j) = f_2(j) = j$, this “circuit” is reduced to the so-called *CNOT gate*, a key ingredient of many other quantum computation schemes, performing the following two-qubit transform:

⁵⁰ Alternatively, we may perform two sequential experiments on the same black box f , first recording, and then recalling the first experiment's result. However, the Deutsch problem calls for a single-shot experiment.

⁵¹ The XOR sign \oplus should not be confused with the sign \otimes of the direct product of state vectors (which in this section is just implied).

$$\hat{C}|j_1 j_2\rangle = |j_1\rangle|j_2 \oplus j_1\rangle.$$

(8.145a) CNOT function

Let us use Eq. (142) to spell out this function for all four possible input qubit combinations:

$$\hat{C}|00\rangle = |00\rangle, \quad \hat{C}|01\rangle = |01\rangle, \quad \hat{C}|10\rangle = |11\rangle, \quad \hat{C}|11\rangle = |10\rangle. \quad (8.145b)$$

In plain English, this means that acting on a basis state $j_1 j_2$, the CNOT gate leaves the state of the first, *source* qubit (shown by the upper horizontal line in Fig. 5) intact, but flips the state of the second, *target* qubit if the first one is in the basis state 1. In even simpler words, the state j_1 of the source qubit controls the NOT function acting on the target qubit; hence the gate's name CNOT – the semi-acronym of “Controlled NOT”.

For the quantum function (144), with an arbitrary and unknown f , the Deutsch problem may be solved within the general scheme shown in Fig. 3, with the particular structure of the unitary-transform box U spelled out in Fig. 4b, which involves just one implementation of the function f . Here the single-qubit quantum gate $\hat{\mathcal{H}}$ performs the *Hadamard* (or “Walsh-Hadamard” or “Walsh”) transform,⁵² whose operator is defined by the following actions on the qubit’s basis states:

$$\hat{\mathcal{H}}|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle), \quad \hat{\mathcal{H}}|1\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle), \quad (8.146) \quad \text{Hadamard transform}$$

- see also the two leftmost state label columns in Fig. 4b.⁵³ Since this operator has to be linear (to be quantum-mechanically realistic), it needs to perform the action (146) on the basis states even when they are parts of a linear superposition – as they are, for example, for the two right Hadamard gates in Fig. 4b. For example, as immediately follows from Eqs. (146) and the operator’s linearity,

$$\hat{\mathcal{H}}(\hat{\mathcal{H}}|0\rangle) = \hat{\mathcal{H}}\left(\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\right) = \frac{1}{\sqrt{2}}\hat{\mathcal{H}}(|0\rangle + \hat{\mathcal{H}}|1\rangle) = \frac{1}{\sqrt{2}}\left(\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) + \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)\right) = |0\rangle. \quad (8.147a)$$

Absolutely similarly, we may get⁵⁴

$$\hat{\mathcal{H}}(\hat{\mathcal{H}}|1\rangle) = |1\rangle. \quad (8.147b)$$

Now let us carry out a sequential analysis of the “circuit” shown in Fig. 4b. Since the input states of the gate f in this particular circuit are described by Eqs. (146), its output state’s ket is

$$\hat{f}(\hat{\mathcal{H}}|0\rangle\hat{\mathcal{H}}|1\rangle) = \hat{f}\left(\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)\right) = \frac{1}{2}(\hat{f}|00\rangle - \hat{f}|01\rangle + \hat{f}|10\rangle - \hat{f}|11\rangle). \quad (8.148)$$

Now we may apply Eq. (144) to each component in the parentheses:

⁵² Named after mathematicians J. Hadamard (1865-1963) and J. Walsh (1895-1973). To avoid any chance of confusion between the Hadamard transform’s operator $\hat{\mathcal{H}}$ and the general Hamiltonian operator \hat{H} , in these notes they are typeset using different fonts.

⁵³ Note that according to Eq. (146), the operator $\hat{\mathcal{H}}$ does *not* belong to the class of transforms \hat{U} described by Eq. (140) – while the whole “circuit” shown in Fig. 4b, does – see below.

⁵⁴ Since the states 0 and 1 form a full basis of a single qubit, both Eqs. (147) may be summarized as an operator equality: $\hat{\mathcal{H}}^2 = \hat{I}$. It is also easy to verify that the Hadamard transform of an arbitrary state may be represented on the Bloch sphere (Fig. 5.3) as a π -rotation about the direction that bisects the angle between the x - and z -axes.

$$\begin{aligned}
\hat{f}|00\rangle - \hat{f}|01\rangle + \hat{f}|10\rangle - \hat{f}|11\rangle &\equiv \hat{f}|0\rangle|0\rangle - \hat{f}|0\rangle|1\rangle + \hat{f}|1\rangle|0\rangle - \hat{f}|1\rangle|1\rangle \\
&= |0\rangle|0 \oplus f(0)\rangle - |0\rangle|1 \oplus f(0)\rangle + |1\rangle|0 \oplus f(1)\rangle - |1\rangle|1 \oplus f(1)\rangle \quad (8.149) \\
&\equiv |0\rangle(|0 \oplus f(0)\rangle - |1 \oplus f(0)\rangle) + |1\rangle(|0 \oplus f(1)\rangle - |1 \oplus f(1)\rangle).
\end{aligned}$$

Note that the contents of the first parentheses of the last expression, characterizing the state of the target qubit, is equal to $(|0\rangle - |1\rangle) \equiv (-1)^0 (|0\rangle - |1\rangle)$ if $f(0) = 0$ (and hence $0 \oplus f(0) = 0$ and $1 \oplus f(0) = 1$), and to $(|1\rangle - |0\rangle) \equiv (-1)^1 (|0\rangle - |1\rangle)$ in the opposite case $f(0) = 1$, so that both cases may be described in one shot by rewriting the parentheses as $(-1)^{f(0)} (|0\rangle - |1\rangle)$. The second parentheses is absolutely similarly controlled by the value of $f(1)$, so that the outputs of the gate f are unentangled:

$$\hat{f}(\hat{\mathcal{H}}|0\rangle\hat{\mathcal{H}}|1\rangle) = \frac{1}{2}((-1)^{f(0)}|0\rangle + (-1)^{f(1)}|1\rangle)(|0\rangle - |1\rangle) = \pm \frac{1}{\sqrt{2}}(|0\rangle + (-1)^F|1\rangle) \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle), \quad (8.150)$$

where the last step has used the fact that the classical Boolean function F , defined by Eq. (142), is equal to $\pm[f(1) - f(0)]$ – please compare the last two columns in Eq. (141). The front sign \pm in Eq. (150) may be prescribed to any of the component ket-vectors – for example to that of the target qubit, as shown by the third column of state labels in Fig. 4b.

This intermediate result is already rather remarkable. Indeed, it shows that, despite the superficial impression one could get from Fig. 5, the gates f and C , being “controlled” by the source qubit, may change that qubit’s state as well! This fact (partly reflected by the vertical direction of the control lines in Figs. 4 and 5, symbolizing the same stage of the system’s time evolution) shows how careful one should be interpreting quantum-computational “circuits”, thriving on qubits’ entanglement, because the “signals” on different sections of a “wire” may differ – see Fig. 4b again.

At the last stage of the circuit shown in Fig. 4b, the qubit components of the state (150) are fed into one more pair of Hadamard gates, whose outputs therefore are

$$\hat{\mathcal{H}} \frac{1}{\sqrt{2}}(|0\rangle + (-1)^F|1\rangle) = \frac{1}{\sqrt{2}}(\hat{\mathcal{H}}|0\rangle + (-1)^F \hat{\mathcal{H}}|1\rangle), \quad \text{and} \quad \hat{\mathcal{H}} \left(\pm \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \right) = \pm \frac{1}{\sqrt{2}}(\hat{\mathcal{H}}|1\rangle - \hat{\mathcal{H}}|0\rangle). \quad (8.151)$$

Now using Eqs. (146) again, we see that the output state ket-vectors of the source and target qubits are, respectively,

$$\frac{1+(-1)^F}{2}|0\rangle + \frac{1-(-1)^F}{2}|1\rangle, \quad \text{and} \quad \pm|1\rangle. \quad (8.152)$$

Since, according to Eq. (142), the Boolean function F may take only values 0 or 1, the final state of the source qubit is always one of its basis states j , namely the one with $j = F$. Its measurement tells us whether the function f , participating in Eq. (144), is constant or balanced – see Eq. (141) again.⁵⁵

Thus, the quantum circuit shown in Fig. 4b indeed solves the Deutsch problem in one shot. Reviewing our analysis, we may see that this is possible because the unitary transform performed by the quantum gate f is applied to the entangled states (146) rather than to the basis states. Due to this trick, the quantum state components depending on $f(0)$ and $f(1)$ are processed simultaneously, in parallel. This

⁵⁵ Note that the last Hadamard transform of the target qubit (i.e. the Hadamard gate shown in the lower right corner of Fig. 4b) is not necessary for the Deutsch problem’s solution – though it should be included if we want the whole circuit to satisfy the condition (140).

quantum parallelism may be extended to circuits with many ($N \gg 1$) qubits and, for some tasks, provide a dramatic performance increase – for example, reducing the necessary circuit component number from $O(2^N)$ to $O(N^p)$, where p is a finite (and not very big) number.

However, this efficiency comes at a high price. Indeed, let us discuss the possible physical implementation of quantum gates, starting from the single-qubit case, on an example of the Hadamard gate (146). With the linearity requirement, its action on the arbitrary state (133) should be

$$\hat{\mathcal{H}}|\alpha\rangle = a_0\hat{\mathcal{H}}|0\rangle + a_1\hat{\mathcal{H}}|1\rangle = a_0 \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) + a_1 \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) = \frac{1}{\sqrt{2}}(a_0 + a_1)|0\rangle + \frac{1}{\sqrt{2}}(a_0 - a_1)|1\rangle, \quad (8.153)$$

meaning that the state probability amplitudes in the end ($t = \mathcal{T}$) and in the beginning ($t = 0$) of the qubit evolution in time have to be related as

$$a_0(\mathcal{T}) = \frac{a_0(0) + a_1(0)}{\sqrt{2}}, \quad a_1(\mathcal{T}) = \frac{a_0(0) - a_1(0)}{\sqrt{2}}. \quad (8.154)$$

This task may be again performed using the Rabi oscillations, which were discussed in Sec. 6.5, i.e. by applying to the qubit (a two-level system), for a limited time period \mathcal{T} , a weak sinusoidal external signal of frequency ω equal to the intrinsic quantum oscillation frequency $\omega_{nn'}$ defined by Eq. (6.85). The analysis of the Rabi oscillations was carried out in Sec. 6.5, even for non-vanishing (though small) detuning $\Delta = \omega - \omega_{nn'}$, but only for the particular initial conditions when at $t = 0$ the system was fully in one on the basis states (there labeled as n'), i.e. the counterpart state (there labeled n) was empty. For our current purposes we need to find the amplitudes $a_{0,1}(t)$ for arbitrary initial conditions $a_{0,1}(0)$, subject only to the time-independent normalization condition $|a_0|^2 + |a_1|^2 = 1$. For the case of exact tuning, $\Delta = 0$, the solution of the system (6.94) is elementary,⁵⁶ and gives the following solution:⁵⁷

$$\begin{aligned} a_0(t) &= a_0(0) \cos \Omega t - i a_1(0) e^{i\varphi} \sin \Omega t, \\ a_1(t) &= a_1(0) \cos \Omega t - i a_0(0) e^{-i\varphi} \sin \Omega t, \end{aligned} \quad (8.155)$$

where Ω is the Rabi oscillation frequency (6.99), in the exact-tuning case proportional to the amplitude $|A|$ of the external ac drive $A = |A|\exp\{i\varphi\}$ – see Eq. (6.86). Comparing these expressions with Eqs. (154), we see that for $t = \mathcal{T} = \pi/4\Omega$ and $\varphi = \pi/2$ they “almost” coincide, besides the opposite sign of $a_1(\mathcal{T})$. Conceptually the simplest way to correct this deficiency is to follow the *ac* “ $\pi/4$ -pulse”, just discussed, by a short *dc* “ π -pulse” of the duration $\mathcal{T} = \pi/\delta$, which temporarily creates a small additional energy difference δ between the basis states 0 and 1. According to the basic Eq. (1.62), such difference creates an additional phase difference $\mathcal{T}\delta/\hbar$ between the states, equal to π for the “ π -pulse”.

Another way (that may be also useful for two-qubit operations) is to use another, auxiliary energy level E_2 whose distances from the basic levels E_1 and E_0 are significantly different from the difference $(E_1 - E_0)$ – see Fig. 6a. In this case, the weak external ac field tuned to any of the three potential quantum transition frequencies $\omega_{nn'} \equiv (E_n - E_{n'})/\hbar$ initiates such transitions between the corresponding states only, with a negligible perturbation of the third state. (Such transitions may be

⁵⁶ An alternative way to analyze the qubit evolution is to use the Bloch equation (5.21), with an appropriate function $\mathbf{Q}(t)$ describing the control field.

⁵⁷ To comply with our current notation, the coefficients $a_{n'}$ and a_n of Sec. 6.5 are replaced with a_0 and a_1 .

again described by Eqs. (155), with the appropriate index changes.) For the Hadamard transform implementation, it is sufficient to apply (after the already discussed $\pi/4$ -pulse of frequency ω_{10} , and with the initially empty level E_2), an additional π -pulse of frequency ω_{20} , with any phase φ . Indeed, according to the first of Eqs. (155), with the due replacement $a_1(0) \rightarrow a_2(0) = 0$, such pulse flips the sign of the amplitude $a_0(t)$, while the amplitude $a_1(t)$, not involved in this additional transition, remains unchanged.

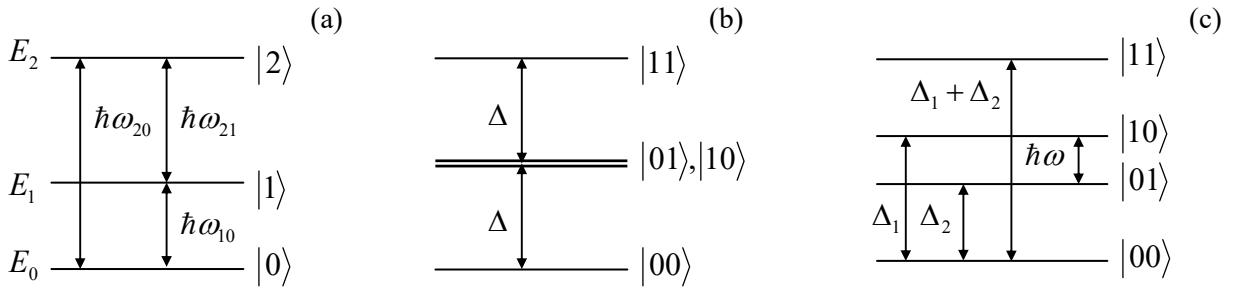

Fig. 8.6. Energy-level schemes used for unitary transformations of (a) single qubits and (b, c) two-qubit systems.

Now let me describe the conceptually simplest (though, for some qubit types, not the most practically convenient) scheme for the implementation of two-qubit gates, on an example of the CNOT gate whose operation is described by Eq. (145). For that, evidently, the involved qubits have to interact for some time \mathcal{T} . As was repeatedly discussed in the two last chapters, in most cases such interaction of two subsystems is factorable – see Eq. (6.145). For qubits, i.e. two-level systems, each of the component operators may be represented by a 2×2 matrix in the basis of states 0 and 1. According to Eq. (4.106), such matrix may be always expressed as a linear combination ($bI + \mathbf{c} \cdot \boldsymbol{\sigma}$), where b and three Cartesian components of the vector \mathbf{c} are c -numbers. Let us consider the simplest form of such factorable interaction Hamiltonian:

$$\hat{H}_{\text{int}}(t) = \begin{cases} \kappa \hat{\sigma}_z^{(1)} \hat{\sigma}_z^{(2)}, & \text{for } 0 < t < \mathcal{T}, \\ 0, & \text{otherwise,} \end{cases} \quad (8.156)$$

where the upper index is the qubit number and κ is a c -number constant.⁵⁸ According to Eq. (4.175), by the end of the interaction period, this Hamiltonian produces the following unitary transform:

$$\hat{U}_{\text{int}} = \exp \left\{ -\frac{i}{\hbar} \hat{H}_{\text{int}} \mathcal{T} \right\} \equiv \exp \left\{ -\frac{i}{\hbar} \kappa \hat{\sigma}_z^{(1)} \hat{\sigma}_z^{(2)} \mathcal{T} \right\}. \quad (8.157)$$

Since in the basis of unperturbed two-bit basis states $|j_1 j_2\rangle$, the product operator $\hat{\sigma}_z^{(1)} \hat{\sigma}_z^{(2)}$ is diagonal, so is the unitary operator (157), with the following action on these states:

⁵⁸ The assumption of simultaneous time independence of the basis state vectors and the interaction operator (within the time interval $0 < t < \mathcal{T}$) is possible only if the basis state energy difference Δ of both qubits is exactly the same. In this case, the simple physical explanation of the time evolution (156) follows from Figs. 6b,c, which show the spectrum of the total energy $E = E_1 + E_2$ of the two-bit system. In the absence of interaction (Fig. 6b), the energies of two basis states, $|01\rangle$ and $|10\rangle$, are equal, enabling even a weak qubit interaction to cause their substantial evolution in time – see Sec. 6.7. If the qubit energies are different (Fig. 6c), the interaction may still be reduced, in the rotating-wave approximation, to Eq. (156), by compensating the energy difference ($\Delta_1 - \Delta_2$) with an external ac signal of frequency $\omega = (\Delta_1 - \Delta_2)/\hbar$ – see Sec. 6.5.

$$\hat{U}_{\text{int}}|j_1 j_2\rangle = \exp\left\{i\theta\sigma_z^{(1)}\sigma_z^{(2)}\right\}|j_1 j_2\rangle, \quad (8.158)$$

where $\theta \equiv -\kappa\mathcal{T}\hbar$, and σ_z are the eigenvalues of the Pauli matrix σ_z for the basis states of the corresponding qubit: $\sigma_z = +1$ for $|j\rangle = |0\rangle$, and $\sigma_z = -1$ for $|j\rangle = |1\rangle$. Let me, for clarity, spell out Eq. (158) for the particular case $\theta = -\pi/4$ (corresponding to the qubit coupling time $\mathcal{T} = \pi\hbar/4\kappa$):

$$\hat{U}_{\text{int}}|00\rangle = e^{-i\pi/4}|00\rangle, \quad \hat{U}_{\text{int}}|01\rangle = e^{i\pi/4}|01\rangle, \quad \hat{U}_{\text{int}}|10\rangle = e^{i\pi/4}|10\rangle, \quad \hat{U}_{\text{int}}|11\rangle = e^{-i\pi/4}|11\rangle. \quad (8.159)$$

In order to compensate the undesirable parts of this joint phase shift of the basis states, let us now apply similar individual “rotations” of each qubit by angle $\theta' = +\pi/4$, using the following product of two independent operators, plus (just for the result’s clarity) a common, and hence inconsequential, phase shift $\theta'' = -\pi/4$:⁵⁹

$$\hat{U}_{\text{com}} = \exp\left\{i\theta'\left(\hat{\sigma}_z^{(1)} + \hat{\sigma}_z^{(2)}\right) + i\theta''\right\} \equiv \exp\left\{i\frac{\pi}{4}\hat{\sigma}_z^{(1)}\right\} \exp\left\{i\frac{\pi}{4}\hat{\sigma}_z^{(2)}\right\} e^{-i\pi/4}. \quad (8.160)$$

Since this operator is also diagonal in the $|j_1 j_2\rangle$ basis, it is easy to calculate the change of the basis states by the total unitary operator $\hat{U}_{\text{tot}} \equiv \hat{U}_{\text{com}} \hat{U}_{\text{int}}$:

$$\hat{U}_{\text{tot}}|00\rangle = |00\rangle, \quad \hat{U}_{\text{tot}}|01\rangle = |01\rangle, \quad \hat{U}_{\text{tot}}|10\rangle = |10\rangle, \quad \hat{U}_{\text{tot}}|11\rangle = -|11\rangle. \quad (8.161)$$

This result already shows the main “miracle action” of two-qubit gates, such as the one shown in Fig. 4b: the source qubit is left intact (only if it is in one of the basis states!), while the state of the target qubit is altered. True, this change (of the sign) is still different from the CNOT operator’s action (145), but may be readily used for its implementation by sandwiching of the transform U_{tot} between two Hadamard transforms of the target qubit alone:

$$\hat{C} = \frac{1}{2}\hat{\mathcal{H}}^{(2)}\hat{U}_{\text{tot}}\hat{\mathcal{H}}^{(2)}. \quad (8.162)$$

So, we have spent quite a bit of time on the discussion of the CNOT gate,⁶⁰ and now I can reward the reader for their effort with a bit of good news: it has been proved that an *arbitrary* unitary transform that satisfies Eq. (140), i.e. may be used within the general scheme outlined in Fig. 3, may be decomposed into a set of CNOT gates, possibly augmented with simpler single-qubit gates – for example, the Hadamard gate plus the $\pi/2$ rotation discussed above.⁶¹ Unfortunately, I have no time for a

⁵⁹ As Eq. (4.175) shows, each of the component unitary transforms $\exp\{i\theta'\hat{\sigma}_z\}$ may be created by applying to each qubit, for time interval $\mathcal{T} = \hbar\theta'/\kappa'$, a constant external field described by Hamiltonian $\hat{H} = -\kappa'\hat{\sigma}_z$. We already know that for a charged, spin-½ particle, such Hamiltonian may be created by applying a z-oriented external dc magnetic field – see Eq. (4.163). For most other physical implementations of qubits, the organization of such a Hamiltonian is also straightforward – see, e.g., Fig. 7.4 and its discussion.

⁶⁰ As was discussed above, this gate is identical to the two-qubit gate shown in Fig. 5a for $f = f_3$, i.e. $f(j) = j$. The implementation of the gate of f for 3 other possible functions f requires straightforward modifications, whose analysis is left for the reader’s exercise.

⁶¹ This fundamental importance of the CNOT gate was perhaps a major reason why David Wineland, the leader of the NIST group that had demonstrated its first experimental implementation in 1995 (following the theoretical suggestion by J. Cirac and P. Zoller), was awarded the 2012 Nobel Prize in Physics – shared with Serge Haroche, the leader of another group working towards quantum computation.

detailed discussion of more complex circuits.⁶² The most famous of them is the scheme for integer number factoring, suggested in 1994 by Peter Winston Shor.⁶³ Due to its potential practical importance for breaking broadly used communication encryption schemes such as the RSA code,⁶⁴ this opportunity has incited much enthusiasm and triggered experimental efforts to implement quantum gates and circuits using a broad variety of two-level quantum systems. By now, the following experimental options have given the most significant results:⁶⁵

(i) Trapped ions. The first experimental demonstrations of quantum state manipulation (including the already mentioned first CNOT gate) have been carried out using deeply cooled atoms in optical traps, similar to those used in frequency and time standards. Their total spins are natural qubits, whose states may be manipulated using the Rabi transfers excited by suitably tuned lasers. The spin interactions with the environment may be very weak, resulting in large dephasing times T_2 – up to a few seconds. Since the distances between ions in the traps are relatively large (of the order of a micron), their direct spin-spin interaction is even weaker, but the ions may be made effectively interacting either via their mechanical oscillations about the potential minima of the trapping field, or via photons in external electromagnetic resonators (“cavities”).⁶⁶ Perhaps the main challenge of using this approach for quantum computation is poor “scalability”, i.e. the enormous experimental difficulty of creating and managing large ordered systems of individually addressable qubits. So far, only a-few-qubit systems have been demonstrated.⁶⁷

(ii) Nuclear spins are also typically very weakly connected to their environment, with dephasing times T_2 exceeding 10 seconds in some cases. Their eigenenergies E_0 and E_1 may be split by external dc magnetic fields (typically, of the order of 10 T), while the interstate Rabi transfers may be readily achieved by using the nuclear magnetic resonance, i.e. the application of external ac fields with frequencies $\omega = (E_1 - E_0)/\hbar$ – typically, of a few hundred MHz. The challenges of this option include the weakness of spin-spin interactions (typically mediated through molecular electrons), resulting in a very slow spin evolution, whose time scale \hbar/κ may become comparable with T_2 , and also very small level separations $E_1 - E_0$, corresponding to a few K, i.e. much smaller than the room temperature, creating a challenge of qubit state preparation.⁶⁸ Despite these challenges, the nuclear spin option was used for the first implementation of the Shor algorithm for factoring of a small number ($15 = 5 \times 3$) as early as 2001.⁶⁹ However, the extension of this success to larger systems, beyond the set of spins inside one molecule, is extremely challenging.

⁶² For that, the reader may be referred to either the monographs by Nielsen-Chuang and Reiffel-Polak, cited above, or to a shorter (but much more formal) textbook by N. Mermin, *Quantum Computer Science*, Cambridge U. Press, 2007.

⁶³ A clear description of this algorithm may be found in several accessible sources, including *Wikipedia* – see the article *Shor's Algorithm*.

⁶⁴ Named after R. Rivest, A. Shamir, and L. Adleman, the authors of the first open publication of the code in 1977, but actually invented earlier (in 1973) by C. Cocks.

⁶⁵ For a discussion of other possible implementations (such as quantum dots and dopants in crystals) see, e.g., T. Ladd *et al.*, *Nature* **464**, 45 (2010), and references therein.

⁶⁶ A brief discussion of such interactions (so-called *Cavity QED*) will be given in Sec. 9.4 below.

⁶⁷ See, e.g., S. Debnath *et al.*, *Nature* **536**, 63 (2016). Note also the related work on arrays of trapped, optically-coupled neutral atoms – see, e.g., J. Perczel *et al.*, *Phys. Rev. Lett.* **119**, 023603 (2017) and references therein.

⁶⁸ This challenge may be partly mitigated using ingenious spin manipulation techniques such as *refocusing* – see, e.g., either Sec. 7.7 in Nielsen and Chuang, or the J. Keeler's monograph cited at the end of Sec. 6.5.

⁶⁹ B. Lanyon *et al.*, *Phys. Rev. Lett.* **99**, 250505 (2001).

(iii) Josephson-junction devices. Much better scalability may be achieved with solid-state devices, especially using superconductor integrated circuits including weak contacts – Josephson junctions (see their brief discussion in Sec. 1.6). The qubits of this type are based on the fact that the energy U of such a junction is a highly nonlinear function of the Josephson phase difference φ – see Sec. 1.6. Indeed, combining Eqs. (1.73) and (1.74), we can readily calculate $U(\varphi)$ as the work \mathcal{W} of an external circuit increasing the phase from, say, zero to some value φ :

$$U(\varphi) - U(0) = \int_{\varphi'=0}^{\varphi'=\varphi} d\mathcal{W} = \int_{\varphi'=0}^{\varphi'=\varphi} IVdt = \frac{2eI_c}{\hbar} \int_{\varphi'=0}^{\varphi'=\varphi} \sin \varphi' \frac{d\varphi'}{dt} dt = \frac{2eI_c}{\hbar} (1 - \cos \varphi). \quad (8.163)$$

There are several options of using this nonlinearity for creating qubits;⁷⁰ currently the leading option, called the *phase qubit*, is using two lowest eigenstates localized in one of the potential wells of the periodic potential (163). A major problem of such qubits is that at the very bottom of this well the potential $U(\varphi)$ is almost quadratic, so that the energy levels are nearly equidistant – cf. Eqs. (2.262), (6.16), and (6.23). This is even more true for the so-called “transmons” (and “Xmons”, and “Gatemons”, and several other very similar devices⁷¹) – the currently used phase qubits versions, where a Josephson junction is made a part of an external electromagnetic oscillator, making its relative total nonlinearity (anharmonism) even smaller. As a result, the external rf drive of frequency $\omega = (E_1 - E_0)/\hbar$, used to arrange the state transforms described by Eq. (155), may induce simultaneous undesirable transitions to (and between) higher energy levels. This effect may be mitigated by a reduction of the ac drive amplitude, but at a price of the proportional increase of the operation time and hence of dephasing – see below. (I am leaving a quantitative estimate of such an increase for the reader’s exercise.)

Since the coupling of Josephson-junction qubits may be most readily controlled (and, very importantly, kept stable if so desired), they have been used to demonstrate the largest prototype quantum computing systems to date, despite quite modest dephasing times T_2 – for purely integrated circuits, in the tens of microseconds at best, even at operating temperatures in tens of mK. By the time of this writing (mid-2019), several groups have announced chips with a few dozen of such qubits, but to the best of my knowledge, only their smaller subsets could be used for high-fidelity quantum operations.⁷²

(iv) Optical systems, attractive because of their inherently enormous bandwidth, pose a special challenge for quantum computation: due to the virtual linearity of most electromagnetic media at reasonable light power, the implementation of qubits (i.e. two-level systems), and interaction Hamiltonians such as the one given by Eq. (156), is problematic. In 2001, a very smart way around this

⁷⁰ The “most quantum” option in this technology is to use Josephson junctions very weakly coupled to their dissipative environment (so that the effective resistance shunting the junction is much higher than the quantum resistance unit $R_Q \equiv (\pi/2) \hbar/e^2 \sim 10^4 \Omega$). In this case, the Josephson phase variable φ behaves as a coordinate of a 1D quantum particle, moving in the 2π -periodic potential (163), forming the energy band structure $E(q)$ similar to those discussed in Sec. 2.7. Both theory and experiment show that in this case, the quantum states in adjacent Brillouin zones differ by the charge of one Cooper pair $2e$. (This is exactly the effect responsible for the Bloch oscillations of frequency (2.252).) These two states may be used as the basis states of *charge qubits*. Unfortunately, such qubits are rather sensitive to charged impurities, randomly located in the junction’s vicinity, causing uncontrollable changes of its parameters, so that currently, to the best of my knowledge, this option is not actively pursued.

⁷¹ For a recent review of these devices see, e.g., G. Wendum, *Repts. Progr. Phys.* **80**, 106001 (2017), and references therein.

⁷² See, e.g., C. Song *et al.*, *Phys. Rev. Lett.* **119**, 180511 (2017) and references therein.

hurdle was invented.⁷³ In this *KLM scheme* (also called the “linear optical quantum computing”), nonlinear elements are not needed at all, and quantum gates may be composed just of linear devices (such as optical waveguides, mirrors, and beam splitters), plus single-photon sources and detectors. However, estimates show that this approach requires a much larger number of physical components than those using nonlinear quantum systems such as usual qubits,⁷⁴ so that right now it is not very popular.

So, despite more than two decades of large-scale efforts, the progress of quantum computing development has been rather modest. The main culprit here is the unintentional coupling of qubits to their environment, leading most importantly to their state dephasing, and eventually to errors. Let me discuss this major issue in detail.

Of course, some error probability exists in classical digital logic gates and memory cells as well.⁷⁵ However, in this case, there is no conceptual problem with the device state measurement, so that the error may be detected and corrected in many ways. Conceptually,⁷⁶ the simplest of them is the so-called *majority voting logic* – using several similar logic circuits working in parallel and fed with identical input data. Evidently, two such devices can detect a single error in one of them, while three devices in parallel may correct such error, by taking two coinciding output signals for the genuine one.

For quantum computation, the general idea of using several devices (say, qubits) for coding the same information remains valid; however, there are two major complications. First, as we know from Chapter 7, the environment’s dephasing effect may be described as a slow random drift of the probability amplitudes a_j , leading to the deviation of the output state α_{fin} from the required form (140), and hence to a non-vanishing probability of wrong qubit state readout – see Fig. 3. Hence the quantum error correction has to protect the result not against possible random state flips $0 \leftrightarrow 1$, as in classical digital computers, but against these “creeping” analog errors.

Second, the qubit state is impossible to copy exactly (*clone*) without disturbing it, as follows from the following simple calculation.⁷⁷ Cloning some state α of one qubit to another qubit that is initially in an independent state (say, the basis state $|0\rangle$), without any change of α , means the following transformation of the two-qubit ket: $|\alpha 0\rangle \rightarrow |\alpha\alpha\rangle$. If we want such transform to be performed by a real quantum system, whose evolution is described by a unitary operator \hat{u} , and to be correct for an arbitrary state α , it has to work not only for both basis states of the qubit:

$$\hat{u}|00\rangle = |00\rangle, \quad \hat{u}|10\rangle = |11\rangle, \quad (8.164)$$

but also for their arbitrary linear combination (133). Since the operator \hat{u} has to be linear, we may use that relation, and then Eq. (164) to write

⁷³ E. Knill *et al.*, *Nature* **409**, 46 (2001).

⁷⁴ See, e.g., Y. Li *et al.*, *Phys. Rev. X* **5**, 041007 (2015).

⁷⁵ In modern integrated circuits, such “soft” (runtime) errors are created mostly by the high-energy neutron component of cosmic rays, and also by the α -particles emitted by radioactive impurities in silicon chips and their packaging.

⁷⁶ Practically, the majority voting logic increases circuit complexity and power consumption, so that it is used only in most critical points. Since in modern digital integrated circuits the bit error rate is very small ($< 10^{-5}$), in most of them, less radical but also less penalizing schemes are used – if used at all.

⁷⁷ Amazingly, this simple *no-cloning theorem* was discovered as late as 1982 (to the best of my knowledge, independently by W. Wootters and W. Zurek, and by D. Dieks), in the context of work toward quantum cryptography – see below.

$$\hat{u}|\alpha 0\rangle \equiv \hat{u}(a_0|0\rangle + a_1|1\rangle)|0\rangle \equiv a_0\hat{u}|00\rangle + a_1\hat{u}|10\rangle = a_0|00\rangle + a_1|11\rangle. \quad (8.165)$$

On the other hand, the desired result of the state cloning is

$$|\alpha\alpha\rangle = (a_0|0\rangle + a_1|1\rangle)(a_0|0\rangle + a_1|1\rangle) \equiv a_0^2|00\rangle + a_0a_1(|10\rangle + |01\rangle) + a_1^2|11\rangle, \quad (8.166)$$

i.e. is evidently different, so that, for an arbitrary state α , and an arbitrary unitary operator \hat{u} ,

$$\hat{u}|\alpha 0\rangle \neq |\alpha\alpha\rangle, \quad \text{No-cloning theorem} \quad (8.167)$$

meaning that the qubit state cloning is indeed impossible.⁷⁸ This problem may be, however, indirectly circumvented – for example, in the way shown in Fig. 7a.

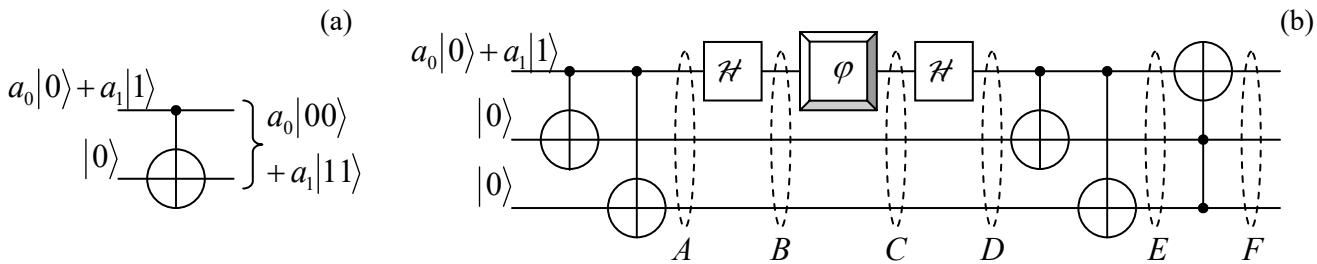

Fig. 8.7. (a) Quasi-cloning, and (b) detection and correction of dephasing errors in a single qubit.

Here the CNOT gate, whose action is described by Eq. (145), entangles an arbitrary input state (133) of the source qubit with a basis initial state of an ancillary target qubit – frequently called the *ancilla*. Using Eq. (145), we can readily calculate the output two-qubit state's vector:

$$|\alpha\rangle_{N=2} = \hat{C}(a_0|0\rangle + a_1|1\rangle)|0\rangle \equiv a_0\hat{C}|00\rangle + a_1\hat{C}|10\rangle = a_0|00\rangle + a_1|11\rangle. \quad \text{Quasi-cloning} \quad (8.168)$$

We see that this circuit does perform the operation (165), i.e. gives the initial source qubit's probability amplitudes a_0 and a_1 equally to two qubits, i.e. duplicates the input information. However, in contrast with the “genuine” cloning, it changes the state of the source qubit as well, making it entangled with the target (ancilla) qubit. Such “quasi-cloning” is the key element of most suggested quantum error correction techniques.

Consider, for example, the three-qubit “circuit” shown in Fig. 7b, which uses two ancilla qubits – see the two lower “wires”. At its first two stages, the double application of the quasi-cloning produces an intermediate state A with the following ket-vector:

$$|A\rangle = a_0|000\rangle + a_1|111\rangle, \quad (8.169)$$

which is an evident generalization of Eq. (168).⁷⁹ Next, subjecting the source qubit to the Hadamard transform (146), we get the three-qubit state B represented by the state vector

⁷⁸ Note that this does not mean that two (or several) qubits cannot be put into the same, arbitrary quantum state – theoretically, with arbitrary precision. Indeed, they may be first set into their lowest-energy stationary states, and then driven into the same arbitrary state (133) by exerting on them similar classical external fields. So, the no-cloning theorem pertains only to qubits in *unknown* states α – but this is exactly what we need for error correction – see below.

$$|B\rangle = a_0 \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)|00\rangle + a_1 \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)|11\rangle. \quad (8.170)$$

Now let us assume that at this stage, the source qubit comes into contact with a dephasing environment – in Fig. 7b, symbolized by the single-qubit “gate” φ . As we know from Chapter 7 (see Eq. (7.22) and its discussion, and also Sec. 7.3), its effect may be described by a random shift of the relative phase of two states:⁸⁰

$$|0\rangle \rightarrow e^{i\varphi}|0\rangle, \quad |1\rangle \rightarrow e^{-i\varphi}|1\rangle. \quad (8.171)$$

As a result, for the intermediate state C (see Fig. 7b) we may write

$$|C\rangle = a_0 \frac{1}{\sqrt{2}}(e^{i\varphi}|0\rangle + e^{-i\varphi}|1\rangle)|00\rangle + a_1 \frac{1}{\sqrt{2}}(e^{i\varphi}|0\rangle - e^{-i\varphi}|1\rangle)|11\rangle. \quad (8.172)$$

At this stage, in this simple theoretical model, the coupling with the environment is completely stopped (ahh, if this could be possible! we might have quantum computers by now :-), and the source qubit is fed into one more Hadamard gate. Using Eqs. (146) again, for the state D after this gate we get

$$|D\rangle = a_0(\cos\varphi|0\rangle + i\sin\varphi|1\rangle)|00\rangle + a_1(i\sin\varphi|0\rangle + \cos\varphi|1\rangle)|11\rangle. \quad (8.173)$$

Now the qubits are passed through the second, similar pair of CNOT gates – see Fig. 7b. Using Eq. (145), for the resulting state E we readily get the following expression:

$$|E\rangle = a_0 \cos\varphi|000\rangle + a_0 i \sin\varphi|111\rangle + a_1 i \sin\varphi|011\rangle + a_1 \cos\varphi|100\rangle, \quad (8.174a)$$

whose right-hand side may be evidently grouped as

$$|E\rangle = (a_0|0\rangle + a_1|1\rangle)\cos\varphi|00\rangle + (a_1|0\rangle + a_0|1\rangle)i\sin\varphi|11\rangle. \quad (8.174b)$$

This is already a rather remarkable result. It shows that if we measured the ancilla qubits at stage E , and both results corresponded to states 0, we might be 100% sure that the source qubit (which is not affected by these measurements!) is in its initial state even after the interaction with the environment. The only result of an increase of this unintentional interaction (as quantified by the r.m.s. magnitude of the random phase shift φ) is the growth of the probability,

$$W = \sin^2 \varphi, \quad (8.175)$$

of getting the opposite result, which signals a dephasing-induced error in the source qubit. Such implicit measurement, without disturbing the source qubit, is called *quantum error detection*.

An even more impressive result may be achieved by the last component of the circuit, the so-called *Toffoli* (or “CCNOT”) gate, denoted by the rightmost symbol in Fig. 7b. This three-qubit gate is conceptually similar to the CNOT gate discussed above, besides that it flips the basis state of its target qubit only if *both* source qubits are in state 1. (In the circuit shown in Fig. 7b, the former role is played

⁷⁹ Such state is also the 3-qubit example of the so-called *Greeenberger-Horne-Zeilinger (GHZ) states*, which are frequently called the “most entangled” states of a system of $N > 2$ qubits.

⁸⁰ Let me emphasize again that Eq. (171) is strictly valid only if the interaction with the environment is a pure dephasing, i.e. does not include the energy relaxation of the qubit or its thermal activation to the higher-energy eigenstate; however, it is a reasonable description of errors in the frequent case when $T_2 \ll T_1$.

by our source qubit, while the latter role, by the two ancilla qubits.) According to its definition, the Toffoli gate does not affect the first parentheses in Eq. (174b), but flips the source qubit's states in the second parentheses, so that for the output three-qubit state F we get

$$|F\rangle = (a_0|0\rangle + a_1|1\rangle) \cos \varphi |00\rangle + (a_0|0\rangle + a_1|1\rangle) i \sin \varphi |11\rangle. \quad (8.176a)$$

Obviously, this result may be factored as

$$|F\rangle = (a_0|0\rangle + a_1|1\rangle)(\cos \varphi |00\rangle + i \sin \varphi |11\rangle), \quad (8.176b)$$

showing that now the source qubit is again fully unentangled from the ancilla qubits. Moreover, calculating the norm squared of the second operand, we get

$$(\cos \varphi |00\rangle - i \sin \varphi |11\rangle)(\cos \varphi |00\rangle + i \sin \varphi |11\rangle) = \cos^2 \varphi + \sin^2 \varphi = 1, \quad (8.177)$$

so that the final state of the source qubit *exactly* coincides with its initial state. This is the famous miracle of *quantum state correction*, taking place “automatically” – without any qubit measurements, and for any random phase shift φ .

The circuit shown in Fig. 7b may be further improved by adding Hadamard gate pairs, similar to that used for the source qubit, to the ancilla qubits as well. It is straightforward to show that if the dephasing is small in the sense that the W given by Eq. (175) is much less than 1, this modified circuit may provide a substantial error probability reduction (to $\sim W^2$) even if the ancilla qubits are also subjected to a similar dephasing and the source qubits, at the same stage – i.e. between the two Hadamard gates. Such perfect automatic correction of *any* error (not only of an inner dephasing of a qubit and its relaxation/excitation, but also of the mutual dephasing between qubits) of *any* used qubit needs even more parallelism. The first circuit of that kind, based on nine parallel qubits, which is a natural generalization of the circuit discussed above, was invented in 1995 by the same P. Shor. Later, five-qubit circuits enabling similar error correction were suggested. (The further parallelism reduction has been proved impossible.)

However, all these results assume that the error correction circuits as such are perfect, i.e. completely isolated from the environment. In the real world, this cannot be done. Now the key question is what maximum level W_{\max} of the error probability in each gate (including those in the used error correction scheme) can be automatically corrected, and how many qubits with $W < W_{\max}$ would be required to implement quantum computers producing important practical results – first of all, factoring of large numbers.⁸¹ To the best of my knowledge, estimates of these two related numbers have been made only for some very specific approaches, and they are rather pessimistic. For example, using the so-called *surface codes*, which employ many physical qubits for coding an informational one, and hence increase its fidelity, W_{\min} may be increased to a few times 10^{-3} , but then we would need $\sim 10^8$ physical qubits for the Shor’s algorithm implementation.⁸² This is very far from what currently looks doable using the existing approaches.

Because of this hard situation, the current development of quantum computing is focused on finding at least *some* problems that could be within the reach of either the existing systems, or their immediate extensions, and simultaneously would present some practical interest – a typical example of a

Quantum
error
correction

⁸¹ In order to compete with the existing classical factoring algorithms, such numbers should have at least 10^3 bits.

⁸² A. Fowler *et al.*, *Phys. Rev. A* **86**, 032324 (2012).

technology in the search for applications. Currently, to the best of my knowledge, all suggested problems of this kind address either specially crafted mathematical problems,⁸³ or properties of some simple physical systems – such as the molecular hydrogen⁸⁴ or the deuteron (the deuterium’s nucleus, i.e. the proton-neutron system).⁸⁵ In the latter case, the interaction between the qubits of the computational system is organized so that the system’s Hamiltonian is similar to that of the quantum system of interest. (For this work, *quantum simulation* is a more adequate name than “quantum computation”.)⁸⁶

Such simulations are pursued by some teams using schemes different from that shown in Fig. 3. Of those, the most developed is the so-called *adiabatic quantum computation*,⁸⁷ which drops the hardest requirement of negligible interaction with the environment. In this approach, the qubit system is first prepared in a certain initial state, and then is let evolve on its own, with no effort to couple-uncouple qubits by external control signals during the evolution.⁸⁸ Due to the interaction with the environment, in particular the dephasing and the energy dissipation it imposes, the system eventually relaxes to a final incoherent state, which is then measured. (This reminds the scheme shown in Fig. 3, with the important difference that the transform U should not necessarily be unitary.) From numerous runs of such an experiment, the outcome statistics may be revealed. Thus, at this approach the interaction with the environment is allowed to play a certain role in the system evolution, though every effort is made to reduce it, thus slowing down the relaxation process – hence the word “adiabatic” in the name of this approach. This slowness allows the system to exhibit *some* quantum properties, in particular quantum tunneling⁸⁹ *through* the energy barriers separating close energy minima in the multi-dimensional space of states. This tunneling creates a substantial difference in the finite state statistics from that in purely classical systems, where such barriers may be overcome only by thermally-activated jumps *over* them.⁹⁰

Due to technical difficulties of the organization and precise control of long-range interaction in multi-qubit systems, the adiabatic quantum computing demonstrations so far have been limited to a few simple arrays described by the so-called *extended quantum Ising* (“spin-glass”) model

$$\hat{H} = -J \sum_{\{j,j'\}} \hat{\sigma}_z^{(j)} \hat{\sigma}_z^{(j')} - \sum_j h_j \hat{\sigma}_z^{(j)}, \quad (8.178)$$

where the curly brackets denote the summation over pairs of close (though not necessarily closest) neighbors. Though the Hamiltonian (178) is the traditional playground of phase transitions theory (see,

⁸³ F. Arute *et al.*, *Nature* **574**, 505 (2019). Note that the claim of the first achievement of “quantum supremacy”, made in this paper, refers only to an artificial, specially crafted mathematical problem, and does not change my assessment of the current status of this technology.

⁸⁴ P. O’Malley *et al.*, *Phys. Rev. X* **6**, 031007 (2016).

⁸⁵ E. Dumitrescu *et al.*, *Phys. Lett. Lett.* **120**, 210501 (2018).

⁸⁶ To the best of my knowledge, this idea was first put forward by Yuri I. Malin in his book *Computable and Incomputable* published in 1980, i.e. before the famous 1982 paper by Richard Feynman. Unfortunately, since the book was in Russian, this suggestion was acknowledged by the international community only much later.

⁸⁷ Note that the qualifier “quantum” is important in this term, to distinguish this research direction from the *classical* adiabatic (or “reversible”) computation – see, e.g., SM Sec. 2.3 and references therein.

⁸⁸ Recently, some hybrids of this approach with the “usual” scheme of quantum computation have been demonstrated, in particular, using some control of inter-bit coupling during the relaxation process – see, e.g., R. Barends *et al.*, *Nature* **534**, 222 (2016).

⁸⁹ As a reminder, this process was repeatedly discussed in this course, starting from Sec. 2.3.

⁹⁰ A quantitative discussion of such jumps may be found in SM Sec. 5.6.

e.g., SM Chapter 4), to the best of my knowledge there are not many practically important tasks that could be achieved by studying the statistics of its solutions. Moreover, even for this limited task, the speed of the largest experimental adiabatic quantum “computers”, with several hundreds of Josephson-junction qubits⁹¹ is still comparable with that of classical, off-the-shelf semiconductor processors (with the dollar cost lower by many orders of magnitude), and no dramatic change of this comparison is predicted for realistic larger systems.

To summarize the current (circa mid-2019) situation with the quantum computation development, it faces a very hard challenge of mitigating the effects of unintentional coupling with the environment. This problem is exacerbated by the lack of algorithms, beyond Shor’s factoring, that would give quantum computation a substantial advantage over the classical competition in solving real-world problems, and hence a much broader potential customer base that would provide the field with the necessary long-term motivation and resources. So far, even the leading experts in this field abstain from predictions on when quantum computation may become a self-supporting commercial technology.⁹²

There seem to be somewhat better prospects for another application of entangled qubit systems, namely to telecommunication cryptography.⁹³ The goal here is more modest: to replace the currently dominating classical encryption, based on the public-key RSA code mentioned above, that may be broken by factoring very large numbers, with a quantum encryption system that would be fundamentally unbreakable. The basis of this opportunity is the measurement postulate and the no-cloning theorem: if a message is carried over by a qubit, it is impossible for an eavesdropper (in cryptography, traditionally called *Eve*) to either measure or copy it faithfully, without also disturbing its state. However, as we have seen from the discussion of Fig. 7a, state *quasi*-cloning using entangled qubits is possible, so that the issue is far from being simple, especially if we want to use a publicly distributed quantum key, in some sense similar to the classical public key used at the RSA encryption. Unfortunately, I would not have time/space to discuss various options for quantum encryption, but cannot help demonstrating how counter-intuitive they may be, on the famous example of the so-called *quantum teleportation* (Fig. 8).⁹⁴

Suppose that some party A (in cryptography, traditionally called *Alice*) wants to send to party B (*Bob*) the full information about the pure quantum state α of a qubit, unknown to either party. Instead of sending her qubit directly to Bob, Alice asks *him* to send *her* one qubit (β) of a pair of other qubits, prepared in a certain entangled state, for example in the singlet state described by Eq. (11); in our current notation

$$|\beta\beta'\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle). \quad (8.179)$$

The initial state of the whole three-qubit system may be represented in the form

⁹¹ See, e.g., R. Harris *et al.*, *Science* **361**, 162 (2018). Similar demonstrations with trapped-ion systems so far have been on a smaller scale, with a few tens of qubits – see, e.g., J. Zhang *et al.*, *Nature* **551**, 601 (2017).

⁹² See the publication *Quantum Computing: Progress and Prospects*, The National Academies Press, 2019.

⁹³ This field was pioneered in the 1970s by S. Wiesner. Its important theoretical aspect (which I, unfortunately, also will not be able to cover) is the distinguishability of different but close quantum states – for example, of an original qubit set, and that slightly corrupted by noise. A good introduction to this topic may be found, for example, in Chapter 9 of the monograph by Nielsen and Chuang, cited above.

⁹⁴ This procedure had been first suggested in 1993 by Charles Henry Bennett, and then repeatedly demonstrated experimentally – see, e.g., L. Steffen *et al.*, *Nature* **500**, 319 (2013), and literature therein.

$$|\alpha\beta\beta'\rangle = (a_0|0\rangle + a_1|1\rangle)|\beta\beta'\rangle = \frac{a_0}{\sqrt{2}}|001\rangle - \frac{a_0}{\sqrt{2}}|010\rangle + \frac{a_1}{\sqrt{2}}|010\rangle - \frac{a_1}{\sqrt{2}}|111\rangle, \quad (8.180a)$$

which may be equivalently rewritten as the following linear superposition,

$$\begin{aligned} |\alpha\beta\beta'\rangle &= \frac{1}{2}|\alpha\beta\rangle_s^+(-a_1|0\rangle + a_0|1\rangle) + \frac{1}{2}|\alpha\beta\rangle_s^- (a_1|0\rangle + a_0|1\rangle) \\ &\quad + \frac{1}{2}|\alpha\beta\rangle_e^+(-a_0|0\rangle + a_1|1\rangle) + \frac{1}{2}|\alpha\beta\rangle_e^- (-a_0|0\rangle - a_1|1\rangle), \end{aligned} \quad (8.180b)$$

of the following four states of the qubit pair $\alpha\beta$:

$$|\alpha\beta\rangle_s^\pm \equiv \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle), \quad |\alpha\beta\rangle_e^\pm \equiv \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle). \quad (8.181)$$

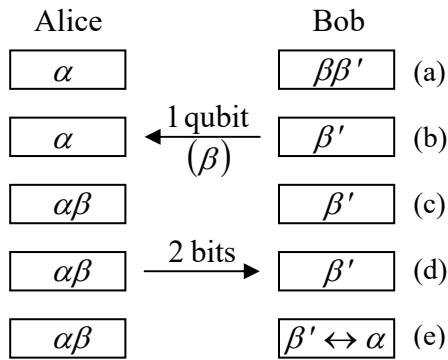

Fig. 8.8. Sequential stages of a “quantum teleportation” procedure: (a) the initial state with entangled qubits β and β' , (b) the back transfer of the qubit β , (c) the measurement of the pair $\alpha\beta$, (d) the forward transfer of two classical bits with the measurement results, and (e) the final state, with the state of the qubit β' mirroring the initial state of the qubit α .

After having received qubit β from Bob, Alice measures which of these four states does the pair $\alpha\beta$ have. This may be achieved, for example, by measurement of one observable represented by the operator $\hat{\sigma}_z^{(\alpha)}\hat{\sigma}_z^{(\beta)}$ and another one corresponding to $\hat{\sigma}_x^{(\alpha)}\hat{\sigma}_x^{(\beta)}$ – cf. Eq. (156). (Since all four states (181) are eigenstates of both these operators, these two measurements do not affect each other and may be performed in any order.) The measured eigenvalue of the former operator enables distinguishing the couples of states (181) with different values of the lower index, while the latter measurement distinguishes the states with different upper indices.

Then Alice reports the measurement result (which may be coded with just two classical bits) to Bob over a classical communication channel. Since the measurement places the pair $\alpha\beta$ *definitely* into the corresponding state, the remaining Bob’s bit β' is now *definitely* in the unentangled single-qubit state that is represented by the corresponding parentheses in Eq. (180b). Note that each of these parentheses contains both coefficients $a_{0,1}$, i.e. the whole information about the initial state that the qubit α had initially. If Bob likes, he may now use appropriate single-qubit operations, similar to those discussed earlier in this section, to move his qubit β' into the state *exactly* similar to the initial state of qubit α . (This fact does not violate the no-cloning theorem (167), because the measurement has already changed the state of α .) This is, of course, a “teleportation” only in a very special sense of this term, but a good example of the importance of qubit entanglement’s preservation at their spatial transfer. For this course, this was also a good primer for the forthcoming discussion of the *EPR paradox* and *Bell’s inequalities* in Chapter 10.

Returning for just a minute to quantum cryptography: since its most common quantum key distribution protocols⁹⁵ require just a few simple quantum gates, whose experimental implementation is not a large technological challenge, the main focus of the current effort is on decreasing the single-photon dephasing in long electromagnetic-wave transmission channels,⁹⁶ with sufficiently high qubit transfer fidelity. The recent progress was rather impressive, with the demonstrated transfer of entangled qubits over landlines longer than 100 km,⁹⁷ and over at least one satellite-based line longer than 1,000 km;⁹⁸ and also the whole quantum key distribution over a comparable distance, though for now at a very low rate yet.⁹⁹ Let me hope that if not the author of this course, then its readers will see this technology used in practical secure telecommunication systems.

8.6. Exercise problems

8.1. Prove that Eq. (30) indeed yields $E_g^{(1)} = (5/4)E_H$.

8.2. For a dilute gas of helium atoms in their ground state, with n atoms per unit volume, calculate its:

- (i) electric susceptibility χ_e , and
- (ii) magnetic susceptibility χ_m ,

and compare the results.

Hint: You may use the model solution of Problems 6.8 and 6.14, and the results of the variational description of the helium atom's ground state in Sec. 2.

8.3. Calculate the expectation values of the following observables: $\mathbf{s}_1 \cdot \mathbf{s}_2$, $S^2 \equiv (\mathbf{s}_1 + \mathbf{s}_2)^2$, and $S_z \equiv s_{1z} + s_{2z}$, for the singlet and triplet states of the system of two spins- $1/2$, defined by Eqs. (18) and (21), directly, without using the general Eq. (48). Compare the results with those for the system of two classical geometric vectors of length $\hbar/2$ each.

8.4. Discuss the factors $\pm 1/\sqrt{2}$ that participate in Eqs. (18) and (20) for the entangled states of the system of two spins- $1/2$, in terms of Clebsch-Gordan coefficients similar to those discussed in Sec. 5.7.

8.5.* Use the perturbation theory to calculate the contribution into the so-called *hyperfine splitting* of the ground energy of the hydrogen atom,¹⁰⁰ due to the interaction between the spins of its nucleus (proton) and electron.

⁹⁵ Two of them are the BB84 suggested in 1984 by C. Bennett and G. Brassard, and the EPRBE suggested in 1991 by A. Ekert. For details, see, e.g., either Sec. 12.6 in the repeatedly cited monograph by Nielsen and Chuang, or the review by N. Gisin *et al.*, *Rev. Mod. Phys.* **74**, 145 (2002).

⁹⁶ For their quantitative discussion see, e.g., EM Sec. 7.8.

⁹⁷ See, e.g., T. Herbst *et al.*, *Proc. Natl. Acad. Sci.* **112**, 14202 (2015), and references therein.

⁹⁸ J. Yin *et al.*, *Science* **356**, 1140 (2017).

⁹⁹ H.-L. Yin *et al.*, *Phys. Rev. Lett.* **117**, 190501 (2016).

¹⁰⁰ This effect was discovered experimentally by A. Michelson in 1881 and explained theoretically by W. Pauli in 1924.

Hint: The proton's magnetic moment operator is described by the same Eq. (4.115) as the electron, but with a positive gyromagnetic factor $\gamma_p = g_p e / 2m_p \approx 2.675 \times 10^8 \text{ s}^{-1}\text{T}^{-1}$, whose magnitude is much smaller than that of the electron ($|\gamma_e| \approx 1.761 \times 10^{11} \text{ s}^{-1}\text{T}^{-1}$), due to the much higher mass, $m_p \approx 1.673 \times 10^{-27} \text{ kg} \approx 1,835 m_e$. (The *g*-factor of the proton is also different, $g_p \approx 5.586$.¹⁰¹)

8.6. In the simple case of just two similar spin-interacting particles, distinguishable by their spatial location, the famous *Heisenberg model* of ferromagnetism¹⁰² is reduced to the following Hamiltonian:

$$H = -J \hat{\mathbf{s}}_1 \cdot \hat{\mathbf{s}}_2 - \gamma \mathcal{B} \cdot (\hat{\mathbf{s}}_1 + \hat{\mathbf{s}}_2),$$

where J is the spin interaction constant, γ is the gyromagnetic ratio of each particle, and \mathcal{B} is the external magnetic field. Find the stationary states and energies of this system for spin- $\frac{1}{2}$ particles.

8.7. Two particles, both with spin- $\frac{1}{2}$ but different gyromagnetic ratios γ_1 and γ_2 , are placed to external magnetic field \mathcal{B} . In addition, their spins interact as in the Heisenberg model:

$$\hat{H}_{\text{int}} = -J \hat{\mathbf{s}}_1 \cdot \hat{\mathbf{s}}_2.$$

Find the eigenstates and eigenenergies of the system.

8.8. Two similar spin- $\frac{1}{2}$ particles, with gyromagnetic ratio γ , localized at two points separated by distance a , interact via the field of their magnetic dipole moments. Calculate stationary states and energies of the system.

8.9. Consider the permutation of two identical particles, each of spin s . How many different symmetric and antisymmetric spin states can the system have?

8.10. For a system of two identical particles with $s = 1$:

- (i) List all spin states forming the uncoupled-representation basis.
- (ii) List all possible pairs $\{S, M_S\}$ of the quantum numbers describing the states of the coupled-representation basis – see Eq. (48).
- (iii) Which of the $\{S, M_S\}$ pairs describe the states symmetric, and which the states antisymmetric, with respect to the particle permutation?

8.11. Represent the operators of the total kinetic energy and the total orbital angular momentum of a system of two particles, with masses m_1 and m_2 , as combinations of terms describing the center-of-mass motion and the relative motion. Use the results to calculate the energy spectrum of the so-called

¹⁰¹ The anomalously large value of the proton's *g*-factor results from the composite quark-gluon structure of this particle. (An exact calculation of g_p remains a challenge for quantum chromodynamics.)

¹⁰² It was suggested in 1926, independently by W. Heisenberg and P. Dirac. A discussion of thermal motion effects on this and other similar systems (especially the Ising model of ferromagnetism) may be found in SM Chapter 4.

positronium – a metastable “atom”¹⁰³ consisting of one electron and its positively charged antiparticle, the positron.

8.12. Two particles with similar masses m and charges q are free to move along a round, plane ring of radius R . In the limit of strong Coulomb interaction of the particles, find the lowest eigenenergies of the system, and sketch the system of its energy levels. Discuss possible effects of particle indistinguishability.

8.13. Low-energy spectra of many diatomic molecules may be well described by modeling the molecule as a system of two particles connected with a light and elastic, but very stiff spring. Calculate the energy spectrum of a molecule within this model. Discuss possible effects of nuclear spins on spectra of the so-called *homonuclear* diatomic molecules, formed by two similar atoms.

8.14. Two indistinguishable spin- $\frac{1}{2}$ particles are attracting each other at contact:

$$U(x_1, x_2) = -w\delta(x_1 - x_2), \quad \text{with } w > 0,$$

but are otherwise free to move along the x -axis. Find the energy and the orbital wavefunction of the ground state of the system.

8.15. Calculate the energy spectrum of the system of two identical spin- $\frac{1}{2}$ particles, moving along the x -axis, which is described by the following Hamiltonian:

$$\hat{H} = \frac{\hat{p}_1^2}{2m_0} + \frac{\hat{p}_2^2}{2m_0} + \frac{m_0\omega_0^2}{2}(x_1^2 + x_2^2 + \alpha x_1 x_2),$$

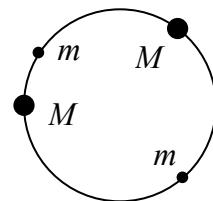

and the degeneracy of each energy level.

8.16.* Two indistinguishable spin- $\frac{1}{2}$ particles are confined to move around a circle of radius R , and interact only at a very short arc distance $l = R\varphi \equiv R(\varphi_1 - \varphi_2)$ between them, so that the interaction potential U may be well approximated with a delta function of φ . Find the ground state and its energy, for the following two cases:

- (i) the “orbital” (spin-independent) repulsion: $\hat{U} = w\delta(\varphi)$,
- (ii) the spin-spin interaction: $\hat{U} = -w\hat{\mathbf{s}}_1 \cdot \hat{\mathbf{s}}_2\delta(\varphi)$,

both with constant $w > 0$. Analyze the trends of your results in the limits $w \rightarrow 0$ and $w \rightarrow \infty$.

8.17. Two particles of mass M , separated by two much lighter particles of mass $m \ll M$, are placed on a ring of radius R – see the figure on the right. The particles strongly repulse at contact, but otherwise, each of them is free to move along the ring. Calculate the lower part of the energy spectrum of the system.

¹⁰³ Its lifetime (either 0.124 ns or 138 ns, depending on the parallel or antiparallel configuration of the component spins), is limited by the weak interaction of its components, which causes their annihilation with the emission of several gamma-ray photons.

8.18. N indistinguishable spin- $\frac{1}{2}$ particles move in a spherically-symmetric quadratic potential $U(\mathbf{r}) = m\omega_0^2 r^2/2$. Neglecting the direct interaction of the particles, find the ground-state energy of the system.

8.19. Use the Hund rules to find the values of the quantum numbers L , S , and J in the ground states of the atoms of carbon and nitrogen. Write down the Russell-Saunders symbols for these states.

8.20. $N \gg 1$ indistinguishable, non-interacting quantum particles are placed in a hard-wall, rectangular box with sides a_x , a_y , and a_z . Calculate the ground-state energy of the system, and the average forces it exerts on each face of the box. Can we characterize the forces by certain pressure P ?

Hint: Consider separately the cases of bosons and fermions.

8.21.* Explore the *Thomas-Fermi model*¹⁰⁴ of a heavy atom, with the nuclear charge $Q = Ze \gg e$, in which the interaction between electrons is limited to their contribution to the common electrostatic potential $\phi(\mathbf{r})$. In particular, derive the ordinary differential equation obeyed by the radial distribution of the potential, and use it to estimate the effective radius of the atom.

8.22.* Use the Thomas-Fermi model, explored in the previous problem, to calculate the total binding energy of a heavy atom. Compare the result with that for the simpler model, in that the Coulomb electron-electron interaction is completely ignored.

8.23. A system of three similar spin- $\frac{1}{2}$ particles is described by the Heisenberg Hamiltonian (cf. Problems 6 and 7):

$$\hat{H} = -J(\hat{\mathbf{s}}_1 \cdot \hat{\mathbf{s}}_2 + \hat{\mathbf{s}}_2 \cdot \hat{\mathbf{s}}_3 + \hat{\mathbf{s}}_3 \cdot \hat{\mathbf{s}}_1),$$

where J is the spin interaction constant. Find the stationary states and energies of this system, and give an interpretation of your results.

8.24. For a system of three spins- $\frac{1}{2}$, find the common eigenstates and eigenvalues of the operators \hat{S}_z and \hat{S}^2 , where

$$\hat{\mathbf{S}} \equiv \hat{\mathbf{s}}_1 + \hat{\mathbf{s}}_2 + \hat{\mathbf{s}}_3$$

is the vector operator of the total spin of the system. Do the corresponding quantum numbers S and M_S obey Eqs. (48)?

8.25. Explore basic properties of the Heisenberg model (which was the subject of Problems 6, 7, and 23), for a 1D chain of N spins- $\frac{1}{2}$:

$$\hat{H} = -J \sum_{\{j,j'\}} \hat{\mathbf{s}}_j \cdot \hat{\mathbf{s}}_{j'} - \gamma \mathcal{B} \cdot \sum_j \hat{\mathbf{s}}_j, \quad \text{with } J > 0,$$

where the summation is over all N spins, with the symbol $\{j,j'\}$ meaning that the first sum is only over the adjacent spin pairs. In particular, find the ground state of the system and its lowest excited states in the absence of external magnetic field \mathcal{B} , and also the dependence of their energies on the field.

¹⁰⁴ It was suggested in 1927, independently, by L. Thomas and E. Fermi.

Hint: For the sake of simplicity, you may assume that the first sum includes the term $\hat{\mathbf{s}}_N \cdot \hat{\mathbf{s}}_1$ as well. (Physically, this means that the chain is bent into a closed loop.¹⁰⁵)

8.26. Compose the simplest model Hamiltonians, in terms of the second quantization formalism, for systems of indistinguishable particles moving in the following external potentials:

- (i) two weakly coupled potential wells, with on-site particle interactions (giving additional energy J per each pair of particles in the same potential well), and
- (ii) a periodic 1D potential, with the same particle interactions, in the tight-binding limit.

8.27. For each of the Hamiltonians composed in the previous problem, derive the Heisenberg equations of motion for particle creation/annihilation operators:

- (i) for bosons, and
- (ii) for fermions.

8.28. Express the ket-vectors of all possible Dirac states for the system of three indistinguishable

- (i) bosons, and
- (ii) fermions,

via those of the single-particle states β , β' , and β'' they occupy.

8.29. Explain why the general perturbative result (8.126), when applied to the ${}^4\text{He}$ atom, gives the correct¹⁰⁶ expression (8.29) for the ground singlet state, and correct Eqs. (8.39)-(8.42) (with the minus sign in the first of these relations) for the excited triplet states, but cannot describe these results, with the plus sign in Eq. (8.39), for the excited singlet state.

8.30. For a system of two distinct qubits (i.e. two-level systems), introduce a reasonable uncoupled-representation z -basis, and write in this basis the 4×4 matrix of the operator that swaps their states.

8.31. Find a time-independent Hamiltonian that can cause the qubit evolution described by Eqs. (155). Discuss the relation between your result and the time-dependent Hamiltonian (6.86).

¹⁰⁵ Note that for dissipative spin systems, differences between low-energy excitations of open-end and closed-end 1D chains may be substantial even in the limit $N \rightarrow \infty$ – see, e.g., SM Sec. 4.5. However, for our Hamiltonian (and hence dissipation-free) system, the differences are relatively small.

¹⁰⁶ Correct in the sense of the first order of the perturbation theory.

Chapter 9. Introduction to Relativistic Quantum Mechanics

The brief introduction to relativistic quantum mechanics, presented in this chapter, consists of two very different parts. Its first part is a discussion of the basic elements of the quantum theory of the electromagnetic field (usually called quantum electrodynamics, QED), including the field quantization scheme, photon statistics, radiative atomic transitions, the spontaneous and stimulated radiation, and so-called cavity QED. We will see, in particular, that the QED may be considered as the relativistic quantum theory of particles with zero rest mass – photons. The second part of the chapter is a brief review of the relativistic quantum theory of particles with non-zero rest mass, including the Dirac theory of spin-½ particles. These theories mark the point of entry into a more complete relativistic quantum theory – the quantum field theory – which is beyond the scope of this course.¹

9.1. Electromagnetic field quantization²

Classical physics gives us³ the following general relativistic relation between the momentum \mathbf{p} and energy E of a free particle with rest mass m , which may be simplified in two limits – non-relativistic and ultra-relativistic:

$$E = \left[(pc)^2 + (mc^2)^2 \right]^{1/2} \rightarrow \begin{cases} mc^2 + p^2 / 2m, & \text{for } p \ll mc, \\ pc, & \text{for } p \gg mc. \end{cases} \quad (9.1)$$

Free
particle's
relativistic
energy

In both limits, the transfer from classical to quantum mechanics is easier than in the arbitrary case. Since all the previous part of this course was committed to the first, non-relativistic limit, I will now jump to a brief discussion of the ultra-relativistic limit $p \gg mc$, for a particular but very important system – the electromagnetic field. Since the excitations of this field, called *photons*, are currently believed to have zero rest mass m ,⁴ the ultra-relativistic relation $E = pc$ is exactly valid for any photon energy E , and the quantization scheme is rather straightforward.

As usual, the quantization has to be based on the classical theory of the system – in this case, the Maxwell equations. As the simplest case, let us consider the electromagnetic field inside a finite free-space volume limited by ideal walls, which reflect incident waves perfectly.⁵ Inside the volume, the Maxwell equations give a simple wave equation⁶ for the electric field

$$\nabla^2 \mathcal{E} - \frac{1}{c^2} \frac{\partial^2 \mathcal{E}}{\partial t^2} = 0, \quad (9.2)$$

¹ Note that some material covered in this chapter is frequently taught as a part of the quantum field theory. I will focus on the most important results that may be obtained without starting the heavy engines of that theory.

² The described approach was pioneered by the same P. A. M. Dirac as early as 1927.

³ See, e.g., EM Chapter 9.

⁴ By now this fact has been verified experimentally with an accuracy of at least $\sim 10^{-22} m_e$ – see S. Eidelman *et al.*, *Phys. Lett. B* **592**, 1 (2004).

⁵ In the case of finite energy absorption in the walls, or in the wave propagation media (say, described by complex constants ϵ and μ), the system is not energy-conserving (Hamiltonian), i.e. interacts with some dissipative environment. Specific cases of such interaction will be considered in Sections 2 and 3 below.

⁶ See, e.g., EM Eq. (7.3), for the particular case $\epsilon = \epsilon_0$, $\mu = \mu_0$, so that $v^2 \equiv 1/\epsilon\mu = 1/\epsilon_0\mu_0 \equiv c^2$.

and an absolutely similar equation for the magnetic field \mathcal{B} . We may look for the general solution of Eq. (2) in the variable-separating form

$$\mathcal{E}(\mathbf{r}, t) = \sum_j p_j(t) \mathbf{e}_j(\mathbf{r}). \quad (9.3)$$

Physically, each term of this sum is a standing wave whose spatial distribution and polarization (“mode”) are described by the vector function $\mathbf{e}_j(\mathbf{r})$, while the temporal dynamics, by the function $p_j(t)$. Plugging an arbitrary term of this sum into Eq. (2), and separating the variables exactly as we did, for example, in the Schrödinger equation in Sec. 1.5, we get

$$\frac{\nabla^2 \mathbf{e}_j}{\mathbf{e}_j} = \frac{1}{c^2} \frac{\ddot{p}_j}{p_j} = \text{const} \equiv -k_j^2, \quad (9.4)$$

so that the spatial distribution of the mode satisfies the 3D Helmholtz equation:

$$\boxed{\nabla^2 \mathbf{e}_j + k_j^2 \mathbf{e}_j = 0.} \quad (9.5)$$

Equation
for spatial
distribution

The set of solutions of this equation, with appropriate boundary conditions, determines the set of the functions \mathbf{e}_j , and simultaneously the spectrum of the wave number magnitudes k_j . The latter values determine the mode eigenfrequencies, following from Eq. (4):

$$\ddot{p}_j + \omega_j^2 p_j = 0, \quad \text{with } \omega_j \equiv k_j c. \quad (9.6)$$

There is a big philosophical difference between the quantum-mechanical approach to Eqs. (5) and (6), despite their single origin (4). The first (Helmholtz) equation may be rather difficult to solve in realistic geometries,⁷ but it remains intact in the basic quantum electrodynamics, with the scalar components of the vector functions $\mathbf{e}_j(\mathbf{r})$ still treated (at each point \mathbf{r}) as c -numbers. In contrast, the classical Eq. (6) is readily solvable (giving sinusoidal oscillations with frequency ω_j), but this is exactly where we can make the transfer to quantum mechanics, because we already know how to quantize a mechanical 1D harmonic oscillator, which in classics obeys the same equation.

As usual, we need to start with the appropriate Hamiltonian – the operator corresponding to the classical Hamiltonian function H of the proper set of generalized coordinates and momenta. The electromagnetic field’s Hamiltonian function (which in this case coincides with the field’s energy) is⁸

$$H = \int d^3 r \left(\frac{\epsilon_0 \mathcal{E}^2}{2} + \frac{\mathcal{B}^2}{2\mu_0} \right). \quad (9.7)$$

Let us represent the magnetic field in a form similar to Eq. (3),⁹

⁷ See, e.g., various problems discussed in EM Chapter 7, especially in Sec. 7.9.

⁸ See, e.g., EM Sec. 9.8, in particular, Eq. (9.225). Here I am using SI units, with $\epsilon_0 \mu_0 \equiv c^2$; in the Gaussian units, the coefficients ϵ_0 and μ_0 disappear, but there is an additional common factor $1/4\pi$ in the equation for energy. However, if we modify the normalization conditions (see below) accordingly, all the subsequent results, starting from Eq. (10), look similar in any system of units.

⁹ Here I am using the letter q_j instead of x_j , for the generalized coordinate of the field oscillator, in order to emphasize the difference between the former variable, and one of the Cartesian coordinates, i.e. one of the arguments of the c -number functions \mathbf{e} and \mathbf{b} .

$$\mathcal{B}(\mathbf{r}, t) = -\sum_j \omega_j q_j(t) \mathbf{b}_j(\mathbf{r}). \quad (9.8)$$

Since, according to the Maxwell equations, in our case the magnetic field satisfies the equation similar to Eq. (2), the time-dependent amplitude q_j of each of its modes $\mathbf{b}_j(\mathbf{r})$ obeys an equation similar to Eq. (6), i.e. in the classical theory also changes in time sinusoidally, with the same frequency ω_j . Plugging Eqs. (3) and (8) into Eq. (7), we may recast it as

$$H = \sum_j \left[\frac{p_j^2}{2} \int \epsilon_0 e_j^2(\mathbf{r}) d^3 r + \frac{\omega_j^2 q_j^2}{2} \int \frac{1}{\mu_0} b_j^2(\mathbf{r}) d^3 r \right]. \quad (9.9)$$

Since the distribution of constant factors between two multiplication operands in each term of Eq. (3) is so far arbitrary, we may fix it by requiring the first integral in Eq. (9) to equal 1. It is straightforward to check that according to the Maxwell equations, which give a specific relation between vectors \mathcal{E} and \mathcal{B} ,¹⁰ this normalization makes the second integral in Eq. (9) equal 1 as well, and Eq. (9) becomes

$$H = \sum_j H_j, \quad H_j = \frac{p_j^2}{2} + \frac{\omega_j^2 q_j^2}{2}. \quad (9.10a)$$

Note that that p_j is the legitimate generalized momentum corresponding to the generalized coordinate q_j , because it is equal to $\partial L / \partial \dot{q}_j$, where L is the Lagrangian function of the field – see EM Eq. (9.217):

$$L = \int d^3 r \left(\frac{\epsilon_0 \mathcal{E}^2}{2} - \frac{\mathcal{B}^2}{2 \mu_0} \right) = \sum_j L_j, \quad L_j = \frac{p_j^2}{2} - \frac{\omega_j^2 q_j^2}{2}. \quad (9.10b)$$

Hence we can carry out the standard quantization procedure, namely declare H_j , p_j , and q_j the quantum-mechanical operators related exactly as in Eq. (10a),

$$\hat{H}_j = \frac{\hat{p}_j^2}{2} + \frac{\omega_j^2 \hat{q}_j^2}{2}. \quad (9.11)$$

Electro-
magnetic
mode's
Hamiltonian

We see that this Hamiltonian coincides with that of a 1D harmonic oscillator with the mass m_j formally equal to 1,¹¹ and the eigenfrequency equal to ω_j . However, in order to use Eq. (11) in the general Eq. (4.199) for the time evolution of Heisenberg-picture operators \hat{p}_j and \hat{q}_j , we need to know the commutation relation between these operators. To find them, let us calculate the Poisson bracket (4.204) for the functions $A = q_{j'}$ and $B = p_{j''}$, taking into account that in the classical Hamiltonian mechanics, all generalized coordinates q_j and the corresponding momenta p_j have to be considered independent arguments of H , only one term (with $j = j' = j''$) in only one of the sums (12) (namely, with $j' = j''$), gives a non-zero value (-1), so that

$$\{q_{j'}, p_{j''}\}_P \equiv \sum_j \left(\frac{\partial q_{j'}}{\partial p_j} \frac{\partial p_{j''}}{\partial q_j} - \frac{\partial q_{j'}}{\partial q_j} \frac{\partial p_{j''}}{\partial p_j} \right) = -\delta_{jj''}. \quad (9.12)$$

Hence, according to the general quantization rule (4.205), the commutation relation of the operators corresponding to $q_{j'}$ and $p_{j''}$ is

¹⁰ See, e.g., EM Eq. (7.6).

¹¹ Selecting a different normalization of the functions $\mathbf{e}_j(\mathbf{r})$ and $\mathbf{b}_j(\mathbf{r})$, we could readily arrange any value of m_j , and the choice corresponding to $m_j = 1$ is the best one just for the notation simplicity.

$$[\hat{q}_{j'}, \hat{p}_{j''}] = i\hbar\delta_{jj''}, \quad (9.13)$$

i.e. is exactly the same as for the usual Cartesian components of the radius-vector and momentum of a mechanical particle – see Eq. (2.14).

As the reader already knows, Eqs. (11) and (13) open for us several alternative ways to proceed:

(i) Use the Schrödinger-picture wave mechanics based on wavefunctions $\Psi_j(q_j, t)$. As we know from Sec. 2.9, this way is inconvenient for most tasks, because the eigenfunctions of the harmonic oscillator are rather clumsy.

(ii) A substantially better way (for the harmonic oscillator case) is to write the equations of the time evolution of the operators $\hat{q}_j(t)$ and $\hat{p}_j(t)$ in the Heisenberg picture of quantum dynamics.

(iii) An even more convenient approach is to use equations similar to Eqs. (5.65) to decompose the Heisenberg operators $\hat{q}_j(t)$ and $\hat{p}_j(t)$ into the creation-annihilation operators $\hat{a}_j^\dagger(t)$ and $\hat{a}_j(t)$, and work with these operators.

In this chapter, I will mostly use the last route. Replacing m with $m_j \equiv 1$, and ω_0 with ω_j , the last forms of Eqs. (5.65) become

$$\hat{a}_j = \left(\frac{\omega_j}{2\hbar} \right)^{1/2} \left(\hat{q}_j + i \frac{\hat{p}_j}{\omega_j} \right), \quad \hat{a}_j^\dagger = \left(\frac{\omega_j}{2\hbar} \right)^{1/2} \left(\hat{q}_j - i \frac{\hat{p}_j}{\omega_j} \right). \quad (9.14)$$

Due to Eq. (13), the creation-annihilation operators obey the commutation similar to Eq. (5.68),

$$[\hat{a}_j, \hat{a}_{j'}^\dagger] = \hat{I}\delta_{jj'}. \quad (9.15)$$

As a result, according to Eqs. (3) and (8), the quantum-mechanical operators of the electric and magnetic fields are sums over all *field oscillators*:

$$\hat{\mathcal{E}}(\mathbf{r}, t) = i \sum_j \left(\frac{\hbar\omega_j}{2} \right)^{1/2} \mathbf{e}_j(\mathbf{r}) \left(\hat{a}_j^\dagger - \hat{a}_j \right), \quad (9.16a)$$

$$\hat{\mathcal{B}}(\mathbf{r}, t) = \sum_j \left(\frac{\hbar\omega_j}{2} \right)^{1/2} \mathbf{b}_j(\mathbf{r}) \left(\hat{a}_j^\dagger + \hat{a}_j \right), \quad (9.16b)$$

Electro-magnetic fields' operators

and Eq. (11) for the j^{th} mode's Hamiltonian becomes

$$\hat{H}_j = \hbar\omega_j \left(\hat{a}_j^\dagger \hat{a}_j + \frac{1}{2} \hat{I} \right) = \hbar\omega_j \left(\hat{n}_j + \frac{1}{2} \hat{I} \right), \quad \text{with } \hat{n}_j \equiv \hat{a}_j^\dagger \hat{a}_j, \quad (9.17)$$

absolutely similar to Eq. (5.72) for a mechanical oscillator.

Now comes a very important conceptual step. From Sec. 5.4 we know that the eigenfunctions (Fock states) n_j of the Hamiltonian (17) have energies

$$E_j = \hbar\omega_j \left(n_j + \frac{1}{2} \right), \quad n_j = 0, 1, 2, \dots \quad (9.18)$$

Electro-magnetic mode's eigen-energies

and, according to Eq. (5.89), the operators \hat{a}_j^\dagger and \hat{a}_j act on the eigenkets of these partial states as

$$\hat{a}_j |n_j\rangle = (n_j)^{1/2} |n_j - 1\rangle, \quad \hat{a}_j^\dagger |n_j\rangle = (n_j + 1)^{1/2} |n_j + 1\rangle, \quad (9.19)$$

regardless of the quantum states of other modes. These rules coincide with the definitions (8.64) and (8.68) of bosonic creation-annihilation operators, and hence their action may be considered as the creation/annihilation of certain bosons. Such a “particle” (actually, an *excitation*, with energy $\hbar\omega_j$, of an electromagnetic field oscillator) is exactly what is, strictly speaking, called a *photon*. Note immediately that according to Eq. (16), such an excitation does not change the spatial distribution of the j^{th} mode of the field. So, such a “global” photon is an excitation created simultaneously at all points of the field confinement region.

If this picture is too contrary to the intuitive image of a particle, please recall that in Chapter 2, we discussed a similar situation with the fundamental solutions of the Schrödinger equation of a free non-relativistic particle: they represent sinusoidal de Broglie waves existing simultaneously in all points of the particle confinement region. The (partial :-) reconciliation with the classical picture of a moving particle might be obtained by using the linear superposition principle to assemble a quasi-localized wave packet, as a group of sinusoidal waves with close wave numbers. Very similarly, we may form a similar wave packet using a linear superposition of the “global” photons with close values of \mathbf{k}_j (and hence ω_j), to form a quasi-localized photon. An additional simplification here is that the dispersion relation for electromagnetic waves (at least in free space) is linear:

$$\frac{\partial\omega_j}{\partial k_j} = c = \text{const}, \quad \text{i.e. } \frac{\partial^2\omega_j}{\partial k_j^2} = 0, \quad (9.20)$$

so that, according to Eq. (2.39a), the electromagnetic wave packets (i.e. space-localized photons) do not spread out during their propagation. Note also that due to the fundamental classical relations $\mathbf{p} = \mathbf{n}E/c$ for the linear momentum of the traveling electromagnetic wave packet of energy E , propagating along the direction $\mathbf{n} \equiv \mathbf{k}/k$, and $\mathbf{L} = \pm\mathbf{n}E/\omega_j$ for its angular momentum,¹² such photon may be prescribed the linear momentum $\mathbf{p} = \mathbf{n}\hbar\omega_j/c \equiv \hbar\mathbf{k}$ and the angular momentum $\mathbf{L} = \pm\mathbf{n}\hbar$, with the sign depending on the direction of its circular polarization (“helicity”).

This electromagnetic field quantization scheme should look very straightforward, but it raises an important conceptual issue of the ground state energy. Indeed, Eq. (18) implies that the total ground-state (i.e., the lowest) energy of the field is

$$E_g = \sum_j (E_g)_j = \sum_j \frac{\hbar\omega_j}{2}. \quad (9.21)$$

Ground-state energy of EM field

Since for any realistic model of the field-confining volume, either infinite or not, the density of electromagnetic field modes only grows with frequency,¹³ this sum diverges on its upper limit, leading to infinite ground-state energy per unit volume. This infinite-energy paradox cannot be dismissed by declaring the ground-state energy of field oscillators unobservable, because this would contradict numerous experimental observations – starting perhaps from the famous *Casimir effect*.¹⁴ The

¹² See, e.g., EM Sections 7.7 and 9.8.

¹³ See, e.g., Eq. (1.1), which is similar to Eq. (1.90) for the de Broglie waves, derived in Sec. 1.7.

¹⁴ This effect was predicted in 1948 by Hendrik Casimir and Dirk Polder, and confirmed semi-quantitatively in experiments by M. Spaarnay, *Nature* **180**, 334 (1957). After this, and several other experiments, a decisive error bar reduction (to about $\sim 5\%$), providing a quantitative confirmation of the Casimir formula (23), was achieved by

conceptually simplest implementation of this effect involves two parallel, perfectly conducting plates of area A , separated by a vacuum gap of thickness $t \ll A^{1/2}$ (Fig. 1).

Fig. 9.1. The simplest geometry of the Casimir effect manifestation.

Rather counter-intuitively, the plates attract each other with a force F proportional to the area A and rapidly increasing with the decrease of t , even in the absence of any explicit electromagnetic field sources. The effect's explanation is that the energy of each electromagnetic field mode, including its ground-state energy, exerts average pressure,

$$\langle \mathcal{P}_j \rangle = -\frac{\partial E_j}{\partial V}, \quad (9.22)$$

on the walls constraining it to volume V . While the field's pressure on the external surfaces on the plates is due to the contributions (22) of all free-space modes, with arbitrary values of k_z (the z -component of the wave vector \mathbf{k}_j), in the gap between the plates the spectrum of k_z is limited to the multiples of π/t , so that the pressure on the internal surfaces is lower. This is why the net force exerted on the plates may be calculated as the sum of the contributions (22) from all "missing" low-frequency modes in the gap, with the minus sign. In the simplest model when the plates are made of an ideal conductor, which provides boundary conditions $\mathcal{E}_\tau = \mathcal{B}_n = 0$ on their surfaces,¹⁵ such calculation is quite straightforward (and is hence left for the reader's exercise), and its result is

$$F = -\frac{\pi^2 A \hbar c}{240 t^4}. \quad (9.23)$$

Casimir
effect

Note that for such calculation, the high-frequency divergence of Eq. (21) is not important, because it participates in the forces exerted on all surfaces of each plate, and cancels out from the net pressure. In this way, the Casimir effect not only confirms Eq. (21), but also teaches us an important lesson on how to deal with the divergences of such sums at $\omega_j \rightarrow \infty$. The lesson is: just get accustomed to the idea that the divergence exists, and ignore this fact while you can, i.e. if the final result you are interested in is finite. However, for some more complex problems of quantum electrodynamics (and the

S. Lamoreaux, *Phys. Rev. Lett.* **78**, 5 (1997) and by U. Mohideen and A. Roy, *Phys. Rev. Lett.* **81**, 004549 (1998). Note also that there are other experimental confirmations of the reality of the ground-state electromagnetic field, including, for example, the experiments by R. Koch *et al.* already discussed in Sec. 7.5, and the recent spectacular direct observations by C. Riek *et al.*, *Science* **350**, 420 (2015).

¹⁵ For realistic conductors, the reduction of t below $\sim 1 \mu\text{m}$ causes significant deviations from this simple model, and hence from Eq. (23). The reason is that for gaps so narrow, the depth of field penetration into the conductors (see, e.g., EM Sec. 6.2), at the important frequencies $\omega \sim c/t$, becomes comparable with t , and an adequate theory of the Casimir effect has to involve a certain model of the penetration. (It is curious that in-depth analyses of this problem, pioneered in 1956 by E. Lifshitz, have revealed a deep relation between the Casimir effect and the London dispersion force which was the subject of Problems 3.16, 5.15, and 6.18 – for a review see, e.g., either I. Dzhalyoshinskii *et al.*, *Sov. Phys. Uspekhi* **4**, 153 (1961), or K. Milton, *The Casimir Effect*, World Scientific, 2001. Recent experiments in the $100 \text{ nm} - 2 \mu\text{m}$ range of t , with an accuracy better than 1%, have allowed not only to observe the effects of field penetration on the Casimir force, but even to make a selection between some approximate models of the penetration – see D. Garcia-Sanchez *et al.*, *Phys. Rev. Lett.* **109**, 027202 (2012)).

quantum theory of any other fields), this simplest approach becomes impossible, and then more complex, *renormalization* techniques become necessary. For their study, I have to refer the reader to a quantum field theory course – see the references at the end of this chapter.

9.2. Photon absorption and counting

As a matter of principle, the Casimir effect may be used to measure quantum effects in not only the free-space electromagnetic field but also that the field arriving from active sources – lasers, etc. However, usually such studies may be done by simpler detectors, in which the absorption of a photon by a single atom leads to its ionization. This ionization, i.e. the emission of a free electron, triggers an avalanche reaction (e.g., an electric discharge in a Geiger-type counter), which may be readily registered using appropriate electronic circuitry. In good photon counters, the first step, the “trigger” atom ionization, is the bottleneck of the whole process (the *photon count*), so that to analyze their statistics, it is sufficient to consider the field’s interaction with just this atom.

Its ionization is a quantum transition from a discrete initial state of the atom to its final, ionized state with a continuous energy spectrum, induced by an external electromagnetic field. This is exactly the situation shown in Fig. 6.12, so we may apply to it the Golden Rule of quantum mechanics in the form (6.149), with the system *a* associated with the electromagnetic field, and system *b* with the trigger atom. The atom’s size is typically much smaller than the radiation wavelength, so that the field-atom interaction may be adequately described in the electric dipole approximation (6.146)

$$\hat{H}_{\text{int}} = -\hat{\mathcal{E}} \cdot \hat{\mathbf{d}}, \quad (9.24)$$

where $\hat{\mathbf{d}}$ is the dipole moment’s operator. Hence we may associate this operator with the operand \hat{B} in Eqs. (6.145)-(6.149), while the electric field operator $\hat{\mathcal{E}}$ is associated with the operand \hat{A} in those relations. First, let us assume that our field consists of only one mode $\mathbf{e}_j(\mathbf{r})$ of frequency ω . Then we can keep only one term in the sum (16a), and drop the index *j*, so that Eq. (6.149) may be rewritten as

$$\begin{aligned} \Gamma &= \frac{2\pi}{\hbar} \left| \langle \text{fin} | \hat{\mathcal{E}}(\mathbf{r}, t) | \text{ini} \rangle \right|^2 \left| \langle \text{fin} | \hat{\mathbf{d}}(t) \cdot \mathbf{n}_e | \text{ini} \rangle \right|^2 \rho_a \\ &= \frac{2\pi}{\hbar} \frac{\hbar\omega}{2} \left| \langle \text{fin} | [\hat{a}^\dagger(t) - \hat{a}(t)] \mathbf{e}(\mathbf{r}) | \text{ini} \rangle \right|^2 \left| \langle \text{fin} | \hat{\mathbf{d}}(t) \cdot \mathbf{n}_e | \text{ini} \rangle \right|^2 \rho_a, \end{aligned} \quad (9.25)$$

where $\mathbf{n}_e \equiv \mathbf{e}(\mathbf{r})/e(\mathbf{r})$ is the local direction of the vector $\mathbf{e}(\mathbf{r})$, symbols “ini” and “fin” denote the initial and final states of the corresponding system (the electromagnetic field in the first long bracket, and the atom in the second bracket), and the density ρ_a of the continuous atomic states should be calculated at its final energy $E_{\text{fin}} = E_{\text{ini}} + \hbar\omega$.

As a reminder, in the Heisenberg picture of quantum dynamics, the initial and final states are time-independent, while the creation-annihilation operators are functions of time. In the Golden Rule formula (25), as in any perturbative result, this time dependence has to be calculated ignoring the perturbation – in this case, the field-atom interaction. For the field’s creation-annihilation operators, this dependence coincides with that of the usual 1D oscillator – see Eq. (5.141), in which ω_0 should be, in our current notation, replaced with ω :

$$\hat{a}(t) = \hat{a}(0)e^{-i\omega t}, \quad \hat{a}^\dagger(t) = \hat{a}^\dagger(0)e^{+i\omega t}. \quad (9.26)$$

Hence Eq. (25) becomes

$$\Gamma = \pi\omega \left| \left\langle \text{fin} \left[\hat{a}^\dagger(0)e^{i\omega t} - \hat{a}(0)e^{-i\omega t} \right] e(\mathbf{r}) \right| \text{ini} \right\rangle^2 \left| \left\langle \text{fin} |\hat{\mathbf{d}}(t) \cdot \mathbf{n}_e| \right| \text{ini} \right\rangle^2 \rho_a. \quad (9.27a)$$

Now let us multiply the first long bracket by $\exp\{i\omega t\}$, and the second one by $\exp\{-i\omega t\}$:

$$\Gamma = \pi\omega \left| \left\langle \text{fin} \left[\hat{a}^\dagger(0)e^{2i\omega t} - \hat{a}(0) \right] e(\mathbf{r}) \right| \text{ini} \right\rangle^2 \left| \left\langle \text{fin} |\hat{\mathbf{d}}(t) \cdot \mathbf{n}_e e^{-i\omega t}| \right| \text{ini} \right\rangle^2 \rho_a. \quad (9.27b)$$

This, mathematically equivalent form of the previous relation shows more clearly that at resonant photon absorption, only the *annihilation* operator gives a significant time-averaged contribution to the first bracket matrix element. (As a reminder, the quantum-mechanical Golden Rule for time-dependent perturbations is a result of averaging over a time interval much larger than $1/\omega$ – see Sec. 6.6.) Similarly, according to Eq. (4.199), the Heisenberg operator of the dipole moment, corresponding to the *increase* of atom's energy by $\hbar\omega$, has the Fourier components that differ in frequency from ω only by $\sim\Gamma \ll \omega$, so that its time dependence virtually compensates the additional factor in the second bracket of Eq. (27b), and this bracket also may have a substantial time average. Hence, in the first bracket we may neglect the fast-oscillating term, whose average over time interval $\sim 1/\Gamma$ is very close to zero.¹⁶

Now let us assume, first, that we use the same detector, characterized by the same matrix element of the quantum transition, i.e. the same second bracket in Eq. (27), and the same final state density ρ_a , for measurement of various electromagnetic fields – or just of the same field at different points \mathbf{r} . Then we are only interested in the behavior of the first, field-related bracket, and may write

$$\Gamma \propto \left| \left\langle \text{fin} |\hat{a}e(\mathbf{r})| \text{ini} \right\rangle \right|^2 \equiv \left\langle \text{fin} |\hat{a}e(\mathbf{r})| \text{ini} \right\rangle \left\langle \text{fin} |\hat{a}e(\mathbf{r})| \text{ini} \right\rangle^* \equiv \left\langle \text{ini} |\hat{a}^\dagger e^*(\mathbf{r})| \text{fin} \right\rangle \left\langle \text{fin} |\hat{a}e(\mathbf{r})| \text{ini} \right\rangle, \quad (9.28)$$

where the creation-annihilation operators are implied to be taken at $t = 0$, i.e. in the Schrödinger picture, and the initial and final states are those of the field alone. Second, let us now calculate the *total* rate of transitions to *all* available final states of the given mode $e(\mathbf{r})$. If such states formed a full and orthonormal set, we could use the closure relation (4.44), applied to the final states, to write

$$\Gamma \propto \sum_{\text{fin}} \left\langle \text{ini} |\hat{a}^\dagger e^*(\mathbf{r})| \text{fin} \right\rangle \left\langle \text{fin} |\hat{a}e(\mathbf{r})| \text{ini} \right\rangle = \left\langle \text{ini} |\hat{a}^\dagger \hat{a}| \text{ini} \right\rangle e^*(\mathbf{r}) e(\mathbf{r}) = \langle n \rangle_{\text{ini}} |e(\mathbf{r})|^2, \quad (9.29)$$

Photon
counting
rate

where, for a given field mode, $\langle n \rangle_{\text{ini}}$ is the expectation value of the operator $\hat{n} \equiv \hat{a}^\dagger \hat{a}$ for the initial state of the electromagnetic field. In the more realistic case of fields in relatively large volumes, $V \gg \lambda^3$, with their virtually continuous spectrum of final states, the middle equality in this relation is not strictly valid, but it is correct to a constant multiplier,¹⁷ which we are currently not interested in. Note, however, that Eq. (29) may be substantially wrong for high- Q electromagnetic resonators (“cavities”), which may make just one (or a few) modes available for transitions. (Quantum electrodynamics of such cavities will be briefly discussed in Sec. 4 below.)

Let us apply Eq. (29) to several possible quantum states of the mode.

¹⁶ This is essentially the same rotating wave approximation (RWA), which was already used in Sec. 6.5 and beyond – see, e.g., the transition from Eq. (6.90) to the first of Eqs. (6.94).

¹⁷ As the Golden Rule shows, this multiplier is proportional to the density ρ_f of the final states of the field.

(i) First, as a sanity check, the ground initial state, $n = 0$, gives no photon absorption at all. The interpretation is easy: the ground state field, cannot emit a photon that would ionize an atom in the counter. Again, this does not mean that the ground-state “motion” is not observable (if you still think so, please review the Casimir effect discussion in Sec. 1), just that it cannot ionize the trigger atom – because it does not have any *spare* energy for doing that.

(ii) All other coherent states (Fock, Glauber, squeezed, etc.) of the field oscillator give the same counting rate, provided that their $\langle n \rangle_{\text{ini}}$ is the same. This result may be less evident if we apply Eq. (29) to the interference of two light beams from the same source – say, in the double-slit or the Bragg-scattering configurations. In this case, we may represent the spatial distribution of the field as a sum

$$e(\mathbf{r}) = e_1(\mathbf{r}) + e_2(\mathbf{r}). \quad (9.30)$$

Here each term describes one possible wave path, so that the operator product in Eq. (29) may be a rapidly changing function of the detector position. For this configuration, our result (29) means that the interference pattern (and its contrast) are independent of the particular state of the electromagnetic field’s mode.

(iii) Surprisingly, the last statement is also valid for a classical mixture of the different eigenstates of the same field mode, for example for its thermal-equilibrium state. Indeed, in this case we need to average Eq. (29) over the corresponding classical ensemble, but it would only result in a different meaning of averaging n in that equation; the field part describing the interference pattern is not affected.

The last result may look a bit counter-intuitive because common sense tells us that the stochasticity associated with thermal equilibrium has to suppress the interference pattern contrast. These expectations are (partly :-) justified because a typical thermal source of radiation produces many field modes j , rather than one mode we have analyzed. These modes may have different wave numbers k_j and hence different field distribution functions $e_j(\mathbf{r})$, resulting in shifted interference patterns. Their summation would indeed smear the interference, suppressing its contrast.

So the use of one photon detector is not the best way to distinguish different quantum states of an electromagnetic field mode. This task, however, may be achieved using the photon counting correlation technique shown in Fig. 2.¹⁸

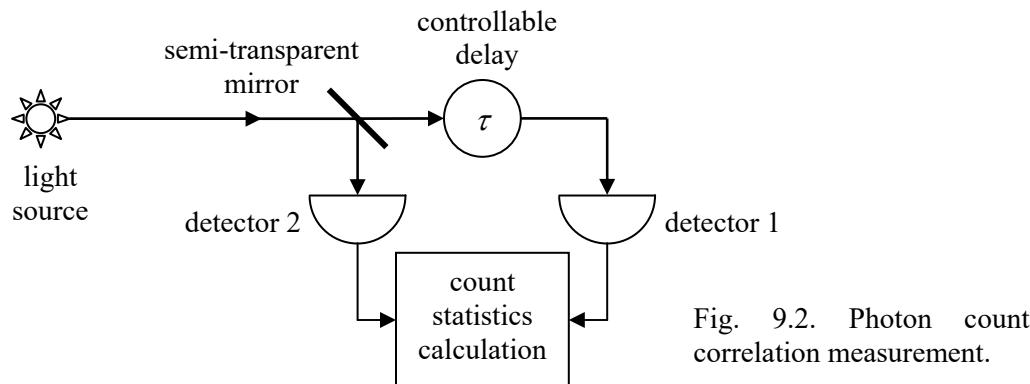

Fig. 9.2. Photon count correlation measurement.

¹⁸ It was pioneered as early as the mid-1950s (i.e. before the advent of lasers), by Robert Hanbury Brown and Richard Twiss. Their second experiment was also remarkable for the rather unusual light source – the star Sirius! (Their work was an effort to improve astrophysics interferometry techniques.)

In this experiment, the counter rate correlation may be characterized by the so-called *second-order correlation function* of the counting rates,

$$g^{(2)}(\tau) \equiv \frac{\langle \Gamma_1(t)\Gamma_2(t-\tau) \rangle}{\langle \Gamma_1(t) \rangle \langle \Gamma_2(t) \rangle}, \quad (9.31)$$

Second-order correlation function

where the averaging may be carried out either over many similar experiments, or over a relatively long time interval $t \gg \tau$, with usual field sources – due to their ergodicity. Using the normalized correlation function (31) is very convenient because the characteristics of both detectors and the beam splitter (e.g., a semi-transparent mirror, see Fig. 2) drop out from this fraction.

Very unexpectedly for the mid-1950s, Hanbury Brown and Twiss discovered that the correlation function depends on time delay τ in the way shown (schematically) with the solid line in Fig. 3. It is evident from Eq. (31) that if the counting events are completely independent, $g^{(2)}(\tau)$ should be equal to 1 – which is always the case in the limit $\tau \rightarrow \infty$. (As will be shown in the next section, the characteristic time of this approach is usually between 10^{-11} s and 10^{-8} s, so that for its measurement, the delay time control may be provided just by moving one of the detectors by a human-scale distance between a few millimeters to a few meters.) Hence, the observed behavior at $\tau \rightarrow 0$ corresponds to a *positive* correlation of detector counts at small time delays, i.e. to a *higher* probability of the nearly simultaneous arrival of photons to both counters. This counter-intuitive effect is called *photon bunching*.

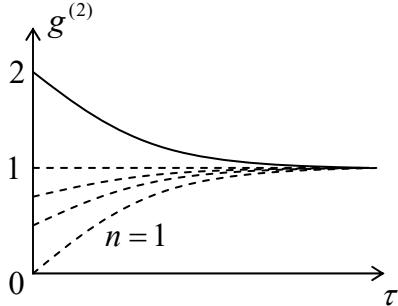

Fig. 9.3. Photon bunching (solid line) and antibunching for various n (dashed lines). The lines approach level $g^{(2)} = 1$ at $\tau \rightarrow \infty$ (on the time scale depending on the light source).

Let us use our simple single-mode model to analyze this experiment. Now the elementary quantum process characterized by the numerator of Eq. (31), is the correlated, simultaneous ionization of two trigger atoms, at two spatial-temporal points $\{\mathbf{r}_1, t\}$ and $\{\mathbf{r}_2, t - \tau\}$, by the same field mode, so that we need to make the following replacement in the first of Eqs. (25):

$$\hat{\mathcal{E}}(\mathbf{r}, t) \rightarrow \text{const} \times \hat{\mathcal{E}}(\mathbf{r}_1, t) \hat{\mathcal{E}}^*(\mathbf{r}_2, t - \tau). \quad (9.32)$$

Repeating all the manipulations done above for the single-counter case, we get

$$\langle \Gamma_1(t)\Gamma_2(t-\tau) \rangle \propto \langle \text{ini} | \hat{a}(t)^\dagger \hat{a}(t-\tau)^\dagger \hat{a}(t-\tau) \hat{a}(t) | \text{ini} \rangle e^*(\mathbf{r}_1) e^*(\mathbf{r}_2) e(\mathbf{r}_1) e(\mathbf{r}_2). \quad (9.33)$$

Plugging this expression, as well as Eq. (29) for single-counter rates, into Eq. (31), we see that the field distribution factors (as well as the detector-specific brackets and the density of states ρ_a) cancel, giving a very simple final expression:

$$g^{(2)}(\tau) = \frac{\langle \hat{a}^\dagger(t) \hat{a}^\dagger(t-\tau) \hat{a}(t-\tau) \hat{a}(t) \rangle}{\langle \hat{a}^\dagger(t) \hat{a}(t) \rangle^2}, \quad (9.34)$$

where the averaging should be carried out, as before, over the initial state of the field.

Still, the calculation of this expression for arbitrary τ may be quite complex, because in many cases the relaxation of the correlation function to the asymptotic value $g^{(2)}(\infty)$ is due to the interaction of the light source with the environment, and hence requires the open-system techniques that were discussed in Chapter 7. However, the zero-delay value $g^{(2)}(0)$ may be calculated straightforwardly, because the time arguments of all operators are equal, so that we may write

Zero-delay correlation

$$g^{(2)}(0) = \frac{\langle \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \rangle}{\langle \hat{a}^\dagger \hat{a} \rangle^2}. \quad (9.35)$$

Let us evaluate this ratio for the simplest states of the field.

(i) The n^{th} Fock state. In this case, it is convenient to act with the annihilation operators upon the ket-vectors, and by the creation operators, upon the bra-vectors, using Eqs. (19):

Photon anti-bunching

$$g^{(2)}(0) = \frac{\langle n | \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} | n \rangle}{\langle n | \hat{a}^\dagger \hat{a} | n \rangle^2} = \frac{\langle n-2 | [n(n-1)]^{1/2} [n(n-1)]^{1/2} | n-2 \rangle}{\langle n-1 | n^{1/2} n^{1/2} | n-1 \rangle^2} = \frac{n(n-1)}{n^2} \equiv 1 - \frac{1}{n}. \quad (9.36)$$

We see that the correlation function at small delays is suppressed rather than enhanced – see the dashed lines in Fig. 3. This *photon antibunching* effect has a very simple handwaving explanation: a single photon emitted by the wave source may be absorbed by just one of the detectors. For the initial state $n = 1$, this is the only option, and it is very natural that Eq. (36) predicts no simultaneous counts at $\tau = 0$. Despite this theoretical simplicity, reliable observations of the antibunching have not been carried out until 1977,¹⁹ due to the experimental difficulty of driving electromagnetic field oscillators into their Fock states – see Sec. 4 below.

(ii) The Glauber state α . A similar procedure, but now using Eq. (5.124) and its Hermitian conjugate, $\langle \alpha | \hat{a}^\dagger = \langle \alpha | \alpha^*$, yields

Glauber field statistics

$$g^{(2)}(0) = \frac{\langle \alpha | \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} | \alpha \rangle}{\langle \alpha | \hat{a}^\dagger \hat{a} | \alpha \rangle^2} = \frac{\alpha^* \alpha^* \alpha \alpha}{(\alpha^* \alpha)^2} \equiv 1, \quad (9.37)$$

for any parameter α . We see that the result is different from that for the Fock states, unless in the latter case $n \rightarrow \infty$. (We know that the Fock and Glauber properties should also coincide for the ground state, but at that state the correlation function's value is uncertain, because there are no photon counts at all.)

(iii) Classical mixture. From Chapter 7, we know that such statistical ensembles cannot be described by single state vectors, and require the density matrix w for their description. Here, we may combine Eqs. (35) and (7.5) to write

$$g^{(2)}(0) = \frac{\text{Tr}(\hat{w} \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a})}{\left[\text{Tr}(\hat{w} \hat{a}^\dagger \hat{a}) \right]^2}. \quad (9.38)$$

¹⁹ By H. J. Kimble *et al.*, *Phys. Rev. Lett.* **39**, 691 (1977). For a detailed review of phonon antibunching, see, e.g., H. Paul, *Rev. Mod. Phys.* **54**, 1061 (1982).

Spelling out this expression is easy for the field in thermal equilibrium at some temperature T , because its density matrix is diagonal in the basis of Fock states n – see Eqs. (7.24):

$$w_{nn'} = W_n \delta_{nn'}, \quad W_n = \exp\left\{-\frac{E_n}{k_B T}\right\} / Z \equiv \lambda^n / \sum_{n=0}^{\infty} \lambda^n, \quad \text{where } \lambda \equiv \exp\left\{-\frac{\hbar\omega}{k_B T}\right\}. \quad (9.39)$$

So, for the operators in the numerator and denominator of Eq. (38) we also need just the diagonal terms of the operator products, which have already been calculated – see Eq. (36). As a result, we get

$$g^{(2)}(0) = \frac{\sum_{n=0}^{\infty} W_n n(n-1)}{\left(\sum_{n=0}^{\infty} W_n n\right)^2} = \frac{\sum_{n=0}^{\infty} \lambda^n n(n-1) \times \sum_{n=0}^{\infty} \lambda^n}{\left(\sum_{n=0}^{\infty} \lambda^n n\right)^2}. \quad (9.40)$$

One of the three series involved in this expression is just the usual geometric progression,

$$\sum_{n=0}^{\infty} \lambda^n = \frac{1}{1-\lambda}, \quad (9.41)$$

and the remaining two series may be readily calculated by its differentiation over the parameter λ :

$$\begin{aligned} \sum_{n=0}^{\infty} \lambda^n n &\equiv \lambda \sum_{n=0}^{\infty} \lambda^{n-1} n = \lambda \frac{d}{d\lambda} \sum_{n=0}^{\infty} \lambda^n = \lambda \frac{d}{d\lambda} \frac{1}{1-\lambda} = \frac{\lambda}{(1-\lambda)^2}, \\ \sum_{n=0}^{\infty} \lambda^n n(n-1) &\equiv \lambda^2 \sum_{n=0}^{\infty} \lambda^{n-2} n(n-1) = \lambda^2 \frac{d^2}{d\lambda^2} \left(\sum_{n=0}^{\infty} \lambda^n \right) = \lambda^2 \frac{d^2}{d\lambda^2} \frac{1}{1-\lambda} = \frac{2\lambda^2}{(1-\lambda)^3}, \end{aligned} \quad (9.42)$$

and for the correlation function we get an extremely simple result independent of the parameter λ and hence of temperature:

$$g^{(2)}(0) = \frac{[2\lambda^2/(1-\lambda)^3][1/(1-\lambda)]}{[\lambda/(1-\lambda)^2]^2} \equiv 2. \quad (9.43)$$

Photon bunching

This is exactly the photon bunching effect first observed by Hanbury Brown and Twiss – see Fig. 3. We see that in contrast to antibunching, this is an essentially classical (statistical) effect. Indeed, Eq. (43) allows a purely classical derivation. In the classical theory, the counting rate (of a single counter) is proportional to the wave intensity I , so that Eq. (31) with $\tau = 0$ is reduced to

$$g^{(2)}(0) = \frac{\langle I^2 \rangle}{\langle I \rangle^2}, \quad \text{with } I \propto \overline{E^2(t)} \propto E_\omega E_\omega^*. \quad (9.44)$$

For a sinusoidal field, the intensity is constant, and $g^{(2)}(0) = 1$. (This is also evident from Eq. (37), because the classical state may be considered as a Glauber state with $\alpha \rightarrow \infty$.) On the other hand, if the intensity fluctuates (either in time, or from one experiment to another), the averages in Eq. (44) should be calculated as

$$\langle I^k \rangle = \int_0^\infty w(I) I^k dI, \quad \text{with } \int_0^\infty w(I) dI = 1, \quad \text{and } k = 1, 2, \quad (9.45)$$

where $w(I)$ is the probability density. For classical statistics, the probability is an exponential function of the electromagnetic field energy, and hence its intensity:

$$w(I) = Ce^{-\beta I}, \quad \text{where } \beta \propto 1/k_B T, \quad (9.46)$$

so that Eqs. (45) yield:²⁰

$$\begin{aligned} \int_0^\infty C \exp\{-\beta I\} dI &\equiv C/\beta = 1, \quad \text{and hence } C = \beta, \\ \langle I^k \rangle &= \int_0^\infty w(I) I^k dI = C \int_0^\infty \exp\{-\beta I\} I^k dI = \frac{1}{\beta^k} \int_0^\infty \exp\{-\xi\} \xi^k d\xi = \begin{cases} 1/\beta, & \text{for } k=1, \\ 2/\beta^2, & \text{for } k=2. \end{cases} \end{aligned} \quad (9.47)$$

Plugging these results into Eq. (44), we get $g^{(2)}(0) = 0$, in complete agreement with Eq. (43).

For some field states, including the squeezed ground states ζ discussed at the end of Sec. 5.5, values $g^{(2)}(0)$ may be even higher than 2 – the so-called *super-bunching*. Analyses of two cases of such super-bunching are offered for the reader’s exercise – see the problem list in the chapter’s end.

9.3. Photon emission: spontaneous and stimulated

In our simple model of photon counting, considered in the last section, the trigger atom in the counter *absorbed* a photon. Now let us have a look at the opposite process of *spontaneous emission* of photons by an atom in an excited state, still using the same electric-dipole approximation (24) for the atom-to-field interaction. For this, we may still use the Golden Rule for the model depicted in Fig. 6.12, but now the roles have changed: we have to associate the operator \hat{A} with the electric dipole moment of the atom, while the operator \hat{B} , with the electric field, so that the continuous spectrum of the system b represents the plurality of the electromagnetic field modes into which the spontaneous radiation may happen. Since now the transition *increases* the energy of the electromagnetic field, and *decreases* that of the atom, after the multiplication of the field bracket in Eq. (27a) by $\exp\{-i\omega t\}$, and the second, by $\exp\{+i\omega t\}$, we may keep only the photon *creation* operator whose time evolution (26) compensates this additional fast “rotation”. As a result, the Golden Rule takes the following form:

$$\Gamma_s = \pi\omega \left| \langle \text{fin} | \hat{a}^\dagger | 0 \rangle \right|^2 \left| \langle \text{fin} | \hat{\mathbf{d}} \cdot \mathbf{e}(\mathbf{r}) | \text{ini} \rangle \right|^2 \rho_f, \quad (9.48)$$

Spontaneous
photon
emission
rate

where all operators and states are time-independent (i.e. taken in the Schrödinger picture), and ρ_f is the density of final states of the electromagnetic field – which in this problem plays the role of the atom’s environment.²¹ Here the electromagnetic field oscillator has been assumed to be initially in the ground state – the assumption that will be changed later in this section.

This relation, together with Eq. (19), shows that for the field’s matrix element be different from zero, the final state of the field has to be the first excited Fock state, $n = 1$. (By the way, *this* is exactly

²⁰ See, e.g., MA Eq. (6.7c) with $n = 0$ and $n = 1$.

²¹ Here the sum over all electromagnetic field modes j may be smuggled back. Since in the quasi-static approximation $k_j a \ll 1$, which is necessary for the interaction representation by Eq. (24), the matrix elements in Eq. (48) are virtually independent on the direction of the wave vectors, and their magnitudes are fixed by ω , the summation is reduced to the calculation of the total ρ_f for all modes, and the averaging of $e^2(\mathbf{r})$ – see below.

the most practicable way of generating an excited Fock state of a field oscillator.) With that, Eq. (48) yields

$$\Gamma_s = \pi\omega \left| \langle \text{fin} | \hat{\mathbf{d}} \cdot \mathbf{e}(\mathbf{r}) | \text{ini} \rangle \right|^2 \rho_f \equiv \pi\omega \left| \langle \text{fin} | \hat{d}e_d(\mathbf{r}) | \text{ini} \rangle \right|^2 \rho_f, \quad (9.49)$$

where the density ρ_f of the excited electromagnetic field states should be calculated at the energy $E = \hbar\omega$, and e_d is the Cartesian component of the vector $\mathbf{e}(\mathbf{r})$ along the electric dipole's direction. The expression for the density ρ_f was our first formula in this course – see Eq. (1.1).²² From it, we get

$$\rho_f \equiv \frac{dN}{dE} = V \frac{\omega^2}{\pi^2 \hbar c^3}, \quad (9.50)$$

where the bounding volume V should be large enough to ensure spectrum's virtual continuity: $V \gg \lambda^3 = (2\pi c/\omega)^3$. Because of that, in the normalization condition used to simplify Eq. (9), we may consider $e^2(\mathbf{r})$ constant. Let us represent this square as a sum of squares of the three Cartesian components of the vector $\mathbf{e}(\mathbf{r})$: one of those (e_d) aligned with the dipole's direction; due to the space isotropy we may write

$$e^2 \equiv e_d^2 + e_{\perp 1}^2 + e_{\perp 2}^2 = 3e_d^2. \quad (9.51)$$

As a result, the normalization condition yields

$$e_d^2 = \frac{1}{3\epsilon_0 V}. \quad (9.52)$$

and Eq. (49) gives the famous (and very important) formula²³

$$\Gamma_s = \frac{1}{4\pi\epsilon_0} \frac{4\omega^3}{3\hbar c^3} \left| \langle \text{fin} | \hat{\mathbf{d}} | \text{ini} \rangle \right|^2 \equiv \frac{1}{4\pi\epsilon_0} \frac{4\omega^3}{3\hbar c^3} \langle \text{fin} | \hat{\mathbf{d}} | \text{ini} \rangle \cdot \langle \text{ini} | \hat{\mathbf{d}} | \text{fin} \rangle^*. \quad (9.53)$$

Free-space spontaneous emission rate

Leaving a comparison of this formula with the classical theory of radiation,²⁴ and the exact evaluation of Γ_s for a particular transition in the hydrogen atom, for reader's exercises, let me just estimate its order of magnitude. Assuming that $d \sim er_B \equiv eh^2/m_e(e^2/4\pi\epsilon_0)$ and $\hbar\omega \sim E_H \equiv m_e(e^2/4\pi\epsilon_0)^2/h^2$, and taking into account the definition (6.62) of the fine structure constant $\alpha \approx 1/137$, we get

$$\frac{\Gamma}{\omega} \sim \left(\frac{e^2}{4\pi\epsilon_0 \hbar c} \right)^3 \equiv \alpha^3 \sim 3 \times 10^{-7}. \quad (9.54)$$

This estimate shows that the emission lines at atomic transitions are typically very sharp. With the present-day availability of high-speed electronics, it also makes sense to evaluate the time scale $\tau = 1/\Gamma$ of the typical quantum transition: for a typical optical frequency $\omega \sim 3 \times 10^{15} \text{ s}^{-1}$, it is close to 1 ns. This is

²² If the same atom is placed into a high- Q resonant cavity (see, e.g., EM 7.9), the rate of its photon emission is strongly suppressed at frequencies between the cavity resonances (where $\rho_f \rightarrow 0$) – see, e.g., the review by S. Haroche and D. Kleppner, *Phys. Today* **42**, 24 (Jan. 1989). On the other hand, the emission is strongly (by a factor $\sim (\lambda^3/V)Q$, where V is cavity's volume) enhanced at resonance frequencies – the so-called *Purcell effect*, discovered by E. Purcell in the 1940s. For a brief discussion of this and other quantum electrodynamic effects in cavities, see the next section.

²³ This was the breakthrough result obtained by P. Dirac in 1927, which jumpstarted the whole field of quantum electrodynamics. An equivalent expression was obtained from more formal arguments in 1930 by V. Weisskopf and E. Wigner, so that sometimes Eq. (53) is (very unfairly) called the “Weisskopf-Wigner formula”.

²⁴ See, e.g., EM Sec. 8.2, in particular Eq. (8.29).

exactly the time constant that determines the time-delay dependence of the photon counting statistics of the spontaneously emitted radiation – see Fig. 3. Colloquially, this is the temporal scale of the photon emitted by an atom.²⁵

Note, however, that the above estimate of τ is only valid for a transition with a non-zero electric-dipole matrix element. If it equals zero, i.e. the transition does not satisfy the *selection rules*,²⁶ – say, due to the initial and final state symmetry – it is “forbidden”. The “forbidden” transition may still take place due to a different, smaller interaction (say, via a magnetic dipole field of the atom, or its quadrupole electric field²⁷), but takes much longer. In some cases the increase of τ is rather dramatic – sometimes to hours! Such long-lasting radiation is called the *luminescence* – or the *fluorescence* if the initial atom’s excitation was due to external radiation of a higher frequency, followed first by non-radiative transitions down the ladder of energy levels.

Now let us consider a more general case when the electromagnetic field mode of frequency ω is initially in an arbitrary Fock state n , and from it may either get energy $\hbar\omega$ from the atomic system (*photon emission*) or, vice versa, give such energy back to the atom (*photon absorption*). For the photon emission rate, an evident generalization of Eq. (48) gives

$$\frac{\Gamma_e}{\Gamma_s} \equiv \frac{\Gamma_{n \rightarrow \text{fin}}}{\Gamma_{0 \rightarrow 1}} = \frac{\left| \langle \text{fin} | \hat{a}^\dagger | n \rangle \right|^2}{\left| \langle 1 | \hat{a}^\dagger | 0 \rangle \right|^2}, \quad (9.55)$$

where both brackets should be calculated in the Schrödinger picture, and Γ_s is the spontaneous emission rate (48) of the same atomic system. According to the second of Eqs. (19), at the photon emission, the final field state has to be the Fock state with $n' = n + 1$, and Eq. (55) yields

$$\boxed{\Gamma_e = (n + 1)\Gamma_s}. \quad (9.56)$$

Thus the initial field increases the photon emission rate; this effect is called the *stimulated emission of radiation*. Note that the spontaneous emission may be considered as a particular case of the stimulated emission for $n = 0$, and hence interpreted as the emission stimulated by the ground state of the electromagnetic field – one more manifestation of the non-trivial nature of this “vacuum” state.

On the other hand, following the arguments of Sec. 2,²⁸ for the description of radiation *absorption*, the photon creation operator has to be replaced with the annihilation operator, giving the rate ratio

²⁵ The scale $c\tau$ of the spatial extension of the corresponding wave packet is surprisingly macroscopic – in the range of a few millimeters. Such a “human” size of spontaneously emitted photons makes the usual optical table, with its 1-cm-scale components, the key equipment for many optical experiments – see, e.g., Fig. 2.

²⁶ As was already discussed in Sec. 5.6, for a single spin-less particle moving in a spherically-symmetric potential (e.g., a hydrogen-like atom), the orbital selection rules are simple: the only allowed electric-dipole transitions are those with $\Delta l \equiv l_{\text{fin}} - l_{\text{ini}} = \pm 1$ and $\Delta m \equiv m_{\text{fin}} - m_{\text{ini}} = 0$ or ± 1 . The simplest example of the transition that does *not* satisfy this rule, i.e. is “forbidden”, is that between the *s*-states ($l = 0$) with $n = 2$ and $n = 1$; because of that, the lifetime of the lowest excited *s*-state of a hydrogen atom is as long as ~ 0.15 s.

²⁷ See, e.g., EM Sec. 8.9.

²⁸ Note, however, a major difference between the rate Γ discussed in Sec. 2, and Γ_a in Eq. (57). In our current case, the atomic transition is still between two *discrete* energy levels (see Fig. 4 below), so that the rate Γ_a is

$$\frac{\Gamma_a}{\Gamma_s} = \frac{|\langle \text{fin} | \hat{a} | n \rangle|^2}{|\langle 1 | \hat{a}^\dagger | 0 \rangle|^2}. \quad (9.57)$$

According to this relation and the first of Eqs. (19), the final state of the field at the photon absorption has to be the Fock state with $n' = n - 1$, and Eq. (57) yields

$$\Gamma_a = n \Gamma_s. \quad (9.58)$$

Photon absorption rate

The results (56) and (58) are usually formulated in terms of relations between the *Einstein coefficients* A and B defined in the way shown in Fig. 4, where the two energy levels are those of the atom, Γ_a is the rate of energy absorption from the electromagnetic field in its n^{th} Fock state, and Γ_e is that of energy emission into the field, initially in the same state. In this notation, Eqs. (56) and (58) yield²⁹

$$A_{21} = B_{21} = B_{12}, \quad (9.59)$$

Einstein coefficients' relation

because each of these coefficients equals the spontaneous emission rate Γ_s .

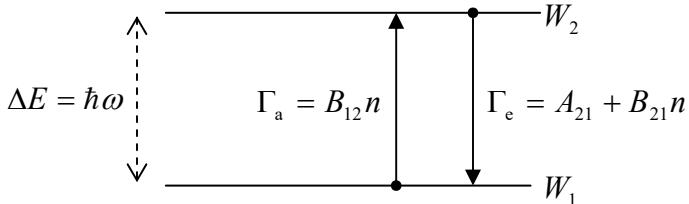

Fig. 9.4. The Einstein coefficients on the atomic quantum transition diagram – cf. Fig. 7.6.

I cannot resist the temptation to use this point for a small detour – an alternative derivation of the Bose-Einstein statistics for photons. Indeed, in the thermodynamic equilibrium, the average probability flows between levels 1 and 2 (see Fig. 4 again) should be equal:³⁰

$$W_2 \langle \Gamma_e \rangle = W_1 \langle \Gamma_a \rangle, \quad (9.60)$$

where W_1 and W_2 are the probabilities for the atomic system to occupy the corresponding levels, so that Eqs. (56) and (58) yield

$$W_2 \Gamma_s \langle 1+n \rangle = W_1 \Gamma_s \langle n \rangle, \quad \text{i.e. } \frac{W_2}{W_1} = \frac{\langle n \rangle}{\langle n \rangle + 1}, \quad (9.61)$$

where $\langle n \rangle$ is the average number of photons in the field causing the interstate transitions. But, on the other hand, for an atomic subsystem only weakly coupled to its electromagnetic environment, we ought to have the Gibbs distribution of these probabilities:

$$\frac{W_2}{W_1} = \frac{\exp\{-E_2/k_B T\}}{\exp\{-E_1/k_B T\}} = \exp\left\{-\frac{\Delta E}{k_B T}\right\} = \exp\left\{-\frac{\hbar\omega}{k_B T}\right\}. \quad (9.62)$$

proportional to ρ_f , the density of final states of the electromagnetic field, i.e. the same density as in Eq. (48) and beyond, while the rate (27) is proportional to ρ_a , the density of final (ionized) states of the “trigger” atom – more exactly, of it’s the electron released at its ionization.

²⁹ These relations were conjectured, from very general arguments, by Albert Einstein as early as 1916.

³⁰ This is just a particular embodiment of the detailed balance equation (7.198).

Requiring Eqs. (61) and (62) to give the same result for the probability ratio, we get the Bose-Einstein distribution for the electromagnetic field in thermal equilibrium:

$$\langle n \rangle = \frac{1}{\exp\{\hbar\omega/k_B T\} - 1} \quad (9.63)$$

- the same result as that obtained in Sec. 7.1 by other means – see Eq. (7.26b).

Now returning to the discussion of Eqs. (56) and (58), their very important implication is the possibility to achieve the stimulated emission of coherent radiation using the level *occupancy inversion*. Indeed, if the ratio W_2/W_1 is larger than that given by Eq. (62), the net power flow from the atomic system into the electromagnetic field,

$$\text{power} = \hbar\omega \times \Gamma_s [W_2(\langle n \rangle + 1) - W_1\langle n \rangle], \quad (9.64)$$

may be positive. The necessary inversion may be produced using several ways, notably by intensive quantum transitions to level 2 from an even higher energy level (which, in turn, is populated, e.g., by absorption of external radiation, usually called *pumping*, at a higher frequency.)

A less obvious, but crucial feature of the stimulated emission is spelled out by Eq. (55): as was mentioned above, it shows that the final state of the field after the absorption of energy $\hbar\omega$ from the atom is a pure (coherent) Fock state $(n + 1)$. Colloquially, one may say that the new, $(n + 1)^{\text{st}}$ photon emitted from the atom is automatically in phase with the n photons that had been in the field mode initially, i.e. joins them coherently.³¹ The idea of stimulated emission of coherent radiation using population inversion³² was first implemented in the early 1950s in the microwave range (*masers*) and in 1960 in the optical range (*lasers*). Nowadays, lasers are ubiquitous components of almost all high-tech systems and constitute one of the cornerstones of our technological civilization.

A quantitative discussion of laser operation is well beyond the framework of this course, and I have to refer the reader to special literature,³³ but still would like to briefly mention two key points:

(i) In a typical laser, each generated electromagnetic field mode is in its Glauber (rather than the Fock) state, so that Eqs. (56) and (58) are applicable only for the n averaged over the Fock-state decomposition of the Glauber state – see Eq. (5.134).

(ii) Since in a typical laser $\langle n \rangle \gg 1$, its operation may be well described using quasiclassical theories that use Eq. (64) to describe the electromagnetic energy balance (with the addition of a term describing the energy loss due to field absorption in external components of the laser, including the useful load), plus the equation describing the balance of occupancies $W_{1,2}$ due to all interlevel transitions – similar to Eq. (60), but including also the contribution(s) from the particular population inversion mechanism used in the laser. At this approach, the role of quantum mechanics in laser science is essentially reduced to the calculation of the parameter Γ_s for the particular system.

This role becomes more prominent when one needs to describe *fluctuations* of the laser field. Here two approaches are possible, following the two options discussed in Chapter 7. If the fluctuations

³¹ It is straightforward to show that this fact is also true if the field is initially in the Glauber state – which is more typical for modes in practical lasers.

³² This idea may be traced back at least to an obscure 1939 publication by V. Fabrikant.

³³ I can recommend, for example, P. Milloni and J. Eberly, *Laser Physics*, 2nd ed., Wiley, 2010, and a less technical text by A. Yariv, *Quantum Electronics*, 3rd ed., Wiley, 1989.

are relatively small, one can linearize the Heisenberg equations of motion of the field oscillator operators near their stationary-lasing “values”, with the Langevin “forces” (also time-dependent operators) describing the fluctuation sources, and use these Heisenberg-Langevin equations to calculate the radiation fluctuations, just as was described in Sec. 7.5. On the other hand, near the lasing threshold, the field fluctuations are relatively large, smearing the phase transition between the no-lasing and lasing states. Here the linearization is not an option, but one can use the density-matrix approach described in Sec. 7.6, for the fluctuation analysis.³⁴ Note that while the laser fluctuations may look like a peripheral issue, pioneering research in that field has led to the development of the general theory of open quantum systems, which was discussed in Chapter 7.

9.4. Cavity QED

Now I have to visit, at least in passing, the field of *cavity quantum electrodynamics* (usually called *cavity QED* for short) – the art and science of creating and using the entanglement between quantum states of an atomic system (either an atom, or an ion, or a molecule, etc.) and the electromagnetic field in a macroscopic volume called the *resonant cavity* (or just “resonator”, or just “cavity”). This field is very popular nowadays, especially in the context of the quantum computation and communication research discussed in Sec. 8.5.³⁵

The discussion in the previous section was based on the implicit assumption that the energy spectrum of the electromagnetic field interacting with an atomic subsystem is essentially continuous, so that its final state is spread among many field modes, effectively losing its coherence with the quantum state of the atomic subsystem. This assumption has justified using the quantum-mechanical Golden Rule for the calculation of the spontaneous and stimulated transition rates. However, the assumption becomes invalid if the electromagnetic field is contained inside a relatively small volume, with its linear size comparable with the radiation wavelength. If the walls of such a cavity mostly reflect, rather than absorb, radiation, then the 0th approximation the energy dissipation may be disregarded, and the particular solutions $\mathbf{e}_j(\mathbf{r})$ of the Helmholtz equation (5) correspond to discrete, well-separated mode wave numbers k_j and hence well-separated frequencies ω_j .³⁶ Due to the energy conservation, an atomic transition corresponding to energy $\Delta E = |E_{\text{ini}} - E_{\text{fin}}|$ may be effective only if the corresponding quantum transition frequency $\Omega \equiv \Delta E/\hbar$ is close to one of these resonance frequencies.³⁷ As a result of such resonant interaction, the quantum states of the atomic system and the resonant electromagnetic mode may become entangled.

A very popular approximation for the quantitative description of this effect is the so-called *Rabi model*,³⁸ in which the atom is treated as a two-level system interacting with a single electromagnetic field mode of the resonant cavity. (As was shown in Sec. 6.5, this model is justified, e.g., if transitions

³⁴ This path has been developed (also in the mid-1960s), by several researchers, notably including M. Sully and W. Lamb – see, e.g., M. Sargent III, M. Scully, and W. Lamb, Jr., *Laser Physics*, Westview, 1977.

³⁵ This popularity was demonstrated, for example, by the award of the 2012 Nobel Prize in Physics to cavity QED experimentalists S. Haroche and D. Wineland.

³⁶ The calculation of such modes and corresponding frequencies for several simple cavity geometries was the subject of EM Sec. 7.8 of this series.

³⁷ On the contrary, if Ω is far from any ω_j , the interaction is suppressed; in particular, the spontaneous emission rate may be much lower than that given by Eq. (53) – so that this result is not as fundamental as it may look.

³⁸ After the pioneering work by I. Rabi in 1936-37.

between all other energy level pairs have considerably different frequencies.) As the reader knows well from Chapters 4-6 (see in particular Sec. 5.1), any two-level system may be described, just as a spin- $\frac{1}{2}$, by the Hamiltonian $b\hat{I} + \mathbf{c} \cdot \hat{\mathbf{\sigma}}$. Since we may always select the energy origin that $b = 0$, and the state basis in which $\mathbf{c} = c\mathbf{n}_z$, the Hamiltonian of the atomic subsystem may be taken in the diagonal form

$$\hat{H}_a = c\hat{\sigma}_z \equiv \frac{\hbar\Omega}{2}\hat{\sigma}_z, \quad (9.65)$$

where $\hbar\Omega \equiv 2c = \Delta E$ is the difference between the energy levels in the absence of interaction with the field. Next, according to Eq. (17), ignoring the constant ground-state energy $\hbar\omega/2$ (which may be always added to the energy at the end – if necessary), the contribution of a single field mode of frequency ω to the total Hamiltonian of the system is

$$\hat{H}_f = \hbar\omega\hat{a}^\dagger\hat{a}. \quad (9.66)$$

Finally, according to Eq. (16a), the electric field of the mode may be represented as

$$\hat{\mathcal{E}}(\mathbf{r}, t) = \frac{1}{i} \left(\frac{\hbar\omega}{2} \right)^{1/2} \mathbf{e}(\mathbf{r}) \left(\hat{a} - \hat{a}^\dagger \right), \quad (9.67)$$

so that in the electric-dipole approximation (24), the cavity-atom interaction may be represented as a product of the field by some (say, y -) Cartesian component³⁹ of the Pauli spin- $\frac{1}{2}$ operator:

$$\hat{H}_{int} = \text{const} \times \hat{\sigma}_y \times \hat{\mathcal{E}} = \text{const} \times \hat{\sigma}_y \times \left(\frac{\hbar\omega}{2} \right)^{1/2} \frac{1}{i} \left(\hat{a} - \hat{a}^\dagger \right) = i\hbar\kappa\hat{\sigma}_y \left(\hat{a} - \hat{a}^\dagger \right), \quad (9.68)$$

where κ is a coupling constant (with the dimension of frequency). The sum of these three terms,

$$\hat{H} \equiv \hat{H}_a + \hat{H}_f + \hat{H}_{int} = \frac{\hbar\Omega}{2}\hat{\sigma}_z + \hbar\omega\hat{a}^\dagger\hat{a} + i\hbar\kappa\hat{\sigma}_y \left(\hat{a} - \hat{a}^\dagger \right). \quad (9.69)$$

Rabi Hamiltonian

giving a very reasonable description of the system, is called the *Rabi Hamiltonian*. Despite its apparent simplicity, using this Hamiltonian for calculations is not that straightforward.⁴⁰ Only in the case when the electromagnetic field is large and hence may be treated classically, the results following from Eq. (69) are reduced to Eqs. (6.94) describing, in particular, the Rabi oscillations discussed in Sec. 6.3.

The situation becomes simpler in the most important case when the frequencies Ω and ω are very close, enabling an effective interaction between the cavity field and the atom even if the coupling constant κ is relatively small. Indeed, if both the κ and the so-called *detuning* (defined similarly to the parameter Δ used in Sec. 6.5),

$$\xi \equiv \Omega - \omega, \quad (9.70)$$

³⁹ The exact component is not important for final results, while intermediate formulas simplify if the interaction is proportional to either pure $\hat{\sigma}_x$ or pure $\hat{\sigma}_y$.

⁴⁰ For example, an exact quasi-analytical expression for its eigenenergies (as zeros of a Taylor series in the parameter κ , with coefficients determined by a recurrence relation) was found only recently – see D. Braak, *Phys. Rev. Lett.* **107**, 100401 (2011).

are much smaller than $\Omega \approx \omega$, the Rabi Hamiltonian may be simplified using the rotating-wave approximation, already used several times in this course. For this, it is convenient to use the *spin ladder operators*, defined absolutely similarly for those of the orbital angular momentum – see Eqs. (5.153):

$$\hat{\sigma}_{\pm} \equiv \hat{\sigma}_x \pm i\hat{\sigma}_y, \quad \text{so that } \hat{\sigma}_y = \frac{\hat{\sigma}_+ - \hat{\sigma}_-}{2i}. \quad (9.71)$$

From Eq. (4.105), it is very easy to find the matrices of these operators in the standard z -basis,

$$\sigma_+ = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}, \quad \sigma_- = \begin{pmatrix} 0 & 0 \\ 2 & 0 \end{pmatrix}, \quad (9.72)$$

and their commutation rules – which turn out to be naturally similar to Eqs. (5.154):

$$[\hat{\sigma}_+, \hat{\sigma}_-] = 4\hat{\sigma}_z, \quad [\hat{\sigma}_z, \hat{\sigma}_{\pm}] = \pm 2\hat{\sigma}_{\pm}. \quad (9.73)$$

In this notation, the Rabi Hamiltonian becomes

$$\hat{H} = \frac{\hbar\Omega}{2}\hat{\sigma}_z + \hbar\omega\hat{a}^\dagger\hat{a} + \frac{\hbar\kappa}{2}(\hat{\sigma}_+ - \hat{\sigma}_-)(\hat{a} - \hat{a}^\dagger), \quad (9.74)$$

and it is straightforward to use Eq. (4.199) and (73) to derive the Heisenberg-picture equations of motion for the involved operators. (Doing this, we have to remember that operators of the “spin” subsystem, on one hand, and of the field mode, on the other hand, are defined in different Hilbert spaces and hence commute – at least at coinciding time moments.) The result (so far, exact!) is

$$\begin{aligned} \dot{\hat{a}} &= -i\omega\hat{a} + \frac{i\kappa}{2}(\hat{\sigma}_+ - \hat{\sigma}_-), & \dot{\hat{a}}^\dagger &= i\omega\hat{a}^\dagger + \frac{i\kappa}{2}(\hat{\sigma}_+ - \hat{\sigma}_-), \\ \dot{\hat{\sigma}}_{\pm} &= \pm i\Omega\hat{\sigma}_{\pm} + 2i\kappa(\hat{a} - \hat{a}^\dagger)\hat{\sigma}_z, & \dot{\hat{\sigma}}_z &= i\kappa(\hat{a}^\dagger - \hat{a})(\hat{\sigma}_+ + \hat{\sigma}_-). \end{aligned} \quad (9.75)$$

At negligible coupling, $\kappa \rightarrow 0$, these equations have simple solutions,

$$\hat{a}(t) \propto e^{-i\omega t}, \quad \hat{a}^\dagger(t) \propto e^{i\omega t}, \quad \hat{\sigma}_{\pm}(t) \propto e^{\pm i\Omega t}, \quad \hat{\sigma}_z(t) \approx \text{const}, \quad (9.76)$$

and the small terms proportional to κ on the right-hand sides of Eqs. (75) cannot affect these time evolution laws dramatically even if κ is not exactly zero. Of those terms, ones with frequencies close to the “basic” frequency of each variable would act in resonance and hence may have a substantial impact on the system’s dynamics, while non-resonant terms may be ignored. In this rotating-wave approximation, Eqs. (75) are reduced to a much simpler system of equations:

$$\begin{aligned} \dot{\hat{a}} &= -i\omega\hat{a} - \frac{i\kappa}{2}\hat{\sigma}_-, & \dot{\hat{a}}^\dagger &= i\omega\hat{a}^\dagger + \frac{i\kappa}{2}\hat{\sigma}_+, \\ \dot{\hat{\sigma}}_+ &= i\Omega\hat{\sigma}_+ + 2i\kappa\hat{a}^\dagger\hat{\sigma}_z, & \dot{\hat{\sigma}}_- &= -i\Omega\hat{\sigma}_- - 2i\kappa\hat{a}\hat{\sigma}_z, & \dot{\hat{\sigma}}_z &= i\kappa(\hat{a}^\dagger\hat{\sigma}_- - \hat{a}\hat{\sigma}_+). \end{aligned} \quad (9.77)$$

Alternatively, these equations of motion may be obtained *exactly* from the Rabi Hamiltonian (74), if it is preliminary cleared of the terms proportional to $\hat{\sigma}_+\hat{a}^\dagger$ and $\hat{\sigma}_-\hat{a}$, that oscillate fast and hence self-average to produce virtually zero effect:

Jaynes-
Cummings
Hamiltonian

$$\hat{H} = \frac{\hbar\Omega}{2}\hat{\sigma}_z + \hbar\omega\hat{a}^\dagger\hat{a} + \frac{\hbar\kappa}{2}\left(\hat{\sigma}_+\hat{a} + \hat{\sigma}_-\hat{a}^\dagger\right), \quad \text{at } \kappa, |\xi| \ll \omega, \Omega. \quad (9.78)$$

This is the famous *Jaynes-Cummings Hamiltonian*,⁴¹ which is basic model used in the cavity QED and its applications.⁴² To find its eigenstates and eigenenergies, let us note that at negligible interaction ($\kappa \rightarrow 0$), the spectrum of the total energy E of the system, which in this limit is the sum of two independent contributions from the atomic and cavity-field subsystems,

$$E|_{\kappa=0} = \pm \frac{\hbar\Omega}{2} + \hbar\omega n \equiv E_n \pm \frac{\hbar\xi}{2}, \quad \text{with } n = 1, 2, \dots, \quad (9.79)$$

consists⁴³ of close level pairs (Fig. 5) centered to values

$$E_n \equiv \hbar\omega\left(n - \frac{1}{2}\right). \quad (9.80)$$

(At the exact resonance $\omega = \Omega$, i.e. at $\xi = 0$, each pair merges into one double-degenerate level E_n .) Since at $\kappa \rightarrow 0$ the two subsystems do not interact, the eigenstates corresponding to the sublevels of the n^{th} pair may be represented by direct products of their independent state vectors:

$$|+\rangle \equiv |\uparrow\rangle \otimes |n-1\rangle \quad \text{and} \quad |-\rangle \equiv |\downarrow\rangle \otimes |n\rangle, \quad (9.81)$$

where the first ket of each product represents the state of the two-level (spin-½-like) atomic subsystem, and the second ket, that of the field oscillator.

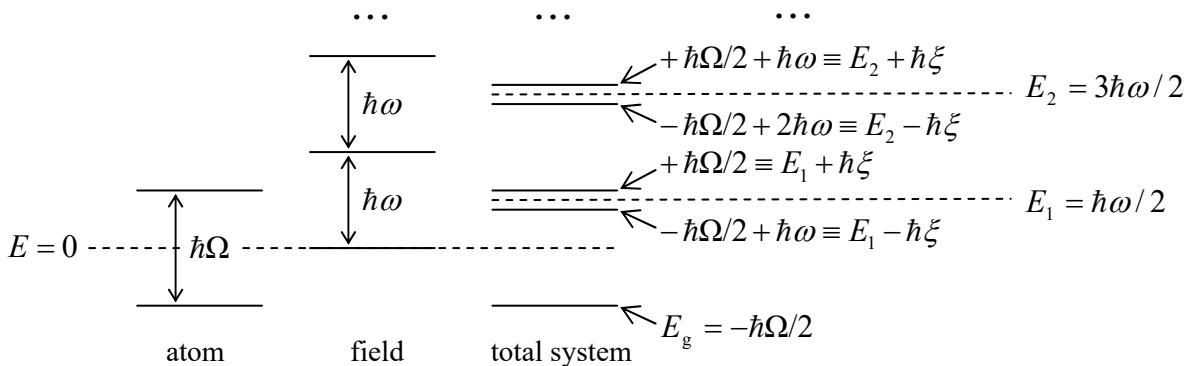

Fig. 9.5. The energy spectrum (79) of the Jaynes-Cummings Hamiltonian in the limit $\kappa \ll |\xi|$. Note again that the energy is referred to the ground-state energy $\hbar\omega/2$ of the cavity field.

As we know from Chapter 6, even weak interaction may lead to strong coherent mixing⁴⁴ of quantum states with close energies (in this case, the two states (81) within each pair with the same n),

⁴¹ It was first proposed and analyzed in 1963 by two engineers, Edwin Jaynes and Fred Cummings, in a *Proc. IEEE* publication, and it took the physics community a while to recognize and acknowledge the fundamental importance of that work.

⁴² For most applications, the baseline Hamiltonian (78) has to be augmented by additional term(s) describing, for example, the incoming radiation and/or the system's coupling to the environment, for example, due to the electromagnetic energy loss in a finite- Q -factor cavity – see Eq. (7.68).

⁴³ Only the ground state level $E_g = -\hbar\Omega/2$ is non-degenerate – see Fig. 5.

while their mixing with the states with farther energies is still negligible. Hence, at $0 < \kappa, |\xi| \ll \omega \approx \Omega$, a good approximation of the eigenstate with $E \approx E_n$ is given by a linear superposition of the states (81):

$$|\alpha_n\rangle = c_+ |+\rangle + c_- |-\rangle \equiv c_+ |\uparrow\rangle \otimes |n-1\rangle + c_- |\downarrow\rangle \otimes |n\rangle, \quad (9.82)$$

Jaynes-Cummings eigenstates

with certain c -number coefficients c_{\pm} . This relation describes the entanglement of the atomic eigenstates \uparrow and \downarrow with the Fock states number n and $n - 1$ of the field mode. Let me leave the (straightforward) calculation of the coefficients $(c_{\pm})^{\pm}$ for each of two entangled states (for each n) for the reader's exercise. (The result for the corresponding two eigenenergies $(E_n)_{\pm}$ may be again represented by the same anticrossing diagram as shown in Figs. 2.29 and 5.1, now with the detuning ξ as the argument.) This calculation shows, in particular, that at $\xi = 0$ (i.e. at $\omega = \Omega$), $|c_+| = |c_-| = 1/\sqrt{2}$ for both states of the pair. This fact may be interpreted as a (coherent!) equal sharing of an energy quantum $\hbar\omega = \hbar\Omega$ by the atom and the cavity field at the exact resonance.

As a (hopefully, self-evident) by-product of the calculation of c_{\pm} is the fact that the dynamics of the state α_n described by Eq. (82), is similar to that of the generic two-level system that was repeatedly discussed in this course – the first time in Sec. 2.6 and then in Chapters 4-6. In particular, if the composite system had been initially prepared to be in one component state, for example $|\uparrow\rangle \otimes |0\rangle$ (i.e. with the atom excited, while the cavity in its ground state), and then allowed to evolve on its own, after some time interval $\Delta t \sim 1/\kappa$ it may be found definitely in the counterpart state $|\downarrow\rangle \otimes |1\rangle$, including the first excited Fock state $n = 1$ of the field mode. If the process is allowed to continue, after the equal time interval Δt , the system returns to the initial state $|\uparrow\rangle \otimes |0\rangle$, etc. This most striking prediction of the Jaynes-Cummings model was directly observed, by G. Rempe *et al.*, only in 1987, although less directly this model was repeatedly confirmed by numerous experiments carried out in the 1960s and 1970s.

This quantized version of the Rabi oscillations can only persist in time if the inevitable electromagnetic energy losses (not described by the basic Jaynes-Cummings Hamiltonian) are somehow compensated – for example, by passing a beam of particles, externally excited into the higher-energy state \uparrow , through the cavity. If the losses become higher, the dissipation suppresses quantum coherence, in our case the coherence between two components of each pair (82), as was discussed in Chapter 7. As a result, the transition from the higher-energy atomic state \uparrow to the lower-energy state \downarrow , giving energy $\hbar\omega$ to the cavity ($n - 1 \rightarrow n$), which is then rapidly drained into the environment, becomes incoherent, so that the system's dynamics is reduced to the Purcell effect, already mentioned in Sec. 3. A quantitative analysis of this effect is left for the reader's exercise.

The number of interesting physics games one can play with such systems – say by adding external sources of radiation at a frequency close to ω and Ω , in particular with manipulated time-dependent amplitude and/or phase, is always unlimited.⁴⁵ Unfortunately, my time/space allowance for the cavity QED is over, and for further discussion, I have to refer the interested reader to special literature.⁴⁶

⁴⁴ In some fields, especially chemistry, such mixing is frequently called *hybridization*.

⁴⁵ Most of them may be described by adding new terms to the basic Jaynes-Cummings Hamiltonian (78).

⁴⁶ I can recommend, for example, either C. Gerry and P. Knight, *Introductory Quantum Optics*, Cambridge U. Press, 2005, or G. Agarwal, *Quantum Optics*, Cambridge U. Press, 2012.

9.5. The Klein-Gordon and relativistic Schrödinger equations

Now let me switch gears and discuss the basics of relativistic quantum mechanics of particles with a non-zero rest mass m . In the ultra-relativistic limit $pc \gg mc^2$ the quantization scheme of such particles may be essentially the same as for electromagnetic waves, but for the intermediate energy range, $pc \sim mc^2$, a more general approach is necessary. Historically, the first attempts⁴⁷ to extend the non-relativistic wave mechanics into the relativistic energy range were based on performing the same transitions from classical observables to their quantum-mechanical operators as in the non-relativistic limit:

$$\mathbf{p} \rightarrow \hat{\mathbf{p}} = -i\hbar\nabla, \quad E \rightarrow \hat{H} = i\hbar \frac{\partial}{\partial t}. \quad (9.83)$$

The substitution of these operators, acting on the Schrödinger-picture wavefunction $\Psi(\mathbf{r},t)$, into the classical relation (1) between the energy E and momentum \mathbf{p} (for of a free particle) leads to the following formulas:

Table 9.1. Deriving the Klein-Gordon equation for a free relativistic particle.⁴⁸

	Non-relativistic limit	Relativistic case
Classical mechanics	$E = \frac{1}{2m} p^2$	$E^2 = c^2 p^2 + (mc^2)^2$
Wave mechanics	$i\hbar \frac{\partial}{\partial t} \Psi = \frac{1}{2m} (-i\hbar\nabla)^2 \Psi$	$\left(i\hbar \frac{\partial}{\partial t}\right)^2 \Psi = c^2 (-i\hbar\nabla)^2 \Psi + (mc^2)^2 \Psi$

The resulting equation for the non-relativistic limit, in the left-bottom cell of the table, is just the usual Schrödinger equation (1.28) for a free particle. Its relativistic generalization, in the right-bottom cell, usually rewritten as

Klein-Gordon equation

$$\left(\frac{1}{c^2} \frac{\partial^2}{\partial t^2} - \nabla^2 \right) \Psi + \mu^2 \Psi = 0, \quad \text{with } \mu \equiv \frac{mc}{\hbar}, \quad (9.84)$$

is called the *Klein-Gordon* (or sometimes “Klein-Gordon-Fock”) *equation*. The fundamental solutions of this equation are the same plane, monochromatic waves

$$\Psi(\mathbf{r},t) \propto \exp\{i(\mathbf{k} \cdot \mathbf{r} - \omega t)\}. \quad (9.85)$$

as in the non-relativistic case. Indeed, such waves are eigenstates of the operators (83), with eigenvalues, respectively,

$$\mathbf{p} = \hbar\mathbf{k}, \quad \text{and } E = \hbar\omega, \quad (9.86)$$

so that their substitution into Eq. (84) immediately returns us to Eq. (1) with the replacements (86):

⁴⁷ This approach was suggested in 1926-1927, i.e. virtually simultaneously, by (at least) V. Fock, E. Schrödinger, O. Klein and W. Gordon, J. Kudar, T. de Donder and F.-H. van der Dungen, and L. de Broglie.

⁴⁸ Note that in the left, non-relativistic column of this table, the energy is referred to the rest energy mc^2 , while in its right, relativistic column, it is referred to zero – see Eq. (1).

$$E_{\pm} = \hbar\omega_{\pm} = \pm \left[(\hbar ck)^2 + (mc^2)^2 \right]^{1/2}. \quad (9.87)$$

Though one may say that this dispersion relation is just a simple combination of the classical relation (1) and the same basic quantum-mechanical relations (86) as in non-relativistic limit, it attracts our attention to the fact that the energy $\hbar\omega$ as a function of the momentum $\hbar k$ has two branches, with $E_-(\mathbf{p}) = -E_+(\mathbf{p})$ – see Fig. 6a. Historically, this fact has played a very important role in spurring the fundamental idea of *particle-antiparticle pairs*. In this idea (very similar to the concept of electrons and holes in semiconductors, which was discussed in Sec. 2.8), what we call the “vacuum” actually corresponds to all quantum states of the lower branch, with energies $E_-(\mathbf{p}) < 0$, being completely filled, while the states on the upper branch, with energies $E_+(\mathbf{p}) > 0$, being empty. Then an externally supplied energy,

$$\Delta E = E_+ - E_- \equiv E_+ + (-E_-) \geq 2mc^2 > 0, \quad (9.88)$$

may bring the system from the lower branch to the upper one (Fig. 6b). The resulting excited state is interpreted as a combination of a particle (formally, of the infinite spatial extension) with the energy E_+ and the momentum \mathbf{p} , and a “hole” (antiparticle) of the *positive* energy ($-E_-$) and the momentum $-\mathbf{p}$. This idea⁴⁹ has led to a search for, and discovery of the positron: the electron’s antiparticle with charge $q = +e$, in 1932, and later of the antiproton and other antiparticles.

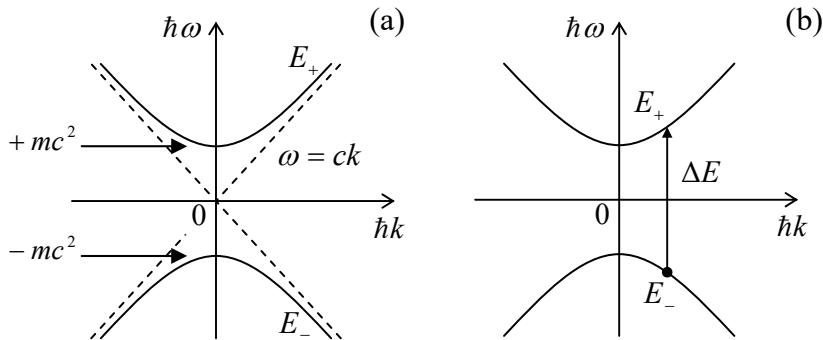

Fig. 9.6. (a) The free-particle dispersion relation resulting from the Klein-Gordon and Dirac equations, and (b) the scheme of creation of a particle-antiparticle pair from the vacuum.

Free particles of a finite spatial extension may be described, in this approach, just as in the non-relativistic Schrödinger equation, by wave packets, i.e. linear superpositions of the de Broglie waves (85) with close wave vectors \mathbf{k} , and the corresponding values of ω given by Eq. (87), with the positive sign for the “usual” particles, and negative sign for antiparticles – see Fig. 6a above. Note that to form, from a particle’s wave packet, a similar wave packet for the antiparticle, with the same phase and group velocities (2.33a) in each direction, we need to change the sign not only before ω , but also before \mathbf{k} , i.e. to replace all component wavefunctions (85), and hence the full wavefunction, with their complex conjugates.

Of more formal properties of Eq. (84), it is easy to prove that its solutions satisfy the same continuity equation (1.52), with the probability current density \mathbf{j} still given by Eq. (1.47), but a different expression for the probability density w – which becomes very similar to that for \mathbf{j} :

$$w = \frac{i\hbar}{2mc^2} \left(\Psi^* \frac{\partial \Psi}{\partial t} - c.c. \right), \quad \mathbf{j} = \frac{i\hbar}{2m} \left(\Psi \nabla \Psi^* - c.c. \right) \quad (9.89)$$

⁴⁹ Due to the same P. A. M. Dirac!

– very much in the spirit of the relativity theory, treating space and time on equal footing. (In the non-relativistic limit $p/mc \rightarrow 0$, Eq. (84) allows the reduction of this expression for w to the non-relativistic Eq. (1.22): $w \rightarrow \Psi\Psi^*$.)

The Klein-Gordon equation may be readily generalized to describe a particle moving in external fields; for example, the electromagnetic field effects on a particle with charge q may be described by the same replacement as in the non-relativistic limit (see Sec. 3.1):

$$\hat{\mathbf{p}} \rightarrow \hat{\mathbf{P}} - q\mathbf{A}(\mathbf{r}, t), \quad \hat{H} \rightarrow \hat{H} - q\phi(\mathbf{r}, t), \quad (9.90)$$

where $\hat{\mathbf{P}} = -i\hbar\nabla$ is the canonical momentum operator (3.25), and the vector- and scalar potentials, \mathbf{A} and ϕ , should be treated appropriately – either as c -number functions if the electromagnetic field quantization is not important for the particular problem, or as operators (see Secs. 1-4 above) if it is.

However, the practical value of the resulting *relativistic Schrödinger equation* is rather limited, for two main reasons. First of all, it does not give the correct description of particles with spin. For example, for the hydrogen-like atom/ion problem, i.e. the motion of an electron with the electric charge $-e$, in the Coulomb central field of an immobile nucleus with charge $+Ze$, the equation may be readily solved exactly⁵⁰ and yields the following spectrum of (doubly-degenerate) energy levels:

$$E = mc^2 \left(1 + \frac{Z^2\alpha^2}{\lambda^2} \right)^{-1/2}, \quad \text{with } \lambda \equiv n + \left[(l + \tfrac{1}{2})^2 - Z^2\alpha^2 \right]^{1/2} - (l + \tfrac{1}{2}), \quad (9.91)$$

where $n = 1, 2, \dots$ and $l = 0, 1, \dots, n - 1$ are the same quantum numbers as in the non-relativistic theory (see Sec. 3.6), and $\alpha \approx 1/137$ is the fine structure constant (6.62). The three leading terms of the Taylor expansion of this result in the small parameter $Z\alpha$ are as follows:

$$E \approx mc^2 \left[1 - \frac{Z^2\alpha^2}{2n^2} - \frac{Z^4\alpha^4}{2n^4} \left(\frac{n}{l + \tfrac{1}{2}} - \frac{3}{4} \right) \right]. \quad (9.92)$$

The first of these terms is just the rest energy of the particle. The second term,

$$E_n = -mc^2 \frac{Z^2\alpha^2}{2n^2} \equiv -\frac{mZ^2e^4}{(4\pi\epsilon_0)^2\hbar^2} \frac{1}{2n^2} \equiv -\frac{E_0}{2n^2}, \quad \text{with } E_0 = Z^2 E_H, \quad (9.93)$$

reproduces the non-relativistic Bohr's formula (3.201). Finally, the third term,

$$-\frac{mc^2}{2n^4} \frac{Z^4\alpha^4}{2n^4} \left(\frac{n}{l + \tfrac{1}{2}} - \frac{3}{4} \right) \equiv -\frac{2E_n^2}{mc^2} \left(\frac{n}{l + \tfrac{1}{2}} - \frac{3}{4} \right), \quad (9.94)$$

is just the perturbative kinetic-relativistic contribution (6.51) to the fine structure of the Bohr levels (93). However, as we already know from Sec. 6.3, for a spin- $\frac{1}{2}$ particle such as the electron, the spin-orbit interaction (6.55) gives an additional contribution to the fine structure, of the same order, so that the net result, confirmed by experiment, is given by Eq. (6.60), i.e. is different from Eq. (94). This is very natural, because the relativistic Schrödinger equation does not have the very notion of spin.

Second, even for massive spinless particles (such as the Z^0 bosons), for which this equation is believed to be valid, the most important problems are related to particle interactions at high energies of

⁵⁰ This task is left for the reader's exercise.

the order of $\Delta E \sim 2mc^2$ and beyond – see Eq. (88). Due to the possibility of creation and annihilation of particle-antiparticle pairs at such energies, the number of particles participating in such interactions is typically considerable (and variable), and the adequate description of the system is given not by the relativistic Schrödinger equation (which is formulated in single-particle terms), but by the *quantum field theory* – to which I will devote only a few sentences in the very end of this chapter.

9.6. Dirac's theory

The real breakthrough toward the quantum relativistic theory of electrons (and other spin- $\frac{1}{2}$ fermions) was achieved in 1928 by P. A. M. Dirac. For that time, the structure of his theory was highly nontrivial. Namely, while formally preserving, in the coordinate representation, the same Schrödinger-picture equation of quantum dynamics as in the non-relativistic quantum mechanics,⁵¹

$$i\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi, \quad (9.95)$$

it postulates that the wavefunction Ψ it describes is not a scalar complex function of time and coordinates, but a *four-component* column-vector (sometimes called the *bispinor*) of such functions, its Hermitian-conjugate bispinor Ψ^\dagger being a 4-component row-vector of their complex conjugates:

$$\Psi = \begin{pmatrix} \Psi_1(\mathbf{r}, t) \\ \Psi_2(\mathbf{r}, t) \\ \Psi_3(\mathbf{r}, t) \\ \Psi_4(\mathbf{r}, t) \end{pmatrix}, \quad \Psi^\dagger = (\Psi_1^*(\mathbf{r}, t), \ \Psi_2^*(\mathbf{r}, t), \ \Psi_3^*(\mathbf{r}, t), \ \Psi_4^*(\mathbf{r}, t)), \quad (9.96)$$

and that the Hamiltonian participating in Eq. (95) is a 4×4 matrix defined in the Hilbert space of bispinors Ψ . For a free particle, the postulated Hamiltonian looks amazingly simple:⁵²

⁵¹ After the “naturally-relativistic” form of the Klein-Gordon equation (84), this apparent return to the non-relativistic Schrödinger equation may look very counter-intuitive. However, it becomes a bit less surprising taking into account the fact (whose proof is left for the reader’s exercise) that Eq. (84) may be also recast into the form (95) for a *two-component* column-vector Ψ (sometimes called *spinor*), with a Hamiltonian which may be represented by a 2×2 matrix – and hence expressed via the Pauli matrices (4.105) and the identity matrix I.

⁵² Moreover, if the time derivative participating in Eq. (95), and the three coordinate derivatives participating (via the momentum operator) in Eq. (97), are merged into one 4-vector operator $\partial/\partial x_k \equiv \{\nabla, \partial/\partial(ct)\}$, the Dirac equation (95) may be rewritten in an even simpler, manifestly Lorentz-invariant 4-vector form (with the implied summation over the repeated index $k = 1, \dots, 4$ – see, e.g., EM Sec. 9.4):

$$\left(\hat{\gamma}_k \frac{\partial}{\partial x_k} + \mu \right) \Psi = 0, \quad \text{where } \hat{\gamma} \equiv \{\hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3\} = \begin{pmatrix} 0 & -i\hat{\sigma} \\ i\hat{\sigma} & 0 \end{pmatrix}, \quad \hat{\gamma}_4 = \hat{\beta},$$

where $\mu \equiv mc/\hbar$ – just as in Eq. (84). Note also that, very counter-intuitively, the Dirac Hamiltonian (97) is *linear* in the momentum, while the non-relativistic Hamiltonian of a particle, as well as the relativistic Schrödinger equation, are *quadratic* in \mathbf{p} . In my humble opinion, the Dirac theory (including the concept of antiparticles it has inspired) may compete for the title of the most revolutionary theoretical idea in physics of all times, despite such strong contenders as Newton’s laws, Maxwell’s equations, Gibbs’ statistical distribution, Bohr’s theory of the hydrogen atom, and Einstein’s general relativity.

$$\hat{H} = c\hat{\mathbf{a}} \cdot \hat{\mathbf{p}} + \hat{\beta}mc^2. \quad (9.97)$$

where $\hat{\mathbf{p}} = -i\hbar\nabla$ is the same 3D vector operator of momentum as in the non-relativistic case, while the operators $\hat{\mathbf{a}}$ and $\hat{\beta}$ may be represented in the following shorthand 2×2 form:

$$\hat{\mathbf{a}} \equiv \begin{pmatrix} \hat{0} & \hat{\sigma} \\ \hat{\sigma} & \hat{0} \end{pmatrix}, \quad \hat{\beta} \equiv \begin{pmatrix} \hat{I} & \hat{0} \\ \hat{0} & -\hat{I} \end{pmatrix}. \quad (9.98a)$$

The operator $\hat{\mathbf{a}}$, composed of the Pauli vector operators $\hat{\sigma}$, is also a vector in the usual 3D space, with each of its 3 Cartesian components being a 4×4 matrix. The particular form of the 2×2 matrices corresponding to the operators $\hat{\sigma}$ and \hat{I} in Eq. (98a) depends on the basis selected for the spin state representation; for example, in the standard z -basis, in which the Cartesian components of $\hat{\sigma}$ are represented by the Pauli matrices (4.105), the 4×4 matrix form of Eq. (98a) is

$$\alpha_x = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}, \quad \alpha_y = \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \\ 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \end{pmatrix}, \quad \alpha_z = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}. \quad (9.98b)$$

It is straightforward to use Eqs. (98) to verify that the matrices α_x , α_y , α_z and β satisfy the following relations:

$$\alpha_x^2 = \alpha_y^2 = \alpha_z^2 = \beta^2 = I, \quad (9.99)$$

$$\alpha_x\alpha_y + \alpha_y\alpha_x = \alpha_y\alpha_z + \alpha_z\alpha_y = \alpha_z\alpha_x + \alpha_x\alpha_z = \alpha_x\beta + \beta\alpha_x = \alpha_y\beta + \beta\alpha_y = \alpha_z\beta + \beta\alpha_z = 0, \quad (9.100)$$

i.e. anticommute.

Using these commutation relations, and acting essentially as in Sec. 1.4, it is straightforward to show that any solution to the Dirac equation obeys the probability conservation law, i.e. the continuity equation (1.52), with the probability density:

$$w = \Psi^\dagger \Psi, \quad (9.101)$$

and the probability current,

$$\mathbf{j} = \Psi^\dagger c\hat{\mathbf{a}} \Psi, \quad (9.102)$$

looking *almost* as in the non-relativistic wave mechanics – cf. Eqs. (1.22) and (1.47). Note, however, the Hermitian conjugation used in these formulas instead of the complex conjugation, to form the scalars w , j_x , j_y , and j_z from the 4-component state vectors (96).

This close similarity is extended to the fundamental, plane-wave solutions of the Dirac equations in free space. Indeed, plugging such solution, in the form

$$\Psi = ue^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)} \equiv \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)}, \quad (9.103)$$

into Eqs. (95) and (97), we see that they are indeed satisfied, provided that a system of four coupled, linear algebraic equations for four complex *c*-number amplitudes $u_{1,2,3,4}$ is satisfied. The condition of its consistency yields the same dispersion relation (87), i.e. the same two-branch diagram shown in Fig. 6, as follows from the Klein-Gordon equation. The difference is that plugging each value of ω , given by Eq. (87), back into the system of the linear equations for four amplitudes u , we get two solutions for their vector $\mathbf{u} \equiv (u_1, u_2, u_3, u_4)$ for each of the two energy branches – see Fig. 6 again. In the standard *z*-basis of spin operators, they may be represented as follows:

$$\text{for } E = E_+ > 0 : \quad \mathbf{u}_{+\uparrow} = c_{+\uparrow} \begin{pmatrix} 1 \\ 0 \\ \frac{cp_z}{E_+ + mc^2} \\ \frac{cp_+}{E_+ + mc^2} \end{pmatrix}, \quad \mathbf{u}_{+\downarrow} = c_{+\downarrow} \begin{pmatrix} 0 \\ 1 \\ \frac{cp_-}{E_+ + mc^2} \\ \frac{-cp_z}{E_+ + mc^2} \end{pmatrix}, \quad (9.104a)$$

$$\text{for } E = E_- < 0 : \quad \mathbf{u}_{-\uparrow} = c_{-\uparrow} \begin{pmatrix} \frac{cp_z}{E_- - mc^2} \\ \frac{cp_+}{E_- - mc^2} \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{u}_{-\downarrow} = c_{-\downarrow} \begin{pmatrix} \frac{cp_-}{E_- - mc^2} \\ \frac{-cp_z}{E_- - mc^2} \\ 0 \\ 1 \end{pmatrix}, \quad (9.104b)$$

where $p_{\pm} \equiv p_x \pm ip_y$, and c_{\pm} are normalization coefficients.

The simplest interpretation of these solutions is that Eq. (103), with the vectors \mathbf{u}_+ given by Eq. (104a), represents a spin-½ particle (say, an electron), while with the vectors \mathbf{u}_- given by Eq. (104b), it represents an antiparticle (a positron), and the two solutions for each particle, indexed with opposite arrows, correspond to two possible directions of the spin-½, $\sigma_z = \pm 1$, i.e. $S_z = \pm \hbar/2$. This interpretation is indeed solid in the non-relativistic limit, when two last components of the vector (104a), and two first components of the vector (104b) are negligibly small:

$$\mathbf{u}_{+\uparrow} \rightarrow \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{u}_{+\downarrow} \rightarrow \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{u}_{-\uparrow} \rightarrow \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{u}_{-\downarrow} \rightarrow \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}, \quad \text{for } \frac{p_{x,y,z}}{mc} \rightarrow 0. \quad (9.105)$$

However, at arbitrary energies, the physical picture is more complex. To show this, let us use the Dirac equation to calculate the Heisenberg-picture law of time evolution of the operator of some Cartesian component of the orbital angular momentum $\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}$, for example of $L_x = yp_z - zp_y$, taking into account that the Dirac operators (98a) commute with those of \mathbf{r} and \mathbf{p} , and also the Heisenberg commutation relations (2.14):

$$i\hbar \frac{\partial \hat{L}_x}{\partial t} = [\hat{L}_x, \hat{H}] = c\hat{\mathbf{a}} \cdot [(\hat{y}\hat{p}_z - \hat{z}\hat{p}_y), \hat{\mathbf{p}}] = -i\hbar c (\hat{\alpha}_z \hat{p}_y - \hat{\alpha}_y \hat{p}_z), \quad (9.106)$$

with similar relations for two other Cartesian components. Since the right-hand side of these equations is different from zero, the orbital momentum is generally *not* conserved – even for a free particle! Let us, however, consider the following vector operator,

$$\hat{\mathbf{S}} \equiv \frac{\hbar}{2} \begin{pmatrix} \hat{\boldsymbol{\sigma}} & \hat{0} \\ \hat{0} & \hat{\boldsymbol{\sigma}} \end{pmatrix}. \quad (9.107a)$$

Spin operator in Dirac's theory

According to Eqs. (4.105), its Cartesian components, in the z -basis, are represented by 4×4 matrices

$$\mathbf{S}_x = \frac{\hbar}{2} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{S}_y = \frac{\hbar}{2} \begin{pmatrix} 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \end{pmatrix}, \quad \mathbf{S}_z = \frac{\hbar}{2} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}. \quad (9.107b)$$

Let us calculate the Heisenberg-picture law of time evolution of these components, for example

$$i\hbar \frac{\partial \hat{S}_x}{\partial t} = [\hat{S}_x, \hat{H}] = c[\hat{S}_x, (\hat{\alpha}_x \hat{p}_x + \hat{\alpha}_y \hat{p}_y + \hat{\alpha}_z \hat{p}_z)]. \quad (9.108)$$

A direct calculation of the commutators of the matrices (98) and (107) yields

$$[\hat{S}_x, \hat{\alpha}_x] = 0, \quad [\hat{S}_x, \hat{\alpha}_y] = i\hbar \hat{\alpha}_z, \quad [\hat{S}_x, \hat{\alpha}_z] = -i\hbar \hat{\alpha}_y, \quad (9.109)$$

so that we finally get

$$i\hbar \frac{\partial \hat{S}_x}{\partial t} = i\hbar c(\hat{\alpha}_z \hat{p}_y - \hat{\alpha}_y \hat{p}_z), \quad (9.110)$$

with similar expressions for the other two components of the operator. Comparing this result with Eq. (106), we see that any Cartesian component of the operator defined similarly to Eq. (5.170),

$$\hat{\mathbf{J}} \equiv \hat{\mathbf{L}} + \hat{\mathbf{S}}, \quad (9.111)$$

is an integral of motion,⁵³ so that this operator may be interpreted as the one representing the total angular momentum of the particle. Hence, the operator (107) *may* be interpreted as the spin operator of a spin-½ particle (e.g., electron). As it follows from the last of Eq. (107b), in the non-relativistic limit the columns (105) represent the eigenkets of the z -component of that operator, with eigenstates $S_z = \pm\hbar/2$, with the sign corresponding to on the arrow index. So, the Dirac theory provides a justification for spin-½ – or, somewhat more humbly, replaces the Pauli Hamiltonian postulate (4.163) with that of a simpler (and hence more plausible), Lorentz-invariant Hamiltonian (97).

Note, however, that this simple interpretation, fully separating a particle from its antiparticle, is not valid for the exact solutions (103)-(104), so that generally the eigenstates of the Dirac Hamiltonian are certain linear (coherent) superpositions of the components describing the particle and its antiparticle – each with both directions of spin. This fact leads to several interesting effects, including the so-called *Klien paradox* at the reflection of a relativistic electron from a potential barrier.⁵⁴

⁵³ It is straightforward to show that this result remains valid for a particle in any central field $U(r)$.

⁵⁴ See, e.g., A. Calogeracos and N. Dombey, *Contemp. Phys.* **40**, 313 (1999).

9.7. Low-energy limit

The generalization of Dirac's theory to the case of a (spin-1/2) particle with an electric charge q , moving in a classically-described electromagnetic field, may be obtained using the same replacement (90). As a result, Eq. (95) turns into

$$\boxed{[c\hat{\mathbf{a}} \cdot (-i\hbar\nabla - q\mathbf{A}) + mc^2\hat{\beta} + (q\phi - \hat{H})]\Psi = 0,} \quad (9.112)$$

Dirac equation
in EM field

where the Hamiltonian operator \hat{H} is understood in the sense of Eq. (95), i.e. as the partial time derivative with the multiplier $i\hbar$. Let us prepare this equation for a low-energy approximation by acting on its left-hand side by a similar square bracket but with the opposite sign before the last parentheses – also an operator! Using Eqs. (99) and (100), and the fact that the space- and time-independent operators $\hat{\mathbf{a}}$ and $\hat{\beta}$ commute with the spin-independent, c -number functions $\mathbf{A}(\mathbf{r}, t)$ and $\phi(\mathbf{r}, t)$, as well as with the Hamiltonian operator $i\hbar\partial/\partial t$, the result is

$$\left\{ c^2[\hat{\mathbf{a}} \cdot (-i\hbar\nabla - q\mathbf{A})]^2 + (mc^2)^2 - c[\hat{\mathbf{a}} \cdot (-i\hbar\nabla - q\mathbf{A}), (q\phi - \hat{H})] - (q\phi - \hat{H})^2 \right\} \Psi = 0. \quad (9.113)$$

A direct calculation of the first square bracket, using Eqs. (98) and (107), yields

$$[\hat{\mathbf{a}} \cdot (-i\hbar\nabla - q\mathbf{A})]^2 \equiv (-i\hbar\nabla - q\mathbf{A})^2 - 2q\hat{\mathbf{S}} \cdot \nabla \times \mathbf{A}. \quad (9.114)$$

But the last vector product on the right-hand side is just the magnetic field – see, e.g., Eqs. (3.21):

$$\mathcal{B} = \nabla \times \mathbf{A}. \quad (9.115)$$

Similarly, we may use the first of Eqs. (3.21), for the electric field,

$$\mathcal{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t}, \quad (9.116)$$

to simplify the commutator participating in Eq. (9.113):

$$[\hat{\mathbf{a}} \cdot (-i\hbar\nabla - q\mathbf{A}), (q\phi - \hat{H})] \equiv -q\hat{\mathbf{a}} \cdot [\hat{H}, \mathbf{A}] - i\hbar q\hat{\mathbf{a}} \cdot [\nabla, \phi] \equiv -i\hbar q \frac{\partial\mathbf{A}}{\partial t} - i\hbar\hat{\mathbf{a}} \cdot \nabla\phi \equiv i\hbar q\hat{\mathbf{a}} \cdot \mathcal{E}. \quad (9.117)$$

As a result, Eq. (113) becomes

$$\left\{ c^2(-i\hbar\nabla - q\mathbf{A})^2 + (q\phi - \hat{H})^2 - (mc^2)^2 - 2qc^2\hat{\mathbf{S}} \cdot \mathcal{B} + i\hbar c q\hat{\mathbf{a}} \cdot \mathcal{E} \right\} \Psi = 0. \quad (9.118)$$

So far, this is an exact result, equivalent to Eq. (112), but it is more convenient for an analysis of the low-energy limit, in which not only the energy offset $E - mc^2$ (which is just the energy used in the non-relativistic mechanics), but also the electrostatic energy of the particle, $|q\langle\phi\rangle|$, are much smaller than the rest energy mc^2 . In this limit, the second and third terms of Eq. (118) almost cancel, and introducing the offset Hamiltonian

$$\hat{H} \equiv \hat{H} - mc^2\hat{I}. \quad (9.119)$$

we may approximate their difference, up to the first non-zero term, as

$$(q\phi\hat{I} - \hat{H})^2 - (mc^2)^2\hat{I} \equiv \left(q\phi\hat{I} - mc^2\hat{I} - \hat{H} \right)^2 - (mc^2)^2\hat{I} \approx 2mc^2\left(\hat{H} - q\phi\hat{I} \right). \quad (9.120)$$

As a result, after the division of all terms by $2mc^2$, Eq. (118) may be approximated as

$$\hat{H}\Psi = \left[\frac{1}{2m}(-i\hbar\nabla - q\mathbf{A})^2 + q\phi - \frac{q}{m}\hat{\mathbf{S}} \cdot \mathcal{B} + \frac{i\hbar q}{2mc}\hat{\mathbf{a}} \cdot \mathcal{E} \right] \Psi. \quad (9.121)$$

Let us discuss this important result. The first two terms in the square brackets give the non-relativistic Hamiltonian (3.26), which was extensively used in Chapter 3 for the discussion of charged particle motion. Note again that the contribution of the vector potential \mathbf{A} into that Hamiltonian is essentially relativistic, in the following sense: when used for the description of magnetic interaction of two charged particles, due to their *orbital* motion with speed $v \ll c$, the magnetic interaction is a factor of $(v/c)^2$ smaller than the electrostatic interaction of the particles.⁵⁵ The reason why we did discuss the effects of \mathbf{A} in Chapter 3 was that it was used there to describe *external* magnetic fields, keeping our analysis valid even for the cases when that field is strong because of being produced by relativistic effects – such as aligned spins of a permanent magnet.

The next, third term in the square brackets of Eq. (121) should be also familiar to the reader: this is the Pauli Hamiltonian – see Eqs. (4.3), (4.5), and (4.163). When justifying this form of interaction in Chapter 4, I referred mostly to the results of Stern-Gerlach-type experiments, but it is extremely pleasing that this result⁵⁶ follows from such a fundamental relativistic treatment as Dirac's theory. As we already know from the discussion of the Zeeman effect in Sec. 6.4, the magnetic field effects on the orbital motion of an electron (described by the orbital angular momentum \mathbf{L}) and its spin \mathbf{S} are of the same order, though quantitatively different.

Finally, the last term in the square brackets of Eq. (121) is also not quite new for us: in particular, it describes the spin-orbit interaction. Indeed, in the case of a classical, spherical-symmetric electric field \mathcal{E} corresponding to the potential $\phi(r) = U(r)/q$, this term may be reduced to Eq. (6.56):

$$\hat{H}_{\text{so}} = \frac{1}{2m^2c^2}\hat{\mathbf{S}} \cdot \hat{\mathbf{L}} \frac{1}{r} \frac{dU}{dr} \equiv -\frac{q}{2m^2c^2}\hat{\mathbf{S}} \cdot \hat{\mathbf{L}} \frac{1}{r}\mathcal{E}. \quad (9.122)$$

The proof of this correspondence requires a bit of additional work.⁵⁷ Indeed, in Eq. (121), the term responsible for the spin-orbit interaction acts on 4-component wavefunctions, while the Hamiltonian (122) is supposed to act on non-relativistic state vectors with an account of spin, whose coordinate representation may be given by 2-component spinors:⁵⁸

⁵⁵ This difference may be traced by classical means – see, e.g., EM Sec. 5.1.

⁵⁶ Note that in this result, the g -factor of the particle is still equal to exactly 2 – see Eq. (4.115) and its discussion in Sec. 4.4. In order to describe the small deviation of g_e from 2, the electromagnetic field should be quantized (just as this was discussed in Secs. 1-4 of this chapter), and its potentials \mathbf{A} and ϕ , participating in Eq. (121), should be treated as operators – rather than as c -number functions as was assumed above.

⁵⁷ The only facts immediately evident from Eq. (121) are that the term we are discussing is proportional to the electric field, as required by Eq. (122), and that it is of the proper order of magnitude. Indeed, Eqs. (101)-(102) imply that in the Dirac theory, $c\hat{\mathbf{a}}$ plays the role of the velocity operator, so that the expectation values of the term are of the order of $\hbar q v \mathcal{E}/2mc^2$. Since the expectation values of the operators participating in the Hamiltonian (122) scale as $S \sim \hbar/2$ and $L \sim mvr$, the spin-orbit interaction energy has the same order of magnitude.

⁵⁸ In this course, the notion of spinor (popular in some textbooks) was not used much; it was introduced earlier only for two-particle states – see Eq. (8.13). For a single particle, such definition is reduced to $\psi(\mathbf{r})|s\rangle$, whose representation in a particular spin-½ basis is the column (123). Note that such spinors may be used as a basis for an expansion of the spin-orbitals $\psi_j(\mathbf{r})$ defined by Eq. (8.125), where the index j is used for numbering both the spin's orientation (i.e. the particular component of the spinor's column) and the orbital eigenfunction.

$$\psi = \begin{pmatrix} \psi_{\uparrow} \\ \psi_{\downarrow} \end{pmatrix}. \quad (9.123)$$

The simplest way to prove the equivalence of these two expressions is not to use Eq. (121) directly, but to return to the Dirac equation (112), for the particular case of motion in a static electric field but no magnetic field, when Dirac's Hamiltonian is reduced to

$$\hat{H} = c\hat{\mathbf{a}} \cdot \hat{\mathbf{p}} + \hat{\beta}mc^2 + U(\mathbf{r}), \quad \text{with } U = q\phi. \quad (9.124)$$

Since this Hamiltonian is time-independent, we may look for its 4-component eigenfunctions in the form

$$\Psi(\mathbf{r}, t) = \begin{pmatrix} \psi_+(\mathbf{r}) \\ \psi_-(\mathbf{r}) \end{pmatrix} \exp\left(-i\frac{E}{\hbar}t\right), \quad (9.125)$$

where each of ψ_{\pm} is a 2-component column of the type (123), representing two spin states of the particle (index +) and its antiparticle (index -). Plugging Eq. (125) into Eq. (95) with the Hamiltonian (124), and using Eq. (98a), we get the following system of two linear equations:

$$[E - mc^2 - U(\mathbf{r})]\psi_+ - c\hat{\mathbf{a}} \cdot \hat{\mathbf{p}}\psi_- = 0, \quad [E + mc^2 - U(\mathbf{r})]\psi_- - c\hat{\mathbf{a}} \cdot \hat{\mathbf{p}}\psi_+ = 0. \quad (9.126)$$

Expressing ψ_- from the latter equation, and plugging the result into the former one, we get the following single equation for the particle's spinor:

$$\left[E - mc^2 - U(\mathbf{r}) - c^2\hat{\mathbf{a}} \cdot \hat{\mathbf{p}} \frac{1}{E + mc^2 - U(\mathbf{r})}\hat{\mathbf{a}} \cdot \hat{\mathbf{p}} \right] \psi_+ = 0. \quad (9.127)$$

So far, this is an exact equation for eigenstates and eigenvalues of the Hamiltonian (124), but it may be substantially simplified in the low-energy limit when both the potential energy⁵⁹ and the non-relativistic eigenenergy

$$\tilde{E} \equiv E - mc^2 \quad (9.128)$$

are much lower than mc^2 . Indeed, in this case, the expression in the denominator of the last term in the brackets of Eq. (127) is close to $2mc^2$. Since $\sigma^2 = 1$, with that replacement, Eq. (127) is reduced to the non-relativistic Schrödinger equation, similar for both spin components of ψ_+ , and hence giving spin-degenerate energy levels. To recover small relativistic and spin-orbit effects, we need a slightly more accurate approximation:

$$\frac{1}{E + mc^2 - U(\mathbf{r})} \equiv \frac{1}{2mc^2 + \tilde{E} - U(\mathbf{r})} \equiv \frac{1}{2mc^2} \left[1 + \frac{\tilde{E} - U(\mathbf{r})}{2mc^2} \right]^{-1} \approx \frac{1}{2mc^2} \left[1 - \frac{\tilde{E} - U(\mathbf{r})}{2mc^2} \right], \quad (9.129)$$

in which Eq. (127) is reduced to

$$\left[\tilde{E} - U(\mathbf{r}) - \frac{\hat{\mathbf{p}}^2}{2m} + \hat{\mathbf{a}} \cdot \hat{\mathbf{p}} \frac{\tilde{E} - U(\mathbf{r})}{(2mc^2)^2} \hat{\mathbf{a}} \cdot \hat{\mathbf{p}} \right] \psi_+ = 0. \quad (9.130)$$

As Eqs. (5.34) shows, the operators of the momentum and of a function of coordinates commute as

$$[\hat{\mathbf{p}}, U(\mathbf{r})] = -i\hbar \nabla U, \quad (9.131)$$

⁵⁹ Strictly speaking, this requirement is imposed on the expectation values of $U(\mathbf{r})$ in the eigenstates to be found.

so that the last term in the square brackets of Eq. (130) may be rewritten as

$$\hat{\sigma} \cdot \hat{p} \frac{\tilde{E} - U(\mathbf{r})}{(2mc)^2} \hat{\sigma} \cdot \hat{p} \equiv \frac{\tilde{E} - U(\mathbf{r})}{(2mc)^2} \hat{p}^2 - \frac{i\hbar}{(2mc)^2} (\hat{\sigma} \cdot \nabla U)(\hat{\sigma} \cdot \hat{p}). \quad (9.132)$$

Since in the low-energy limit, both terms on the right-hand side of this relation are much smaller than the three leading terms of Eq. (130), we may replace the first term's numerator with its non-relativistic approximation $\hat{p}^2 / 2m$. With this replacement, the term coincides with the first relativistic correction to the kinetic energy operator – see Eq. (6.47). The second term, proportional to the electric field $\mathcal{E} = -\nabla\phi = -\nabla U/q$, may be transformed further on, using a readily verifiable identity

$$(\hat{\sigma} \cdot \nabla U)(\hat{\sigma} \cdot \hat{p}) \equiv (\nabla U) \cdot \hat{p} + i\hat{\sigma} \cdot [(\nabla U) \times \hat{p}]. \quad (9.133)$$

Of the two terms on the right-hand side of this relation, only the second one depends on spin,⁶⁰ giving the following spin-orbital interaction contribution to the Hamiltonian,

$$\hat{H}_{\text{so}} = \frac{\hbar}{(2mc)^2} \hat{\sigma} \cdot [(\nabla U) \times \hat{p}] \equiv \frac{q}{2m^2 c^2} \hat{\mathbf{S}} \cdot [(\nabla\phi) \times \hat{p}]. \quad (9.134)$$

For a central potential $\phi(r)$, its gradient has only the radial component: $\nabla\phi = (d\phi/dr)\mathbf{r}/r = -\mathcal{E}\mathbf{r}/r$, and with the angular momentum definition (5.147), Eq. (134) is (finally!) reduced to Eq. (122).

As was shown in Sec. 6.3, the perturbative treatment of Eq. (122), together with the kinetic-relativistic correction (6.47), in the hydrogen-like atom/ion problem, leads to the fine structure of each Bohr level E_n , given by Eq. (6.60):

$$\Delta E_{\text{fine}} = -\frac{2E_n}{mc^2} \left(3 - \frac{4n}{j + \frac{1}{2}} \right). \quad (9.135)$$

This result receives a confirmation from the surprising fact that for the hydrogen-like atom/ion problem, the Dirac equation may be solved *exactly* – without any assumptions. I would not have time/space to reproduce the solution,⁶¹ and will only list the final result for the energy spectrum:

$$\frac{E}{mc^2} = \left\{ 1 + \frac{Z^2 \alpha^2}{\left[n + \left\{ (j + \frac{1}{2})^2 - Z^2 \alpha^2 \right\}^{1/2} - (j + \frac{1}{2}) \right]^2} \right\}^{-1/2}. \quad (9.136)$$

Here $n = 1, 2, \dots$ is the same principal quantum number as in Bohr's theory, while j is the quantum number specifying the eigenvalues (5.175) of J^2 , in our case of a spin-½ particle taking half-integer values: $j = l \pm \frac{1}{2} = 1/2, 3/2, 5/2, \dots$ – see Eq. (5.189). This is natural, because due to the spin-orbit interaction, the orbital momentum and spin are not conserved, while their vector sum, $\mathbf{J} = \mathbf{L} + \mathbf{S}$, is – at least in the absence of an external field. Each energy level (136) is doubly-degenerate, with two eigenstates representing two directions of the spin. (In the low-energy limit, we may say: corresponding to two values of $l = j \mp \frac{1}{2}$, at fixed j .)

⁶⁰ The first term gives a small spin-independent energy shift, which is very difficult to verify experimentally.

⁶¹ Good descriptions of the solution are available in many textbooks (the older the better :-) – see, e.g., Sec. 53 in L. Schiff, *Quantum Mechanics*, 3rd ed., McGraw-Hill (1968).

Speaking of that limit (when $E - mc^2 \sim E_H \ll mc^2$): since according to Eq. (1.13) for E_H , the square of the fine-structure constant $\alpha \equiv e^2/4\pi\epsilon_0\hbar c$ may be represented as the ratio E_H/mc^2 , we may follow this limit expanding Eq. (136) into the Taylor series in $(Z\alpha)^2 \ll 1$. The result,

$$E \approx mc^2 \left[1 - \frac{Z^2 \alpha^2}{2n^2} - \frac{Z^4 \alpha^4}{2n^4} \left(\frac{n}{|j + \frac{1}{2}|} - \frac{3}{4} \right) \right], \quad (9.137)$$

has the same structure, and allows the same interpretation as Eq. (92), but with the last term coinciding with Eq. (6.60) – and with experimental results. Historically, this correct description of the fine structure of the atomic levels provided the decisive proof of Dirac's theory.

However, even such an impressive theory does not have too many direct applications. The main reason for that was already discussed in brief in the end of Sec. 5: due to the possibility of creation and annihilation of particle-antiparticle pairs by an energy influx higher than $2mc^2$, the number of particles participating in high-energy interactions is not fixed. An adequate general description of such situations is given by the quantum field theory, in which the particle's wavefunction is treated as a field to be quantized, using so-called *field operators* $\hat{\Psi}(\mathbf{r}, t)$ – very much similar to the electromagnetic field operators (16). The Dirac equation follows from such theory in the single-particle approximation.

As was mentioned above on several occasions, the quantum field theory is well beyond the time/space limits of this course, and I have to stop here, referring the interested reader to one of several excellent textbooks on this discipline.⁶² However, I would strongly encourage the students going in this direction to start by playing with the field operators on their own, taking clues from Eqs. (16), but replacing the creation/annihilations operators \hat{a}_j^\dagger and \hat{a}_j of the electromagnetic field oscillators with those of the general second quantization formalism outlined in Sec. 8.3.

9.8. Exercise problems

9.1. Prove the Casimir formula, given by Eq. (23), by calculating the net force $F = \mathcal{P}A$ exerted by the electromagnetic field, in its ground state, on two perfectly conducting parallel plates of area A , separated by a vacuum gap of width $t \ll A^{1/2}$.

Hint: Calculate the field energy in the gap volume with and without the account of the plate effect, and then apply the Euler-Maclaurin formula⁶³ to the difference between these two results.

9.2. Electromagnetic radiation by some single-mode quantum sources may have such a high degree of coherence that it is possible to observe the interference of waves from two independent sources with virtually the same frequency, incident on one detector.

(i) Generalize Eq. (29) to this case.

⁶² For a gradual introduction see, e.g., either L. Brown, *Quantum Field Theory*, Cambridge U. Press (1994) or R. Klauber, *Student Friendly Quantum Field Theory*, Sandtrove (2013). On the other hand, M. Srednicki, *Quantum Field Theory*, Cambridge U. Press (2007) and A. Zee, *Quantum Field Theory in a Nutshell*, 2nd ed., Princeton (2010), among others, offer steeper learning curves.

⁶³ See, e.g., MA Eq. (2.12a).

(ii) Use this generalized expression to show that incident waves in different Fock states do not create an interference pattern.

9.3. Calculate the zero-delay value $g^{(2)}(0)$ of the second-order correlation function of a single-mode electromagnetic field in the so-called *Schrödinger-cat state*:⁶⁴ a coherent superposition of two Glauber states, with equal but sign-opposite parameters α , and a certain phase shift between them.

9.4. Calculate the zero-delay value $g^{(2)}(0)$ of the second-order correlation function of a single-mode electromagnetic field in the squeezed ground state ζ defined by Eq. (5.142).

9.5. Calculate the rate of spontaneous photon emission (into unrestricted free space) by a hydrogen atom, initially in the $2p$ state ($n = 2, l = 1$) with $m = 0$. Would the result be different for $m = \pm 1$ for the $2s$ state ($n = 2, l = 0, m = 0$)? Discuss the relation between these quantum-mechanical results and those given by the classical theory of radiation for the simplest classical model of the atom.

9.6. An electron has been placed on the lowest excited level of a spherically-symmetric, quadratic potential well $U(\mathbf{r}) = m_e\omega^2 r^2/2$. Calculate the rate of its relaxation to the ground state, with the emission of a photon (into unrestricted free space). Compare the rate with that for a similar transition of the hydrogen atom, for the case when the radiation frequencies of these two systems are equal.

9.7. Derive an analog of Eq. (53) for the spontaneous photon emission into the free space, due to a change of the *magnetic* dipole moment \mathbf{m} of a small-size system.

9.8. A spin- $1/2$ particle, with a gyromagnetic ratio γ , is in its orbital ground state in dc magnetic field \mathcal{B}_0 . Calculate the rate of its spontaneous transition from the higher to the lower energy level, with the emission of a photon into the free space. Evaluate this rate for an electron in a field of 10 T, and discuss the implications of this result for laboratory experiments with electron spins.

9.9. Calculate the rate of spontaneous transitions between the two sublevels of the ground state of a hydrogen atom, formed as a result of its hyperfine splitting. Discuss the implications of the result for the width of the 21-cm spectral line of hydrogen.

9.10. Find the eigenstates and eigenvalues of the Jaynes-Cummings Hamiltonian (78), and discuss their behavior near the resonance point $\omega = \Omega$.

9.11. Analyze the Purcell effect, mentioned in Secs. 3 and 4, quantitatively; in particular, calculate the so-called *Purcell factor* F_P defined as the ratio of the rate Γ_s of atom's spontaneous emission into a resonant cavity tuned exactly to the quantum transition frequency, to that into the free space.

9.12. Prove that the Klein-Gordon equation (84) may be rewritten in the form similar to the non-relativistic Schrödinger equation (1.25), but for a two-component wavefunction, with the Hamiltonian represented (in the usual z -basis) by the following 2×2 -matrix:

⁶⁴ Its name stems from the well-known *Schrödinger cat paradox*, which is (very briefly) discussed in Sec. 10.1.

$$H = -(\sigma_z + i\sigma_y) \frac{\hbar^2}{2m} \nabla^2 + mc^2 \sigma_z.$$

Use your solution to discuss the physical meaning of the wavefunction's components.

9.13. Calculate and discuss the energy spectrum of a relativistic, spinless, charged particle placed into an external uniform, time-independent magnetic field \mathcal{B} . Use the result to formulate the condition of validity of the non-relativistic theory in this situation.

9.14. Prove Eq. (91) for the energy spectrum of a hydrogen-like atom/ion, starting from the relativistic Schrödinger equation.

Hint: A mathematical analysis of Eq. (3.193) shows that its eigenvalues are given by Eq. (3.201), $\varepsilon_n = -1/2n^2$, with $n = l + 1 + n_r$, where $n_r = 0, 1, 2, \dots$, even if the parameter l is not integer.

9.15. Derive a general expression for the differential cross-section of elastic scattering of a spinless relativistic particle by a static potential $U(\mathbf{r})$, in the Born approximation, and formulate the conditions of its validity. Use these results to calculate the differential cross-section of scattering of a particle with the electric charge $-e$ by the Coulomb electrostatic potential $\phi(\mathbf{r}) = Ze/4\pi\varepsilon_0 r$.

9.16. Starting from Eqs. (95)-(98), prove that the probability density w given by Eq. (101) and the probability current density \mathbf{j} defined by Eq. (102) do indeed satisfy the continuity equation (1.52): $\partial w/\partial t + \nabla \cdot \mathbf{j} = 0$.

9.17. Calculate the commutator of the operator \hat{L}^2 and Dirac's Hamiltonian of a free particle. Compare the result with that for the non-relativistic Hamiltonian, and interpret the difference.

9.18. Calculate commutators of the operators \hat{S}^2 and \hat{J}^2 with Dirac's Hamiltonian (97), and give an interpretation of the results.

9.19. In the Heisenberg picture of quantum dynamics, derive an equation describing the time evolution of free electron's velocity in the Dirac theory. Solve the equation for the simplest state, with definite energy and momentum, and discuss the solution.

9.20. Calculate the eigenstates and eigenenergies of a relativistic spin- $1/2$ particle with charge q , placed into a uniform, time-independent external magnetic field \mathcal{B} . Compare the calculated energy spectrum with those following from the non-relativistic theory and the relativistic Schrödinger equation.

9.21.* Following the discussion at the very end of Section 7, introduce quantum field operators $\hat{\psi}$ that would be related to the usual wavefunctions ψ just as the electromagnetic field operators (16) are related to the classical electromagnetic fields, and explore basic properties of these operators. (For this preliminary study, consider the fixed-time situation.)

Chapter 10. Making Sense of Quantum Mechanics

This (rather brief) chapter addresses some conceptually important issues of quantum measurements and quantum state interpretation. Please note that some of these issues are still subjects of debate¹ – fortunately not affecting quantum mechanics' practical results, discussed in the previous chapters.

10.1. Quantum measurements

The knowledge base outlined in the previous chapters gives us a sufficient background for a (by necessity, very brief) discussion of *quantum measurements*.² Let me start by reminding the reader of the only postulate of the quantum theory that relates it to experiment – so far, meaning *perfect* measurements. In the simplest case when the system is in a coherent (pure) quantum state, its ket-vector may be represented as a linear superposition

$$|\alpha\rangle = \sum_j \alpha_j |a_j\rangle, \quad (10.1)$$

where a_j are the eigenstates of the operator of an observable A , related to its eigenvalues A_j by Eq. (4.68):

$$\hat{A}|a_j\rangle = A_j|a_j\rangle. \quad (10.2)$$

In such a state, the outcome of every single measurement of the observable A may be uncertain, but is restricted to the set of eigenvalues A_j , with the j^{th} outcome probability equal to

$$W_j = |\alpha_j|^2. \quad (10.3)$$

As was discussed in Chapter 7, the state of the system (or rather of the statistical ensemble of macroscopically similar systems we are using for this particular series of similar experiments) may be not coherent, and hence even more uncertain than the state described by Eq. (1). Hence, the measurement postulate means that even if the system is in this (the least uncertain) state, the measurement outcomes are *still* probabilistic.³

If we believe that a particular measurement may be done perfectly, and do not worry too much how exactly, we are subscribing to the *mathematical* notion of measurement, that was, rather reluctantly, used in these notes – up to this point. However, the actual (*physical*) measurements are *always* imperfect, first of all because of the huge gap between the energy-time scale $\hbar \sim 10^{-34}$ J·s of the quantum phenomena in “microscopic” systems such as atoms, and the “macroscopic” scale of the direct human perception, so that the role of the instruments bridging this gap (Fig. 1), is highly nontrivial.

¹ For an excellent review of these controversies, as presented in a few leading textbooks, I highly recommend J. Bell's paper in the collection by A. Miller (ed.), *Sixty-Two Years of Uncertainty*, Plenum, 1989.

² “Quantum measurements” is a very unfortunate and misleading term; it would be more sensible to speak about “measurements of observables in quantum mechanical systems”. However, the former term is so common and compact that I will use it – albeit rather reluctantly.

³ The measurement outcomes become definite only in the trivial case when the system is definitely in one of the eigenstates a_j , say a_0 ; then $\alpha_j = \delta_{j,0} \exp\{i\varphi\}$, and $W_j = \delta_{j,0}$.

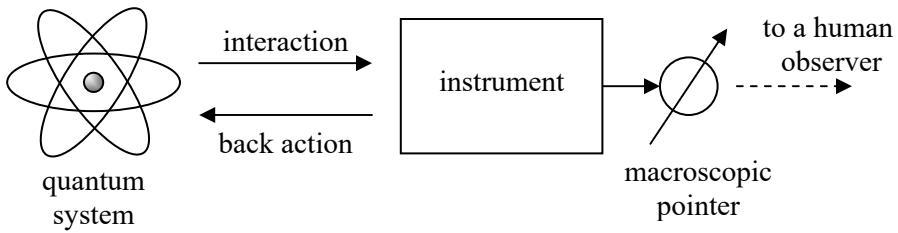

Fig.10.1. The general scheme of a quantum measurement.

Besides the famous Bohr-Einstein discussion in the mid-1930s, which will be briefly reviewed in Sec. 3, the founding fathers of quantum mechanics have not paid much attention to these issues, apparently because of the following reason. At that time it looked like the experimental instruments (at least the best of them :-) were doing exactly what the measurement postulate was telling. For example, the z-oriented Stern-Gerlach experiment (Fig. 4.1) turns two complex coefficients $\alpha\uparrow$ and $\alpha\downarrow$, describing the spin state of the incoming electrons, into a set of particle-counter clicks, with the rates proportional to, respectively, $|\alpha\uparrow|^2$ and $|\alpha\downarrow|^2$. The crude internal nature of these instruments makes more detailed questions unnatural. For example, each click of a Geiger counter involves an effective disappearance of one observed electron in a zillion-particle electric discharge avalanche it has triggered. A century ago, it looked much more important to extend the newly born quantum mechanics to more complex systems (such as atomic nuclei, etc.) than to think about the physics of such instruments.

However, since that time the experimental techniques, notably including high-vacuum and low-temperature systems, micro- and nano-fabrication, and low-noise electronics, have improved quite dramatically. In particular, we now may observe quantum-mechanical behavior of more and more macroscopic objects – such as the micromechanical oscillators mentioned in Sec. 2.9. Moreover, some “macroscopic quantum systems” (in particular, special systems of Josephson junctions, see below) have properties enabling their use as essential parts of measurement setups. Such developments are making the line separating the “micro” and “macro” worlds finer and finer, so that more inquisitive inquiries into the physical nature of quantum measurements are not so hopeless now. In my personal scheme of things,⁴ these inquiries may be grouped as follows:

(i) Does a quantum measurement involve any laws besides those of quantum mechanics? In particular, should it necessarily involve a human/intelligent observer? (The last question is not as laughable as it may look – see below.)

(ii) What is the state of the measured system *just after a single-shot* measurement – meaning a measurement process limited to a time interval much shorter than the time scale of the measured system’s evolution? (This question is a necessary part of any discussion of *repeated measurements* and of their ultimate form – *continuous monitoring* of a certain observable.)

(iii) If a measurement of an observable A has produced a certain outcome A_j , what statements may be made about the state of the system *just before* the measurement? (This question is most closely related to various interpretations of quantum mechanics.)

Let me discuss these issues in the listed order. First of all, I am happy to report that there is a virtual consensus of physicists on some aspects of these issues. According to this consensus, any reasonable quantum measurement needs to result in a certain, distinguishable state of a *macroscopic* output component of the measurement instrument – see Fig. 1. (Traditionally, its component is called a

⁴ Again, this list and some other issues discussed in the balance of this section are still controversial.

pointer, though its role may be played by a printer or a plotter, an electronic circuit sending out the result as a number, etc.). This requirement implies that the measurement process should have the following features:

- provide a large “signal gain”, i.e. some means of mapping the quantum state with its \hbar -scale of action (i.e. of the energy-by-time product) onto a macroscopic position of the pointer with a much larger action scale, and
- if we want to approach the fundamental limit of uncertainty, given by Eq. (3), the instrument should introduce as little additional fluctuations (“noise”) as permitted by the laws of physics.

Both these requirements *are* fulfilled in a well-designed Stern-Gerlach experiment – see Fig. 4.1 again. Indeed, the magnetic field gradient, splitting the electron beam, turns the minuscule (microscopic) energy difference (4.167) between two spin-polarized states into a macroscopic difference between the final positions of two output beams, where their detectors may be located. However, as was noted above, the internal physics of the particle detectors (say, Geiger counters) at this measurement is rather complex, and would not allow us to discuss some aspects of the measurement, in particular to answer the second of inquiries we are working on.

This is why let me describe the scheme of an almost similar “single-shot” measurement of a two-level quantum system, which shares the simplicity, high gain, and low internal noise of the Stern-Gerlach apparatus, but has an advantage that at its certain hardware implementations,⁵ the measurement process allows a thorough, quantitative theoretical description. Let us measure a particle trapped in a double-well potential (Fig. 2), where x is some continuous generalized coordinate – not necessarily a mechanical displacement. Let the particle be initially in a pure quantum state, with the energy close to the well’s bottom. Then, as we know from the discussion of such systems in Secs. 2.6 and 5.1, the state may be described by a ket-vector similar to that of spin-½:

$$|\alpha\rangle = \alpha_{\rightarrow} |\rightarrow\rangle + \alpha_{\leftarrow} |\leftarrow\rangle, \quad (10.4)$$

where the component states \rightarrow and \leftarrow is described by wavefunctions localized near the potential well bottoms at $x \approx \pm x_0$ – see the blue lines in Fig. 2. Our goal is to measure in which well the particle resides at a certain time instant, say at $t = 0$. For that, let us rapidly change, at that moment, the potential profile of the system, so that at $t > 0$, near the origin, it may be well described by an inverted parabola:

$$U(x) \approx -\frac{m\lambda^2}{2} x^2, \quad \text{for } t > 0, \quad |x| \ll x_f. \quad (10.5)$$

⁵ The scheme may be implemented, for example, using a simple Josephson-junction circuit called the *balanced comparator* – see, e.g., T. Walls *et al.*, *IEEE Trans. on Appl. Supercond.* **17**, 136 (2007), and references therein. Experiments have demonstrated that this system may have a measurement variance dominated by the theoretically expected quantum-mechanical uncertainty, at practicable experimental conditions (at temperatures below $\sim 1\text{K}$). A conceptual advantage of this system is that it is based on externally-shunted Josephson junctions, i.e. the devices whose quantum-mechanical model, including its part describing the coupling to the environment, is in a quantitative agreement with experiment – see, e.g., D. Schwartz *et al.*, *Phys. Rev. Lett.* **55**, 1547 (1985). Colloquially, the balanced comparator is a high-gain instrument with a “well-documented Hamiltonian”, eliminating the need for speculations about the environmental effects. In particular, the dephasing process in it, and its time T_2 , are well described by Eqs. (7.89) and (7.142), with the coefficients η equal to the Ohmic conductances G of the shunts.

It is straightforward to verify that the Heisenberg equations of motion in such an inverted potential describe exponential growth of operator \hat{x} in time (proportional to $\exp\{\lambda t\}$) and hence a similar, proportional growth of the expectation value $\langle x \rangle$ and its r.m.s. uncertainty δx .⁶ At this “inflation” stage, the coherence between the two component states \rightarrow and \leftarrow is still preserved, i.e. the time evolution of the system is, in principle, reversible.

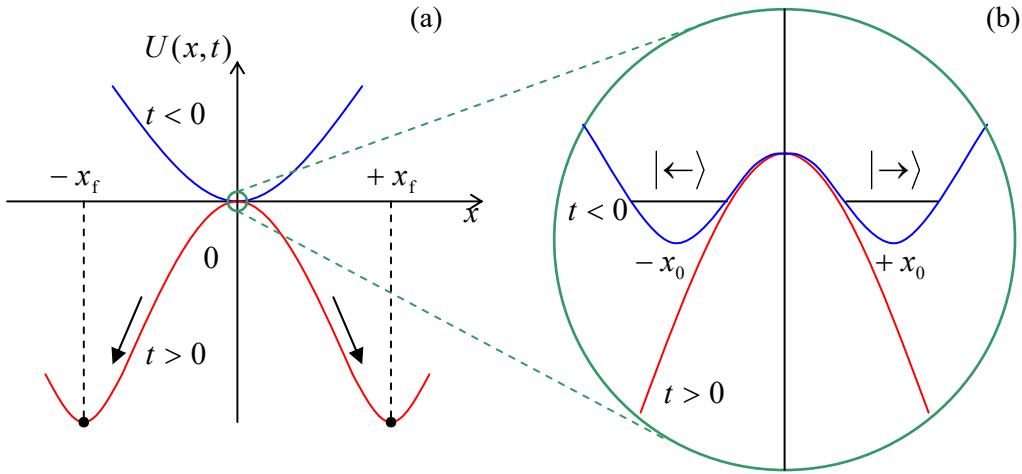

Fig. 10.2. The potential inversion, as viewed on the (a) “macroscopic” and (b) “microscopic” scales of the generalized coordinate x .

Now let the system be weakly coupled, also at $t > 0$, to a dissipative (e.g., Ohmic) environment. As we know from Chapter 7, such coupling ensures the state’s dephasing on some time scale T_2 . If

$$x_0 \ll x_0 \exp\{\lambda T_2\}, x_f, \quad (10.6)$$

then the process, after the potential inversion, consists of two stages, well separated in time:

- the already discussed “inflation” stage, preserving the component the state’s coherence, and
- the dephasing stage, at which the coherence of the component states \rightarrow and \leftarrow is gradually suppressed as described by Eq. (7.89), i.e. the density matrix of the system is gradually reduced to the diagonal form describing a classical mixture of two probability packets with the probabilities (3) equal to, respectively, $W_{\rightarrow} = |\alpha_{\rightarrow}|^2$ and $W_{\leftarrow} = |\alpha_{\leftarrow}|^2 \equiv 1 - |\alpha_{\rightarrow}|^2$.

Besides dephasing, the environment gives the motion certain kinematic friction, with the drag coefficient η (7.141), so that the system eventually settles to rest at one of the macroscopically separated minima $x = \pm x_f$ of the inverted potential (Fig. 2a), thus ensuring a high “signal gain” $x_f/x_0 \gg 1$. As a result, the final probability density distribution $w(x)$ along the x -axis has two narrow, well-separated peaks. But this is just the situation that was discussed in Sec. 2.5 – see, in particular, Fig. 2.17. Since that discussion is very important, let me repeat – or rather rephrase it. The final state of the system is a classical mixture of two well-separated states, with the respective probabilities W_{\leftarrow} and W_{\rightarrow} , whose sum equals 1. Now let us use some detector to test whether the system is in one of these states – say the right

⁶ Somewhat counter-intuitively, the latter growth *improves* the measurement’s fidelity. Indeed, it does not affect the intrinsic “signal-to-noise ratio” $\delta x/\langle x \rangle$, while making the intrinsic (say, quantum-mechanical) uncertainty much larger than the possible noise contribution by the later measurement stage(s).

one. (If x_f is sufficiently large, the noise contribution of this detector into the measurement uncertainty is negligible,⁷ and its physics is unimportant.) If the system has been found at this location (again, the probability of this outcome is $W_{\rightarrow} = |\alpha_{\rightarrow}|^2$), the probability to find it at the counterpart (left) location at a consequent detection turns to zero.

This probability “reduction” is a purely classical (or if you like, mathematical) effect of the statistical ensemble’s re-definition: W_{\leftarrow} equals zero not in the initial ensemble of all similar experiments (where is equals $|\alpha_{\leftarrow}|^2$), but only in the re-defined ensemble of experiments in that the system had been found at the right location. Of course, which ensemble to use, i.e. what probabilities to register/publish is a purely accounting decision, which should be made by a human (or otherwise intelligent :-) observer. If we are only interested in an objective recording of results of a pre-fixed sequence of experiments (i.e. the members of a pre-defined, fixed statistical ensemble), there is no need to include such an observer in any discussion. In any case, this detection/registration process, very common in classical statistics, leaves no space for any mysterious “wave packet reduction” – understood as a hypothetical process that would not obey the regular laws of quantum mechanical evolution.

The state dephasing and ensemble re-definition at measurements are in the core of several paradoxes, of which the so-called *quantum Zeno paradox* is perhaps the most spectacular.⁸ Let us return to a two-level system with the unperturbed Hamiltonian given by Eq. (4.166), the quantum oscillation period $2\pi/\Omega$ much longer than the single-shot measurement time, and the system initially (at $t = 0$) definitely in one of the partial quantum states – for example, a certain potential well of the double-well potential. Then, as we know from Secs. 2.6 and 4.6, the probability to find the system in this initial state at time $t > 0$ is

$$W(t) = \cos^2 \frac{\Omega t}{2} \equiv 1 - \sin^2 \frac{\Omega t}{2}. \quad (10.7)$$

If the time is small enough ($t = dt \ll 1/\Omega$), we may use the Taylor expansion to write

$$W(dt) \approx 1 - \frac{\Omega^2 dt^2}{4}. \quad (10.8)$$

Now, let us use some good measurement scheme (say, the potential inversion discussed above) to measure whether the system is still in this initial state. If it is (as Eq. (8) shows, the probability of such an outcome is nearly 100%), then the system, after the measurement, is in the same state. Let us allow it to evolve again, with the same Hamiltonian. Then the evolution of W will follow the same law

⁷ At the balanced-comparator implementation mentioned above, the final state detection may be readily performed using a “SQUID” magnetometer based on the same Josephson junction technology – see, e.g., EM Sec. 6.5. In this case, the distance between the potential minima $\pm x_f$ is close to one superconducting flux quantum (3.38), while the additional uncertainty induced by the SQUID may be as low as a few millionths of that amount.

⁸ This name, coined by E. Sudarshan and B. Mishra in 1997 (though the paradox had been discussed in detail by A. Turing in 1954) is due to its superficial similarity to the classical paradoxes by the ancient Greek philosopher Zeno of Elea. By the way, just for fun, let us have a look at what happens when Mother Nature is discussed by people that do not understand math and physics. The most famous of the classical Zeno paradoxes is the case of *Achilles and Tortoise*: the fast runner Achilles can apparently never overtake the slower Tortoise, because (in Aristotle’s words) “the pursuer must first reach the point whence the pursued started, so that the slower must always hold a lead”. For a physicist, the paradox has a trivial, obvious resolution, but here is what a philosopher writes about it – not in some year BC, but in the 2010 AD: “Given the history of ‘final resolutions’, from Aristotle onwards, it’s probably foolhardy to think we’ve reached the end.” For me, this is a sad symbol of modern philosophy.

as in Eq. (7). Thus, when the system is measured again at time $2dt$, the probability to find it in the same state both times is

$$W(2dt) \approx W(dt) \left(1 - \frac{\Omega^2 dt^2}{4}\right) = \left(1 - \frac{\Omega^2 dt^2}{4}\right)^2. \quad (10.9)$$

After repeating this cycle N times (with the total time $t = Ndt$ still much less than $N^{1/2}/\Omega$), the probability that the system is still in its initial state is

$$W(Ndt) \equiv W(t) \approx \left(1 - \frac{\Omega^2 dt^2}{4}\right)^N = \left(1 - \frac{\Omega^2 t^2}{4N^2}\right)^N \approx 1 - \frac{\Omega^2 t^2}{4N}. \quad (10.10)$$

Comparing this result with Eq. (7), we see that the process of system's transfer to the opposite partial state has been slowed down rather dramatically, and in the limit $N \rightarrow \infty$ (at fixed t), its evolution is virtually stopped by the measurement process. There is of course nothing mysterious here; the evolution slowdown is due to the quantum state dephasing at each measurement.

This may be the only acceptable occasion for me to mention, very briefly, one more famous – or rather infamous *Schrödinger cat paradox*, so much overplayed in popular publications.⁹ For this thought experiment, there is no need to discuss the (rather complicated :-) physics of the cat. As soon as the charged particle, produced at the radioactive decay, reaches the Geiger counter, the initial coherent superposition of the two possible quantum states (“the decay has happened”)/“the decay has not happened”) of the system is rapidly dephased, i.e. reduced to their classical mixture, leading, correspondingly, to the classical mixture of the final macroscopic states “cat dead”/“cat alive”. So, despite attempts by numerous authors, without a proper physics background, to represent this situation as a mystery whose discussion needs involvement of professional philosophers, hopefully the reader knows enough about dephasing from Chapter 7, to ignore all this babble.

10.2. QND measurements

I hope that the above discussion has sufficiently illuminated the issues of the group (i), so let me proceed to the question group (ii), in particular to the general issue of the *back action* of the instrument upon the system under measurement – symbolized with the back arrow in Fig. 1. In the instruments like the Geiger counter, such back action is large: the instrument essentially destroys (“demolishes”) the state of the system under measurement. Even the “cleaner” potential-inversion measurement, shown in Fig. 2, fully destroys the initial coherence of the system, i.e. perturbs it rather substantially.

However, in the 1970s it was understood that this is not really necessary. For example, in Sec. 7.3, we have already discussed an example of a two-level system coupled with its environment and described by the Hamiltonian (7.68)-(7.70):

$$\hat{H} = \hat{H}_s + \hat{H}_{\text{int}} + \hat{H}_e \{\lambda\}, \quad \text{with } \hat{H}_s = c_z \hat{\sigma}_z, \text{ and } \hat{H}_{\text{int}} = -f \{\lambda\} \hat{\sigma}_z, \quad (10.11)$$

so that

$$[\hat{H}_s, \hat{H}_{\text{int}}] = 0. \quad (10.12)$$

⁹ I fully agree with S. Hawking who has been quoted to say, “When I hear about the Schrödinger cat, I reach for my gun.” The only good aspect of this popularity is that the formulation of this paradox should be so well known to the reader that I do not need to waste time/space repeating it.

Comparing this equality with Eq. (4.199), applied to the explicitly-time-independent Hamiltonian \hat{H}_s ,

$$i\hbar \dot{\hat{H}}_s = [\hat{H}_s, \hat{H}] \equiv [\hat{H}_s, (\hat{H}_s + \hat{H}_{\text{int}} + \hat{H}_e \{\lambda\})] = [\hat{H}_s, \hat{H}_{\text{int}}] = 0, \quad (10.13)$$

we see that in the Heisenberg picture, the Hamiltonian operator (and hence the energy) of the system of our interest does not change in time. On the other hand, if the “environment” in this discussion is the instrument used for the measurement (see Fig. 1 again), the interaction can change its state, so it may be used to measure the system’s energy – or another observable whose operator commutes with the interaction Hamiltonian. Such a trick is called the *quantum non-demolition* (QND), or sometimes “back-action-evading” measurements.¹⁰ Due to the lack of back action of the instrument on the corresponding variable, such measurements allow its continuous monitoring. Let me present a fine example of an actual measurement of this kind – see Fig. 3.¹¹

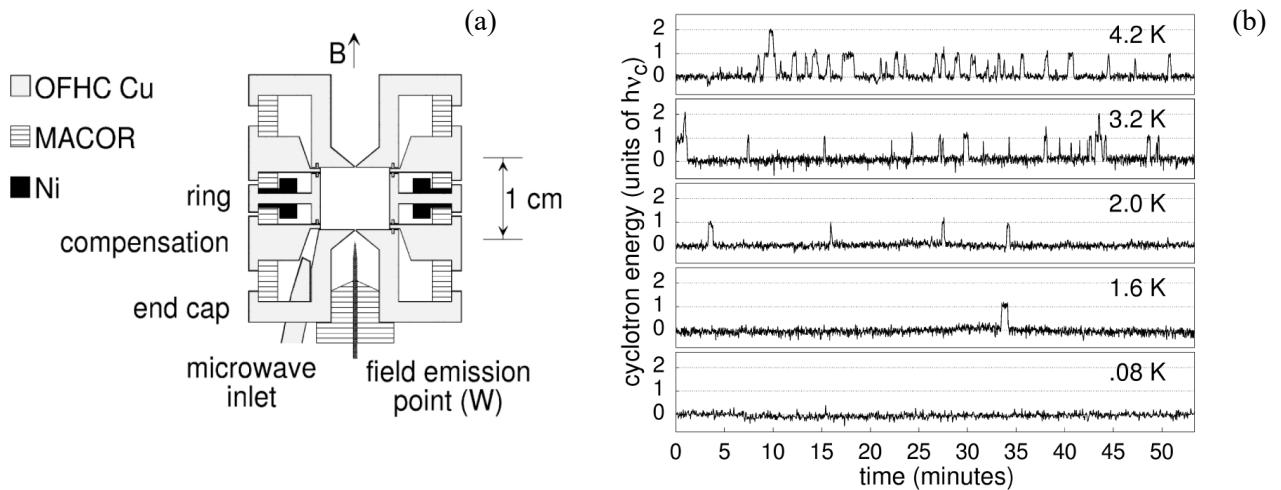

Fig. 10.3. QND measurements of single electron’s energy by Peil and Gabrielse: (a) the experimental setup’s core, and (b) a record of the thermal excitation and spontaneous relaxation of the Fock states. © 1999 APS; reproduced with permission.

In this experiment, a single electron is captured in a *Penning trap* – a combination of a (virtually) uniform magnetic field \mathcal{B} and a quadrupole electric field.¹² This electric field stabilizes the cyclotron orbits but does not have any noticeable effect on electron motion in the plane perpendicular to the magnetic field, and hence on its Landau level energies – see Eq. (3.50):

$$E_n = \hbar \omega_c \left(n + \frac{1}{2} \right), \quad \text{with } \omega_c = \frac{e\mathcal{B}}{m_e}. \quad (10.14)$$

(In the cited work, with $\mathcal{B} \approx 5.3$ T, the cyclic frequency $\omega_c/2\pi$ was about 147 GHz, so that the Landau level splitting $\hbar\omega_c$ was close to 10^{-22} J, i.e. corresponded to $k_B T$ at $T \sim 10$ K, while the physical temperature of the system might be reduced well below that, down to 80 mK). Now note that the

¹⁰ For a detailed discussion of this field see, e.g., V. Braginsky and F. Khalili (ed. by K. Thorne), *Quantum Measurement*, Cambridge U. Press, 1992; for an earlier review, see V. Braginsky *et al.*, *Science* **209**, 547 (1980).

¹¹ S. Peil and G. Gabrielse, *Phys. Rev. Lett.* **83**, 1287 (1999).

¹² It is similar to the 2D system discussed in EM Sec. 2.7, but with additional rotation about one of the axes.

analogy between a Landau-level particle and a harmonic oscillator goes beyond the energy spectrum (14). Indeed, since the Hamiltonian of a 2D particle in a perpendicular magnetic field may be reduced to Eq. (3.47), similar to that of a 1D oscillator, we may repeat all procedures of Sec. 5.4 and rewrite this effective Hamiltonian in the terms of the creation-annihilation operators – see Eq. (5.72):

$$\hat{H}_s = \hbar\omega_c \left(\hat{a}^\dagger \hat{a} + \frac{1}{2} \right). \quad (10.15)$$

In the Peil and Gabrielse experiment, the trapped electron had one more degree of freedom – along the magnetic field. The electric field of the Penning trap created a soft confining potential along this direction (vertical in Fig. 3a; I will take it for the z -axis), so that small electron oscillations along that axis could be well described as those of a 1D harmonic oscillator of much lower eigenfrequency, in that particular experiment with $\omega_z/2\pi \approx 64$ MHz. This frequency could be measured very accurately (with error ~ 1 Hz) by sensitive electronics whose electric field does affect the z -motion of the electron, but not its motion in the perpendicular plane. In an exactly uniform magnetic field, the two modes of electron motion would be completely uncoupled. However, the experimental setup included two special superconducting rings made of niobium (see Fig. 3a), which slightly distorted the magnetic field and created an interaction between the modes, which might be well approximated by the Hamiltonian¹³

$$\hat{H}_{\text{int}} = \text{const} \times \left(\hat{a}^\dagger \hat{a} + \frac{1}{2} \right) \hat{z}^2, \quad (10.16)$$

so that the main condition (12) of a QND measurement was very closely satisfied. At the same time, the coupling (16) ensured that a change of the Landau level number n by 1 changed the z -oscillation eigenfrequency by ~ 12.4 Hz. Since this shift was substantially larger than electronics' noise, rare spontaneous changes of n (due to a weak uncontrolled coupling of the electron to the environment) could be readily measured – moreover, continuously monitored – see Fig. 3b. The record shows spontaneous excitations of the electron to higher Landau levels, with its sequential relaxation, just as described by Eqs. (7.208)-(7.210). The detailed data statistics analysis showed that there was virtually no effect of the measuring instrument on these processes – at least on the scale of minutes, i.e. as many as $\sim 10^{13}$ cyclotron orbit periods.¹⁴

It is important, however, to note that any measurement – QND or not – cannot avoid the uncertainty relations between incompatible variables; in the particular case described above, continuous monitoring of the Landau state number n does not allow the simultaneous monitoring of its quantum phase (which may be defined exactly as in the harmonic oscillator). In this context, it is natural to wonder whether the QND measurement concept may be extended from quadratic-form variables like energy to “usual” observables such as coordinates and momenta, whose uncertainties are bound by the ordinary Heisenberg’s relation (1.35). The answer is yes, but the required methods are a bit more tricky.

For example, let us place an electrically charged particle into a uniform electric field $\mathcal{E} = \mathbf{n}_x \mathcal{E}(t)$ of an instrument, so that their interaction Hamiltonian is

¹³ Here I have simplified the real situation a bit. Actually, in that experiment, there was an electron spin’s contribution to the interaction Hamiltonian as well, but since the used high magnetic field polarized the spins quite reliably, their only effect was a constant shift of the frequency ω_z , which is not important for our discussion.

¹⁴ See also the conceptually similar experiments, performed by different means: G. Nogues *et al.*, *Nature* **400**, 239 (1999).

$$\hat{H}_{\text{int}} = -q\hat{\mathcal{E}}(t)\hat{x}. \quad (10.17)$$

Such interaction may certainly pass the information on the time evolution of the coordinate x to the instrument. However, in this case, Eq. (12) is *not* satisfied – at least for the kinetic-energy part of the particle's Hamiltonian; as a result, the interaction distorts its time evolution. Indeed, writing the Heisenberg equation (4.199) for the x -component of the momentum, we get

$$\dot{\hat{p}} - \dot{\hat{p}} \Big|_{\mathcal{E}=0} = q\hat{\mathcal{E}}(t). \quad (10.18)$$

On the other hand, integrating Eq. (5.139) for the coordinate operator evolution,¹⁵ we get the expression

$$\hat{x}(t) = \hat{x}(t_0) + \frac{1}{m} \int_{t_0}^t \hat{p}(t') dt', \quad (10.19)$$

which shows that the perturbations (18) of the momentum eventually find their way to the coordinate evolution, not allowing its unperturbed sequential measurements.

However, for such an important particular system as a harmonic oscillator, the following trick is possible. For this system, Eqs. (5.139) with the addition (18) may be readily combined to give a second-order differential equation for the coordinate operator, that is absolutely similar to the classical equation of motion of the system, and has a similar solution:¹⁶

$$\hat{x}(t) = \hat{x}(t) \Big|_{\mathcal{E}=0} + \frac{q}{m\omega_0} \int_{-\infty}^t \hat{\mathcal{E}}(t') \sin \omega_0(t-t') dt'. \quad (10.20)$$

This formula confirms that generally, the external field $\mathcal{E}(t)$ (in our case, the sensing field of the measurement instrument) affects the time evolution law – of course. However, Eq. (20) shows that if the field is applied only at moments t'_n separated by intervals $\mathcal{T}/2$, where $\mathcal{T} \equiv 2\pi/\omega_0$ is the oscillation period, its effect on coordinate vanishes at similarly spaced observation instants $t_n = t_{n'} + (m+1/2)\mathcal{T}$. This is the idea of *stroboscopic* QND measurements. Of course, according to Eq. (18), even such measurement strongly perturbs the oscillator momentum, so that even if the values x_n are measured with high accuracy, the Heisenberg's uncertainty relation is not violated.

A direct implementation of the stroboscopic measurements is technically complicated, but this initial idea has opened a way to more practicable solutions. For example, it is straightforward to use the Heisenberg equations of motion to show that if the coupling of two harmonic oscillators, with coordinates x and X , and unperturbed frequencies ω and Ω , is modulated in time as

$$\hat{H}_{\text{int}} \propto \hat{x}\hat{X} \cos \omega t \cos \Omega t, \quad (10.21)$$

¹⁵ This simple relation is limited to 1D systems with Hamiltonians of the type (1.41), but by now the reader certainly knows enough to understand that this discussion may be readily generalized to many other systems.

¹⁶ Note in particular that the function $\sin \omega_0 \tau$ (with $\tau \equiv t - t'$) under the integral, divided by ω_0 , is nothing more than the temporal Green's function $G(\tau)$ of a loss-free harmonic oscillator – see, e.g., CM Sec. 5.1.

then the process in one of the oscillators (say, that with frequency Ω) does not affect dynamics of one of the *quadrature components* of the counterpart oscillator, defined by relations¹⁷

$$\hat{x}_1 \equiv \hat{x} \cos \omega t - \frac{\hat{p}}{m\omega} \sin \omega t, \quad \hat{x}_2 \equiv \hat{x} \sin \omega t + \frac{\hat{p}}{m\omega} \cos \omega t, \quad (10.22)$$

while this component's motion does affect the dynamics of one of the quadrature components of the counterpart oscillator. (For the counterpart couple of quadrature components, the information transfer goes in the opposite direction.) This scheme has been successfully used for QND measurements.¹⁸

Please note that the last two QND measurement examples are based on the idea of a periodic change of a certain parameter in time – either in the short-pulse form or the sinusoidal form. If the only goal of a QND measurement is a sensitive measurement of a weak *classical force* acting on a quantum *probe system*, i.e. a 1D oscillator of eigenfrequency ω_0 , it may be implemented much simpler – just by modulating an oscillator's parameter with a frequency $\omega \approx 2\omega_0$. From the classical dynamics, we know that if the depth of such modulation exceeds a certain threshold value, it results in the excitation of the so-called degenerate parametric oscillations with frequency $\omega/2 \approx \omega_0$, and one of two opposite phases.¹⁹ In the language of Eq. (22), the parametric excitation means exponential growth of one of the quadrature components (with its sign depending on initial conditions), while the counterpart component is suppressed. Close to, but below the excitation threshold, the parameter modulation boosts all fluctuations of the almost-excited component, including its quantum-mechanical uncertainty, and suppresses (*squeezes*) those of the counterpart component. The result is a squeezed state, already discussed in Sec. 5.5 of this course (see in particular Eqs. (5.143) and Fig. 5.8), which allows one to notice the effect of an external force on the oscillator on the backdrop of a quantum uncertainty much smaller than the standard quantum limit (5.99).

In electrical engineering, this fact may be conveniently formulated in terms of *noise parameter* Θ_N of a *linear amplifier* – essentially the tool for continuous monitoring of an input “signal” – e.g., a microwave or optical waveform.²⁰ Namely, Θ_N of “usual” (say, transistor or maser) amplifiers which are equally sensitive to both quadrature components of the signal, Θ_N has the minimum value $\hbar\omega/2$, due to the quantum uncertainty pertinent to the quantum state of the amplifier itself (which therefore plays the role of its “quantum noise”) – the fact that was recognized in the early 1960s.²¹ On the other hand, a

¹⁷ The physical sense of these relations should be clear from Fig. 5.8: they define a system of coordinates rotating clockwise with the angular velocity equal to ω , so that the point representing unperturbed classical oscillations with that frequency is at rest in this rotating frame. (The “probability cloud” representing a Glauber state is also stationary in the coordinates $[x_1, x_2]$.) The reader familiar with the classical theory oscillations may notice that the observables x_1 and x_2 so defined are just the *Poincaré plane* coordinates (“RWA variables”) – see, e.g., CM Sec. 5.3-5.6, and especially Fig. 5.9, where these coordinates are denoted as u and v .

¹⁸ The first, initially imperfect QND experiments were reported by R. Slusher *et al.*, *Phys. Rev. Lett.* **55**, 2409 (1985), and other groups soon after this, using nonlinear interactions of optical waves. Later, the results were much improved – see, e.g., P. Grangier *et al.*, *Nature* **396**, 537 (1998), and references therein. Recently, such experiments were extended to mechanical systems – see, e.g., F. Lecocq *et al.*, *Phys. Rev. X* **5**, 041037 (2015).

¹⁹ See, e.g., CM Sec. 5.5, and also Fig. 5.8 and its discussion in Sec. 5.6.

²⁰ For a quantitative definition of the latter parameter, suitable for the quantum sensitivity range ($\Theta_N \sim \hbar\omega$) as well, see, e.g., I. Devyatov *et al.*, *J. Appl. Phys.* **60**, 1808 (1986). In the classical noise limit ($\Theta_N \gg \hbar\omega$), it coincides with $k_B T_N$, where T_N is a more popular measure of electronics' noise, called the *noise temperature*.

²¹ See, e.g., H. Haus and J. Mullen, *Phys. Rev.* **128**, 2407 (1962).

degenerate parametric amplifier, sensitive to just one quadrature component, may have Θ_N well below $\hbar\omega/2$, due to its ground state squeezing.²²

Let me note that the parameter-modulation schemes of the QND measurements are not limited to harmonic oscillators, and may be applied to other important quantum systems, notably including two-level (i.e. spin-½-like) systems.²³ Such measurements may be an important tool for the further progress of quantum computation and cryptography.²⁴

Finally, let me mention that the composite systems consisting of a quantum subsystem, and a classical subsystem performing its continuous weakly-perturbing measurement and using its results for providing a specially crafted feedback to the quantum subsystem, may have some curious properties, in particular mock a quantum system detached from the environment.²⁵

10.3. Hidden variables and local reality

Now we are ready to proceed to the discussion of the last, hardest group (iii) of the questions posed in Sec. 1, namely on the state of a quantum system *just before* its measurement. After a very important but inconclusive discussion of this issue by Albert Einstein and his collaborators on one side, and Niels Bohr on the other side, in the mid-1930s, such discussions have resumed in the 1950s.²⁶ They have led to a key contribution by John Stewart Bell in the early 1960s, summarized as so-called *Bell's inequalities*, and then to experimental work on better and better verification of these inequalities. (Besides that work, the recent progress, in my humble view, has been rather marginal.)

The central question may be formulated as follows: what *had been* the “real” state of a quantum-mechanical system *just before* a virtually perfect single-shot measurement was performed on it, and gave a certain, documented outcome? To be specific, let us focus again on the example of Stern-Gerlach measurements of spin-½ particles – because of their conceptual simplicity.²⁷ For a single-component system (in this case a single spin-½) the answer to the posed question may look evident. Indeed, as we know, if the spin is in a pure (least-uncertain) state α , i.e. its ket-vector may be expressed in the form similar to Eq. (4),

$$|\alpha\rangle = \alpha_{\uparrow}|\uparrow\rangle + \alpha_{\downarrow}|\downarrow\rangle, \quad (10.23)$$

where, as usual, \uparrow and \downarrow denote the states with definite spin orientations along the z -axis, the probabilities of the corresponding outcomes of the z -oriented Stern-Gerlach experiment are $W_{\uparrow} = |\alpha_{\uparrow}|^2$ and $W_{\downarrow} = |\alpha_{\downarrow}|^2$. Then it looks natural to suggest that if a particular experiment gave the outcome corresponding to the state \uparrow , the spin had been in that state just before the experiment. For a classical

²² See, e.g., the spectacular experiments by B. Yurke *et al.*, *Phys. Rev. Lett.* **60**, 764 (1988). Note also that the squeezed ground states of light are now used to improve the sensitivity of interferometers in gravitational wave detectors – see, e.g., the recent review by R. Schnabel, *Phys. Repts.* **684**, 1 (2017), and the later paper by F. Acernese *et al.*, *Phys. Rev. Lett.* **123**, 231108 (2019).

²⁵ See, e.g., the monograph by H. Wiseman and G. Milburn, *Quantum Measurement and Control*, Cambridge U. Press (2009), more recent experiments by R. Vijay *et al.*, *Nature* **490**, 77 (2012), and references therein.

²⁶ See, e.g., J. Wheeler and W. Zurek (eds.), *Quantum Theory and Measurement*, Princeton U. Press, 1983.

²⁷ As was discussed in Sec. 1, the Stern-Gerlach-type experiments may be readily made virtually perfect, provided that we do not care about the evolution of the system *after* the single-shot measurement.

system such answer would be certainly correct, and the fact that the probability $W_{\uparrow} = |\alpha_{\uparrow}|^2$, defined for the statistical ensemble of *all* experiments (regardless of their outcome), may be less than 1, would merely reflect our ignorance about the *real state* of this particular system before the measurement – which just *reveals* the real situation.

However, as was first argued in the famous *EPR paper* published in 1935 by A. Einstein, B. Podolsky, and N. Rosen, such an answer becomes impossible in the case of an entangled quantum system, if only one of its components is measured with an instrument. The original EPR paper discussed thought experiments with a pair of 1D particles prepared in a quantum state in that both the *sum* of their momenta and the *difference* of their coordinates simultaneously have definite values: $p_1 + p_2 = 0$, $x_1 - x_2 = a$.²⁸ However, usually this discussion is recast into an equivalent Stern-Gerlach experiment shown in Fig. 4a.²⁹ A source emits rare pairs of spin-½ particles, propagating in opposite directions. The particle spin states are random, but with the net spin of the pair definitely equal to zero. After the spatial separation of the particles has become sufficiently large (see below), the spin state of each of them is measured with a Stern-Gerlach detector, with one of them (in Fig. 1, SG₁) somewhat closer to the particle source, so it makes the measurement first, at a time $t_1 < t_2$.

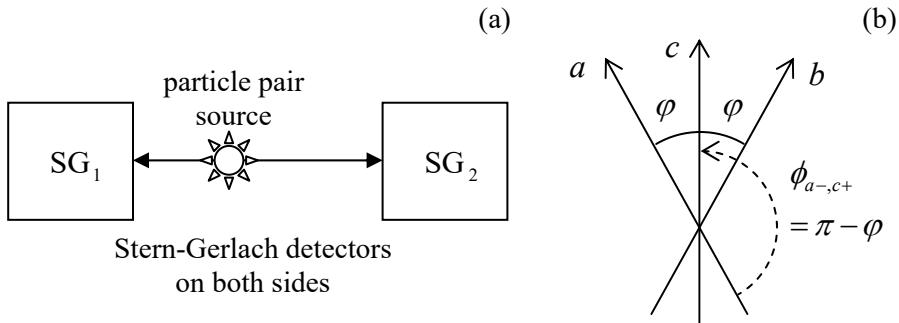

Fig. 10.4. (a) General scheme of two-particle Stern-Gerlach experiments, and (b) the orientation of the detectors, assumed at Wigner's deviation of Bell's inequality (36).

First, let the detectors be oriented say along the same direction, say the z -axis. Evidently, the probability of each detector to give any of the values $s_z = \pm \hbar/2$ is 50%. However, if the first detector had given the result $S_z = -\hbar/2$, then even before the second detector's measurement, we know that the latter will give the result $S_z = +\hbar/2$ with the 100% probability. So far, this situation still allows for a classical interpretation, just as for the single-particle measurements: we may fancy that the second particle has a definite spin before the measurement, and the first measurement just removes our ignorance about that reality. In other words, the change of the probability of the outcome $S_z = +\hbar/2$ at the second detection from 50% to 100% is due to the statistical ensemble re-definition: the 50% probability of this detection belongs to the ensemble of all experiments, while the 100% probability, to the sub-ensemble of experiments with the $S_z = -\hbar/2$ outcome of the first experiment.

However, let the source generate the spin pairs in the entangled, singlet state (8.18),

$$|s_{12}\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle), \quad (10.24)$$

²⁸ This is possible because the corresponding operators commute: $[\hat{p}_1 + \hat{p}_2, \hat{x}_1 - \hat{x}_2] = [\hat{p}_1, \hat{x}_1] - [\hat{p}_2, \hat{x}_2] = 0$.

²⁹ Another equivalent but experimentally more convenient (and as a result, frequently used) technique is the degenerate parametric excitation of entangled optical photon pairs – see, e.g., the publications cited at the end of this section.

that certainly satisfies the above assumptions: the probability of each value of S_z of any particle is 50%, and the sum of both S_z is definitely zero, so that if the first detector's result is $S_z = -\hbar/2$, then the state of the remaining particle is \uparrow , with zero uncertainty. Now let us use Eqs. (4.123) to represent the same state (24) in a different form:

$$|s_{12}\rangle = \frac{1}{\sqrt{2}} \left[\frac{1}{\sqrt{2}}(|\rightarrow\rangle + |\leftarrow\rangle) \frac{1}{\sqrt{2}}(|\rightarrow\rangle - |\leftarrow\rangle) - \frac{1}{\sqrt{2}}(|\rightarrow\rangle - |\leftarrow\rangle) \frac{1}{\sqrt{2}}(|\rightarrow\rangle + |\leftarrow\rangle) \right]. \quad (10.25)$$

Opening the parentheses (carefully, without swapping the ket-vector order, which encodes the particle numbers!), we get an expression similar to Eq. (24), but now for the x -basis:

$$|s_{12}\rangle = \frac{1}{\sqrt{2}}(|\rightarrow\leftarrow\rangle - |\leftarrow\rightarrow\rangle). \quad (10.26)$$

Hence if we use the first detector (closest to the particle source) to measure S_x rather than S_z , then after it had given a certain result (say, $S_x = -\hbar/2$), we know for sure, before the second particle spin's measurement, that its S_x component definitely equals $+\hbar/2$.

So, depending on the experiment performed on the first particle, the second particle, before its measurement, may be in one of two states – either with a definite component S_z or with a definite component S_x , in each case with zero uncertainty. Evidently, this situation cannot be interpreted in classical terms if the particles do not interact during the measurements. A. Einstein was deeply unhappy with such situation because it did not satisfy what, in his view, was the general requirement to any theory, which nowadays is called the *local reality*. His definition of this requirement was as follows: “The real factual situation of system 2 is independent of what is done with system 1 that is spatially separated from the former”. (Here the term “spatially separated” is not defined, but from the context, it is clear that Einstein meant the detector separation by a *superluminal interval*, i.e. by distance

$$|\mathbf{r}_1 - \mathbf{r}_2| > c|t_1 - t_2|, \quad (10.27)$$

where the measurement time difference on the right-hand side includes the measurement duration.) In Einstein's view, since quantum mechanics did not satisfy the local reality condition, it could not be considered a complete theory of Nature.

This situation naturally raises the question of whether *something* (usually called *hidden variables*) may be added to the quantum-mechanical description to enable it to satisfy the local reality requirement. The first definite statement in this regard was John von Neumann's “proof”³⁰ (first famous, then infamous :-) that such variables cannot be introduced; for a while, his work satisfied the quantum mechanics practitioners, who apparently did not pay much attention.³¹ A major new contribution to the problem was made only in the 1960s by J. Bell.³² First of all, he has found an elementary (in his words, “foolish”) error in von Neumann's logic, which voids his “proof”. Second, he has demonstrated that Einstein's local reality condition is *incompatible* with conclusions of quantum mechanics – that had been, by that time, confirmed by too many experiments to be seriously questioned.

³⁰ In his very early book J. von Neumann, *Mathematische Grundlagen der Quantenmechanik* [Mathematical Foundations of Quantum Mechanics], Springer, 1932. (The first English translation was published only in 1955.)

³¹ Perhaps it would not satisfy A. Einstein, but reportedly he did not know about the von Neumann's publication before signing the EPR paper.

³² See, e. g., either J. Bell, *Rev. Mod. Phys.* **38**, 447 (1966) or J. Bell, *Foundations of Physics* **12**, 158 (1982).

Let me describe a particular version of the Bell's result (suggested by E. Wigner), using the same EPR pair experiment (Fig. 4a), in that each SG detector may be oriented in any of 3 directions: a , b , or c – see Fig. 4b. As we already know from Chapter 4, if a fully-polarized beam of spin- $\frac{1}{2}$ particles is passed through a Stern-Gerlach apparatus forming angle ϕ with the polarization axis, the probabilities of two alternative outcomes of the experiment are

$$W(\phi_+) = \cos^2 \frac{\phi}{2}, \quad W(\phi_-) = \sin^2 \frac{\phi}{2}. \quad (10.28)$$

Let us use this formula to calculate all joint probabilities of measurement outcomes, starting from the detectors 1 and 2 oriented, respectively, in the directions a and c . Since the angle between the *negative* direction of the a -axis and the *positive* direction of the c -axis is $\phi_{a-,c+} = \pi - \varphi$ (see the dashed arrow in Fig. 4b), we get

$$W(a_+ \wedge c_+) \equiv W(a_+)W(c_+ | a_+) = W(a_+)W(\phi_{a-,c+}) = \frac{1}{2} \cos^2 \frac{\pi - \varphi}{2} \equiv \frac{1}{2} \sin^2 \frac{\varphi}{2}, \quad (10.29)$$

where $W(x \wedge y)$ is the joint probability of both outcomes x and y , while $W(x | y)$ is the conditional probability of the outcome x , provided that the outcome y has happened. (The first equality in Eq. (29) is the well-known identity of the probability theory.) Absolutely similarly,

$$W(c_+ \wedge b_+) \equiv W(c_+)W(b_+ | c_+) = \frac{1}{2} \sin^2 \frac{\varphi}{2}, \quad (10.30)$$

$$W(a_+ \wedge b_+) \equiv W(a_+)W(b_+ | a_+) = \frac{1}{2} \cos^2 \frac{\pi - 2\varphi}{2} \equiv \frac{1}{2} \sin^2 \varphi. \quad (10.31)$$

Now note that for any angle φ smaller than $\pi/2$ (as in the case shown in Fig. 4b), trigonometry gives

$$\frac{1}{2} \sin^2 \varphi \geq \frac{1}{2} \sin^2 \frac{\varphi}{2} + \frac{1}{2} \sin^2 \frac{\varphi}{2} \equiv \sin^2 \frac{\varphi}{2}. \quad (10.32)$$

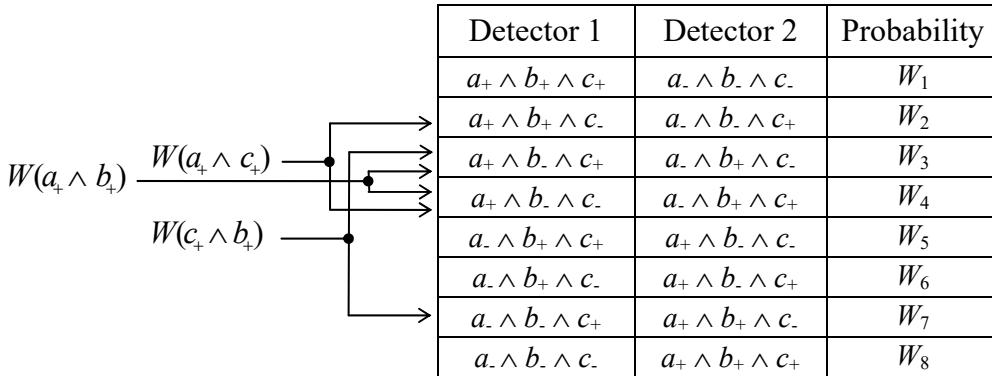

(For example, for $\varphi \rightarrow 0$ the left-hand side of this inequality tends to $\varphi^2/2$, while the right-hand side, to $\varphi^2/4$.) Hence the quantum-mechanical result gives, in particular,

$$W(a_+ \wedge b_+) \geq W(a_+ \wedge c_+) + W(c_+ \wedge b_+), \quad \text{for } |\varphi| \leq \pi/2.$$

(10.33)

Quantum-mechanical result

On the other hand, we can get a different inequality for these probabilities without calculating them from any particular theory, but using the local reality assumption. For that, let us prescribe some probability to each of $2^3 = 8$ possible outcomes of a set of three spin measurements. (Due to zero net spin of particle pairs, the probabilities of the sets shown in both columns of the table have to be equal.)

From the local-reality point of view, these measurement options are independent, so we may write (see the arrows on the left of the table):

$$W(a_+ \wedge c_+) = W_2 + W_4, \quad W(c_+ \wedge b_+) = W_3 + W_7, \quad W(a_+ \wedge b_+) = W_3 + W_4. \quad (10.34)$$

On the other hand, since no probability may be negative (by its very definition), we may always write

$$W_3 + W_4 \leq (W_2 + W_4) + (W_3 + W_7). \quad (10.35)$$

Plugging into this inequality the values of these two parentheses, given by Eq. (34), we get

$$W(a_+ \wedge b_+) \leq W(a_+ \wedge c_+) + W(c_+ \wedge b_+). \quad (10.36)$$

Bell's
inequality
(local-reality
theory)

This is the *Bell's inequality*, which has to be satisfied by *any* local-reality theory; it directly contradicts the quantum-mechanical result (33) – opening the issue to direct experimental testing. Such tests were started in the late 1960s, but the first results were vulnerable to two criticisms:

(i) The detectors were not fast enough and not far enough to have the relation (27) satisfied. This is why, as a matter of principle, there was a chance that information on the first measurement outcome had been transferred (by some, mostly implausible) means to particles before the second measurement – the so-called *locality loophole*.

(ii) The particle/photon detection efficiencies were too low to have sufficiently small error bars for both parts of the inequality – the *detection loophole*.

Gradually, these loopholes have been closed.³³ As expected, substantial violations of the Bell inequalities (36) (or their equivalent forms) have been proved, essentially rejecting any possibility to reconcile quantum mechanics with Einstein's local reality requirement.

10.4. Interpretations of quantum mechanics

The fact that quantum mechanics is incompatible with local reality, makes it reconciliation with our (classically-bred) “common sense” rather challenging. Here is a brief list of the major interpretations of quantum mechanics, that try to provide at least a partial reconciliation of this kind.

(i) The so-called *Copenhagen interpretation* – to which most physicists adhere. This “interpretation” does not really interpret anything; it just accepts the intrinsic stochasticity of measurement results in quantum mechanics, and the absence of local reality, essentially saying: “Do not worry; this is just how it is; live with it”. I generally subscribe to this school of thought, with the following qualification. While the Copenhagen interpretation implies statistical ensembles (otherwise, how would you define the probability? – see Sec. 1.3), its most frequently stated formulations³⁴ do not put a sufficient emphasis on their role, in particular on the ensemble re-definition as the only point of human observer’s involvement in a nearly-perfect measurement process – see Sec. 1 above. The most

³³ Important milestones in that way were the experiments by A. Aspect *et al.*, *Phys. Rev. Lett.* **49**, 91 (1982) and M. Rowe *et al.*, *Nature* **409**, 791 (2001). Detailed reviews of the experimental situation were given, for example, by M. Genovese, *Phys. Repts.* **413**, 319 (2005) and A. Aspect, *Physics* **8**, 123 (2015); see also the later paper by J. Handsteiner *et al.*, *Phys. Rev. Lett.* **118**, 060401 (2017). Presently, a high-fidelity demonstration of the Bell inequality violation has become a standard test in virtually every experiment with entangled qubits used for quantum encryption research – see Sec. 8.5, in particular the paper by J. Lin cited there.

³⁴ With certain pleasant exceptions – see, e.g. L. Ballentine, *Rev. Mod. Phys.* **42**, 358 (1970).

famous objection to the Copenhagen interpretation belongs to A. Einstein: “God does not play dice.” OK, when Einstein speaks, we all should listen, but perhaps when God speaks (through experimental results), we have to pay even more attention.

(ii) *Non-local reality*. After the dismissal of J. von Neumann’s “proof” by J. Bell, to the best of my knowledge, there has been *no* proof that hidden parameters *could not* be introduced, provided that they do not imply the local reality. Of constructive approaches, perhaps the most notable contribution was made by David Joseph Bohm,³⁵ who developed the initial Louis de Broglie’s interpretation of the wavefunction as a “pilot wave”, making it quantitative. In the wave-mechanics version of this concept, the wavefunction governed by the Schrödinger equation, just guides a “real”, point-like classical particle whose coordinates serve as hidden variables. However, this concept does not satisfy the notion of local reality. For example, the measurement of the particle’s coordinate at a certain point \mathbf{r}_1 has to *instantly* change the wavefunction everywhere in space, including the points \mathbf{r}_2 in the superluminal range (27). After A. Einstein’s private criticism, D. Bohm essentially abandoned his theory.³⁶

(iii) The *many-world interpretation*, introduced in 1957 by Hugh Everett and popularized in the 1960s and 1970s by Bruce de Witt. In this interpretation, *all* possible measurement outcomes *do* happen, splitting the Universe into the corresponding number of “parallel multiverses”, so that from one of them, other multiverses and hence other outcomes cannot be observed. Let me leave to the reader an estimate of the rate at which the parallel multiverses have to be constantly generated (say, per second), taking into account that such generation should take place not only at explicit lab experiments but at every irreversible process – such as fission of every atomic nucleus or an absorption/emission of every photon, everywhere in each multiverse – whether its result is formally recorded or not. Nicolaas van Kampen has called this a “mind-boggling fantasy”.³⁷ Even the main proponent of this interpretation, B. de Witt has confessed: “The idea is not easy to reconcile with common sense.” I agree.

(iv) *Quantum logic*. In desperation, some physicists turned philosophers have decided to dismiss the formal logic we are using – in science and elsewhere. From what (admittedly, very little) I have read about this school of thought, it seems that from its point of view, definite statements like “the SG detector has found the spin to be directed along the magnetic field” should not necessarily be either true or false. OK, if we dismiss the formal logic, I do not know how we can use any scientific theory to make any predictions – until the quantum logic experts tell us what to replace it with. To the best of my knowledge, so far they have not done that. I personally trust the opinion by J. Bell, who certainly gave more thought to these issues: “It is my impression that the whole vast subject of Quantum Logic has arisen [...] from the misuse of a word.”

As far as I know, neither of these interpretations has yet provided a suggestion on how it might be tested experimentally to exclude other ones. On the positive side, there is a virtual consensus that quantum mechanics makes correct (if sometimes probabilistic) predictions, which do not contradict any reliable experimental results we are aware of. Maybe, this is not that bad for a scientific theory.³⁸

³⁵ D. Bohm, *Phys. Rev.* **85**, 165; 180 (1952).

³⁶ See, e.g., Sec. 22.19 of his (generally very good) textbook D. Bohm, *Quantum Theory*, Dover, 1979.

³⁷ N. van Kampen, *Physica A* **153**, 97 (1988). By the way, I highly recommend the very reasonable summary of the quantum measurement issues, given in this paper, though believe that the quantitative theory of dephasing, discussed in Chapter 7 of this course, might give additional clarity to some of van Kampen’s statements.

³⁸ For the reader who is not satisfied with this “positivistic” approach, and wants to improve the situation, my earnest advice is to start not from square one, but from reading what other (including some very clever!) people thought about it. The review collection by J. Wheeler and W. Zurek, cited above, may be a good starting point.

Table of Contents

Chapter 1. Review of Thermodynamics (24 pp.)

- 1.1. Introduction: Statistical physics and thermodynamics
- 1.2. The 2nd law of thermodynamics, entropy, and temperature
- 1.3. The 1st and 3rd laws of thermodynamics, and heat capacity
- 1.4. Thermodynamic potentials
- 1.5. Systems with a variable number of particles
- 1.6. Thermal machines
- 1.7. Exercise problems (16)

Chapter 2. Principles of Physical Statistics (44 pp.)

- 2.1. Statistical ensemble and probability
- 2.2. Microcanonical ensemble and distribution
- 2.3. Maxwell's Demon, information, and computing
- 2.4. Canonical ensemble and the Gibbs distribution
- 2.5. Harmonic oscillator statistics
- 2.6. Two important applications
- 2.7. Grand canonical ensemble and distribution
- 2.8. Systems of independent particles
- 2.9. Exercise problems (32)

Chapter 3. Ideal and Not-so-Ideal Gases (34 pp.)

- 3.1. Ideal classical gas
- 3.2. Calculating μ
- 3.3. Degenerate Fermi gas
- 3.4. The Bose-Einstein condensation
- 3.5. Gases of weakly interacting particles
- 3.6. Exercise problems (29)

Chapter 4. Phase Transitions (36 pp.)

- 4.1. First order phase transitions
- 4.2. Continuous phase transitions
- 4.3. Landau's mean-field theory
- 4.4. Ising model: Weiss molecular-field theory
- 4.5. Ising model: Exact and numerical results
- 4.6. Exercise problems (18)

Chapter 5. Fluctuations (44 pp.)

- 5.1. Characterization of fluctuations
- 5.2. Energy and the number of particles
- 5.3. Volume and temperature
- 5.4. Fluctuations as functions of time
- 5.5. Fluctuations and dissipation

- 5.6. The Kramers problem and the Smoluchowski equation
- 5.7. The Fokker-Planck equation
- 5.8. Back to the correlation function
- 5.9. Exercise problems (21)

Chapter 6. Elements of Kinetics (38 pp.)

- 6.1. The Liouville theorem and the Boltzmann equation
- 6.2. The Ohm law and the Drude formula
- 6.3. Electrochemical potential and drift-diffusion equation
- 6.4. Charge carriers in semiconductors: Statics and kinetics
- 6.5. Thermoelectric effects
- 6.6. Exercise problems (15)

Chapter 1. Review of Thermodynamics

This chapter starts with a brief discussion of the subject of statistical physics and thermodynamics, and the relation between these two disciplines. Then I proceed to a review of the basic notions and relations of thermodynamics. Most of this material is supposed to be known to the reader from their undergraduate studies,¹ so the discussion is rather brief.

1.1. Introduction: Statistical physics and thermodynamics

Statistical physics (alternatively called “statistical mechanics”) and *thermodynamics* are two different but related approaches to the same goal: an approximate description of the “internal”² properties of large physical systems, notably those consisting of $N \gg 1$ identical particles – or other components. The traditional example of such a system is a human-scale portion of gas, with the number N of atoms/molecules³ of the order of the Avogadro number $N_A \sim 10^{23}$ (see Sec. 4 below).

The motivation for the statistical approach to such systems is straightforward: even if the laws governing the dynamics of each particle and their interactions were exactly known, and we had infinite computing resources at our disposal, calculating the exact evolution of the system in time would be impossible, at least because it is completely impracticable to measure the exact initial state of each component – in the classical case, the initial position and velocity of each particle. The situation is further exacerbated by the phenomena of chaos and turbulence,⁴ and the quantum-mechanical uncertainty, which do not allow the exact calculation of final positions and velocities of the component particles even if their initial state is known with the best possible precision. As a result, in most situations, only statistical predictions about the behavior of such systems may be made, with the *probability theory* becoming a major tool of the mathematical arsenal.

However, the statistical approach is not as bad as it may look. Indeed, it is almost self-evident that any measurable *macroscopic* variable characterizing a stationary system of $N \gg 1$ particles as a whole (think, e.g., about the stationary pressure P of the gas contained in a fixed volume V) is almost constant in time. Indeed, as we will see below, besides certain exotic exceptions, the relative magnitude of fluctuations – either in time, or among many macroscopically similar systems – of such a variable is of the order of $1/N^{1/2}$, and for $N \sim N_A$ is extremely small. As a result, the *average values* of appropriate macroscopic variables may characterize the state of the system quite well – satisfactory for nearly all practical purposes. The calculation of relations between such average values is the only task of thermodynamics and the main task of statistical physics. (Fluctuations may be important, but due to their smallness, in most cases their analysis may be based on perturbative approaches – see Chapter 5.)

¹ For remedial reading, I can recommend, for example (in the alphabetical order): C. Kittel and H. Kroemer, *Thermal Physics*, 2nd ed., W. H. Freeman (1980); F. Reif, *Fundamentals of Statistical and Thermal Physics*, Waveland (2008); D. V. Schroeder, *Introduction to Thermal Physics*, Addison Wesley (1999).

² Here “internal” is an (admittedly loose) term meaning all the physics unrelated to the motion of the system as a whole. The most important example of internal dynamics is the thermal motion of atoms and molecules.

³ This is perhaps my best chance for a reverent mention of Democritus (circa 460-370 BC) – the Ancient Greek genius who was apparently the first one to conjecture the atomic structure of matter.

⁴ See, e.g., CM Chapters 8 and 9.

Now let us have a fast look at the typical macroscopic variables the statistical physics and thermodynamics should operate with. Since I have already mentioned pressure P and volume V , let me start with this famous pair of variables. First of all, note that volume is an *extensive variable*, i.e. a variable whose value for a system consisting of several non-interacting parts is the sum of those of its parts. On the other hand, pressure is an example of an *intensive variable* whose value is the same for different parts of a system – if they are in equilibrium. To understand why P and V form a natural pair of variables, let us consider the classical playground of thermodynamics, a portion of a gas contained in a cylinder, closed with a movable piston of area A (Fig. 1).

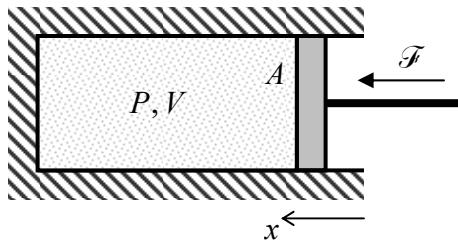

Fig. 1.1. Compressing gas.

Neglecting the friction between the walls and the piston, and assuming that it is being moved so slowly that the pressure P is virtually the same for all parts of the volume at any instant, the elementary work of the external force $\mathcal{F} = PA$, compressing the gas, at a small piston displacement $dx = -dV/A$, is

$$d\mathcal{W} = \mathcal{F}dx \equiv \left(\frac{\mathcal{F}}{A}\right)(Adx) \equiv -PdV. \quad (1.1)$$

Work
on a gas

Of course, the last expression is more general than the model shown in Fig. 1, and does not depend on the particular shape of the system's surface.⁵ (Note that in the notation of Eq. (1), which will be used through the course, the elementary work done *by* the gas *on* the external system equals $-d\mathcal{W}$.)

From the point of analytical mechanics,⁶ V and $(-P)$ is just one of many possible *canonical pairs* of generalized coordinates q_j and generalized forces \mathcal{F}_j , whose products $d\mathcal{W}_j = \mathcal{F}_j dq_j$ give independent contributions to the total work of the environment on the system under analysis. For example, the reader familiar with the basics of electrostatics knows that if the spatial distribution $\mathcal{E}(\mathbf{r})$ of an external electric field does not depend on the electric polarization $\mathcal{P}(\mathbf{r})$ of a dielectric medium placed into the field, its elementary work on the medium is

$$d\mathcal{W} = \int \mathcal{E}(\mathbf{r}) \cdot d\mathcal{P}(\mathbf{r}) d^3r \equiv \int \sum_{j=1}^3 \mathcal{E}_j(\mathbf{r}) d\mathcal{P}_j(\mathbf{r}) d^3r. \quad (1.2a)$$

The most important cases when this condition is fulfilled (and hence Eq. (2a) is valid) are, first, long cylindrical samples in a parallel external field (see, e.g., EM Fig. 3.13) and, second, the polarization of a sample (of any shape) due to that of discrete electric dipoles \mathbf{p}_k , whose electric interaction is negligible. In the latter case, Eq. (2a) may be also rewritten as the sum over the single dipoles, located at points \mathbf{r}_k :⁷

⁵ In order to prove that, it is sufficient to integrate the scalar product $d\mathcal{W} = d\mathcal{F} \cdot d\mathbf{r}$, with $d\mathcal{F} = -\mathbf{n} P d^2r$, where $d\mathbf{r}$ is the surface displacement vector (see, e.g., CM Sec. 7.1), and \mathbf{n} is the outer normal, over the surface.

⁶ See, e.g., CM Chapters 2 and 10.

⁷ Some of my students needed an effort to reconcile the positive signs in Eqs. (2) with the negative sign in the well-known relation $dU_k = -\mathcal{E}(\mathbf{r}_k)d\mathbf{p}_k$ for the potential energy of a dipole in an external electric field – see, e.g.,

$$d\mathcal{W} = \sum_k d\mathcal{W}_k, \quad \text{with } d\mathcal{W}_k = \mathcal{E}(\mathbf{r}_k) \cdot d\mathbf{p}_k. \quad (1.2b)$$

Very similarly, and at the similar conditions on the external magnetic field $\mathcal{H}(\mathbf{r})$, its elementary work on a magnetic medium may be also represented in either of two forms:⁸

$$d\mathcal{W} = \mu_0 \int \mathcal{H}(\mathbf{r}) \cdot d\mathcal{M}(\mathbf{r}) d^3 r \equiv \mu_0 \int \sum_{j=1}^3 \mathcal{H}_j(\mathbf{r}) d\mathcal{M}_j(\mathbf{r}) d^3 r, \quad (1.3a)$$

$$d\mathcal{W} = \sum_k d\mathcal{W}_k, \quad \text{with } d\mathcal{W}_k = \mu_0 \mathcal{H}(\mathbf{r}_k) \cdot d\mathbf{m}_k. \quad (1.3b)$$

where \mathcal{M} and \mathbf{m} are the vectors of, respectively, the medium's magnetization and the magnetic moment of a single dipole. Formulas (2) and (3) show that the roles of generalized coordinates may be played by Cartesian components of the vectors \mathcal{P} (or \mathbf{p}) and \mathcal{M} (or \mathbf{m}), with the components of the electric and magnetic fields playing the roles of the corresponding generalized forces. This list may be extended to other interactions (such as gravitation, surface tension in fluids, etc.). Following tradition, I will use the $\{-P, V\}$ pair in almost all the formulas below, but the reader should remember that they all are valid for any other pair $\{\mathcal{F}_j, q_j\}$.⁹

Again, the specific relations between the variables of each pair listed above may depend on the statistical properties of the system under analysis, but their definitions are not based on statistics. The situation is very different for a very specific pair of variables, *temperature T* and *entropy S*, although these “sister variables” participate in many formulas of thermodynamics exactly as if they were just one more canonical pair $\{\mathcal{F}_j, q_j\}$. However, the very existence of these two notions is due to statistics. Namely, temperature T is an intensive variable that characterizes the degree of thermal “agitation” of the system’s components. On the contrary, the entropy S is an extensive variable that in most cases evades immediate perception by human senses; it is a qualitative measure of the *disorder* of the system, i.e. the degree of our ignorance about its exact microscopic state.¹⁰

The reason for the appearance of the $\{T, S\}$ pair of variables in formulas of thermodynamics and statistical mechanics is that the statistical approach to large systems of particles brings some qualitatively new results, most notably the notion of the *irreversible* time evolution of collective (*macroscopic*) variables describing the system. On one hand, the irreversibility looks absolutely natural in such phenomena as the diffusion of an ink drop in a glass of water. In the beginning, the ink molecules are located in a certain small part of the system’s volume, i.e. to some extent ordered, while at the late stages of diffusion, the position of each molecule in the glass is essentially random. However, as a second thought, the irreversibility is rather surprising, taking into account that the laws governing the

EM Eqs. (3.15). The resolution of this paradox is simple: each term of Eq. (2b) describes the work $d\mathcal{W}_k$ of the electric field on the *internal* degrees of freedom of the k^{th} dipole, changing its *internal* energy E_k : $dE_k = d\mathcal{W}_k$. This energy change may be viewed as coming from the dipole’s potential energy in the field: $dE_k = -dU_k$.

⁸ Here, as in all my series, I am using the SI units; for their translation to the Gaussian units, I have to refer the reader to the EM part of the series.

⁹ Note that in systems of discrete particles, most generalized forces, including the fields \mathcal{E} and \mathcal{H} , differ from the pressure P in the sense that their work may be explicitly partitioned into single-particle components – see Eqs. (2b) and (3b). This fact gives some discretion for the calculations based on thermodynamic potentials – see Sec.4.

¹⁰ The notion of entropy was introduced into thermodynamics in 1865 by Rudolf Julius Emanuel Clausius on a purely phenomenological basis. In the absence of a clue about the entropy’s microscopic origin (which had to wait for the works by L. Boltzmann and J. Maxwell), this was an amazing intellectual achievement.

motion of the system's components are *time-reversible* – such as the Newton laws or the basic laws of quantum mechanics.¹¹ Indeed, if at a late stage of the diffusion process, we reversed the velocities of all molecules exactly and simultaneously, the ink molecules would again gather (for a moment) into the original spot.¹² The problem is that getting the *information* necessary for the exact velocity reversal is not practicable. This example shows a deep connection between statistical mechanics and information theory.

A qualitative discussion of the reversibility-irreversibility dilemma requires a strict definition of the basic notion of statistical mechanics (and indeed of the probability theory), the *statistical ensemble*, and I would like to postpone it until the beginning of Chapter 2. In particular, in that chapter, we will see that the basic law of irreversible behavior is an increase of the entropy S in any closed system. Thus, the statistical mechanics, without defying the “microscopic” laws governing the evolution of system's components, introduces on top of them some new “macroscopic” laws, intrinsically related to the evolution of *information*, i.e. the degree of our knowledge of the microscopic state of the system.

To conclude this brief discussion of variables, let me mention that as in all fields of physics, a very special role in statistical mechanics is played by the *energy* E . To emphasize the commitment to disregard the motion of the system as a whole in this subfield of physics, the E considered in thermodynamics it is frequently called the *internal energy*, though just for brevity, I will skip this adjective in most cases. The simplest example of such E is the sum of kinetic energies of molecules in a dilute gas at their thermal motion, but in general, the internal energy also includes not only the individual energies of the system's components but also their interactions with each other. Besides a few “pathological” cases of very-long-range interactions, these interactions may be treated as local; in this case the internal energy is proportional to N , i.e. is an extensive variable. As will be shown below, other extensive variables with the dimension of energy are often very useful as well, including the (Helmholtz) *free energy* F , the *Gibbs energy* G , the *enthalpy* H , and the *grand potential* Ω . (The collective name for such variables is *thermodynamic potentials*.)

Now, we are ready for a brief discussion of the relationship between *statistical physics* and *thermodynamics*. While the task of statistical physics is to calculate the macroscopic variables discussed above¹³ for various microscopic models of the system, the main role of thermodynamics is to derive some general relations between the average values of the macroscopic variables (also called *thermodynamic variables*) that do not depend on specific models. Surprisingly, it is possible to accomplish such a feat using just a few either evident or very plausible general assumptions (sometimes called the *laws of thermodynamics*), which find their proof in statistical physics.¹⁴ Such general relations allow for a substantial reduction of the number of calculations we have to do in statistical physics: in most cases, it is sufficient to calculate from the statistics just one or two variables, and then use general

¹¹ Because of that, the possibility of the irreversible macroscopic behavior of microscopically reversible systems was questioned by some serious scientists as recently as in the late 19th century – notably by J. Loschmidt in 1876.

¹² While quantum-mechanical effects, with their intrinsic uncertainty, may be quantitatively important in this example, our qualitative discussion does not depend on them. Another classical example is the chaotic motion of a ball on a 2D Sinai billiard – see CM Chapter 9 and in particular Fig. 9.8 and its discussion.

¹³ Several other quantities, for example the heat capacity C , may be calculated as partial derivatives of the basic variables discussed above. Also, at certain conditions, the number of particles N in a certain system may be not fixed and also considered as an (extensive) variable – see Sec. 5 below.

¹⁴ Admittedly, some of these proofs are based on other plausible but deeper postulates, for example the central statistical hypothesis (Sec. 2.2), whose best proof, to my knowledge, is just the whole body of experimental data.

thermodynamic relations to get all other properties of interest. Thus the thermodynamics, sometimes snubbed as a phenomenology, deserves every respect not only as a useful theoretical tool but also as a discipline more general than any particular statistical model. This is why the balance of this chapter is devoted to a brief review of thermodynamics.

1.2. The 2nd law of thermodynamics, entropy, and temperature

Thermodynamics accepts a phenomenological approach to the entropy S , postulating that there is such a unique extensive measure of the aggregate disorder, and that in a *closed system* (defined as a system completely isolated from its environment, i.e. the system with its internal energy fixed) it may only grow in time, reaching its constant (maximum) value at equilibrium:¹⁵

2nd law of
thermo-
dynamics

$$dS \geq 0. \quad (1.4)$$

This postulate is called the *2nd law of thermodynamics* – arguably its only substantial new law.¹⁶

Rather surprisingly, this law, together with the additivity of S in composite systems of non-interacting parts (as an extensive variable), is sufficient for a formal definition of temperature, and a derivation of its basic properties that comply with our everyday notion of this key variable. Indeed, let us consider a closed system consisting of two fixed-volume subsystems (Fig. 2) whose internal relaxation is very fast in comparison with the rate of the thermal flow (i.e. the energy and entropy exchange) between the parts. In this case, on the latter time scale, each part is always in some quasi-equilibrium state, which may be described by a unique relation $E(S)$ between its energy and entropy.¹⁷

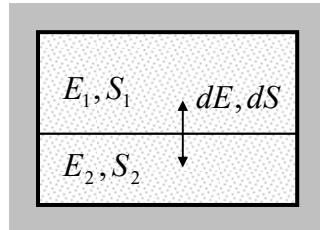

Fig. 1.2. A. composite thermodynamic system.

Neglecting the energy of interaction between the parts (which is always possible at $N \gg 1$, and in the absence of long-range interactions), we may use the extensive character of the variables E and S to write

$$E = E_1(S_1) + E_2(S_2), \quad S = S_1 + S_2, \quad (1.5)$$

for the full energy and entropy of the system. Now let us use them to calculate the following derivative:

¹⁵ Implicitly, this statement also postulates the existence, in a closed system, of *thermodynamic equilibrium*, an asymptotically reached state in which all macroscopic variables, including entropy, remain constant. Sometimes this postulate is called the 0th law of thermodynamics.

¹⁶ Two initial formulations of this law, later proved equivalent, were put forward independently by Lord Kelvin (born William Thomson) in 1851 and by Rudolf Clausius in 1854.

¹⁷ Here we strongly depend on a very important (and possibly the least intuitive) aspect of the 2nd law, namely that the entropy is a *unique* measure of disorder.

$$\frac{dS}{dE_1} = \frac{dS_1}{dE_1} + \frac{dS_2}{dE_1} \equiv \frac{dS_1}{dE_1} + \frac{dS_2}{dE_2} \frac{dE_2}{dE_1} = \frac{dS_1}{dE_1} + \frac{dS_2}{dE_2} \frac{d(E - E_1)}{dE_1}. \quad (1.6)$$

Since the total energy E of the closed system is fixed and hence independent of its re-distribution between the subsystems, we have to take $dE/dE_1 = 0$, and Eq. (6) yields

$$\frac{dS}{dE_1} = \frac{dS_1}{dE_1} - \frac{dS_2}{dE_2}. \quad (1.7)$$

According to the 2nd law of thermodynamics, when the two parts have reached the thermodynamic equilibrium, the total entropy S reaches its maximum, so that $dS/dE_1 = 0$, and Eq. (7) yields

$$\frac{dS_1}{dE_1} = \frac{dS_2}{dE_2}. \quad (1.8)$$

This equality shows that if a thermodynamic system may be partitioned into weakly interacting macroscopic parts, their derivatives dS/dE should be equal in the equilibrium. The reciprocal of this derivative is called *temperature*. Taking into account that our analysis pertains to the situation (Fig. 2) when both volumes $V_{1,2}$ are fixed, we may write this definition as

$$\left(\frac{\partial E}{\partial S} \right)_V \equiv T, \quad (1.9)$$

Definition of temperature

the subscript V meaning that volume is kept constant at the differentiation. (Such notation is common and very useful in thermodynamics, with its broad range of variables.)

Note that according to Eq. (9), if the temperature is measured in energy units¹⁸ (as I will do in this course for the brevity of notation), then S is dimensionless. The transfer to the SI or Gaussian units, i.e. to the temperature T_K measured in kelvins (not “Kelvins”, and not “degrees Kelvin”, please!), is given by the relation $T = k_B T_K$, where the *Boltzmann constant* $k_B \approx 1.38 \times 10^{-23}$ J/K = 1.38×10^{-16} erg/K.¹⁹ In those units, the entropy becomes dimensional: $S_K = k_B S$.

The definition of temperature, given by Eq. (9), is of course in sharp contrast with the popular notion of T as a measure of the average energy of one particle. However, as we will repeatedly see below, in many cases these two notions may be reconciled, with Eq. (9) being more general. In particular, the so-defined T is in semi-quantitative agreement with our everyday notion of temperature:²⁰

(i) according to Eq. (9), the temperature is an intensive variable (since both E and S are extensive), i.e., in a system of similar particles, it is independent of the particle number N ;

¹⁸ Here I have to mention a traditional unit of thermal energy, the calorie, still being used in some applied fields. In the most common modern definition (as the so-called *thermochemical calorie*) it equals exactly 4.148 J.

¹⁹ For the more exact values of this and other constants, see appendix CA: *Selected Physical Constants*. Note that both T and T_K define the natural *absolute* (also called “thermodynamic”) *scale* of temperature, vanishing at the same point – in contrast to such artificial scales as the degrees Celsius (“centigrades”), defined as $T_C \equiv T_K + 273.15$, or the degrees Fahrenheit: $T_F \equiv (9/5)T_C + 32$.

²⁰ Historically, such notion was initially qualitative – just as something distinguishing “hot” from “cold”. After the invention of thermometers (the first one by Galileo Galilei in 1592), mostly based on thermal expansion of fluids, this notion had become quantitative but not very deep: being understood as something “what the thermometer measures” – until its physical sense as a measure of thermal motion’s intensity, was revealed in the 19th century.

- (ii) temperatures of all parts of a system are equal at equilibrium – see Eq. (8);
- (iii) in a closed system whose parts are *not* in equilibrium, thermal energy (*heat*) always flows from a warmer part (with higher T) to the colder part.

In order to prove the last property, let us revisit the closed, composite system shown in Fig. 2, and consider another derivative:

$$\frac{dS}{dt} = \frac{dS_1}{dt} + \frac{dS_2}{dt} \equiv \frac{dS_1}{dE_1} \frac{dE_1}{dt} + \frac{dS_2}{dE_2} \frac{dE_2}{dt}. \quad (1.10)$$

If the internal state of each part is very close to equilibrium (as was assumed from the very beginning) at each moment of time, we can use Eq. (9) to replace the derivatives $dS_{1,2}/dE_{1,2}$ with $1/T_{1,2}$, getting

$$\frac{dS}{dt} = \frac{1}{T_1} \frac{dE_1}{dt} + \frac{1}{T_2} \frac{dE_2}{dt}. \quad (1.11)$$

Since in a closed system $E = E_1 + E_2 = \text{const}$, these time derivatives are related as $dE_2/dt = -dE_1/dt$, and Eq. (11) yields

$$\frac{dS}{dt} = \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \frac{dE_1}{dt}. \quad (1.12)$$

But according to the 2nd law of thermodynamics, this derivative cannot be negative: $dS/dt \geq 0$. Hence,

$$\left(\frac{1}{T_1} - \frac{1}{T_2} \right) \frac{dE_1}{dt} \geq 0. \quad (1.13)$$

For example, if $T_1 > T_2$, then $dE_1/dt \leq 0$, i.e. the warmer part gives energy to its colder counterpart.

Note also that at such a heat exchange, at fixed volumes $V_{1,2}$, and $T_1 \neq T_2$, increases the total system's entropy, without performing any “useful” mechanical work – see Eq. (1).

1.3. The 1st and 3rd laws of thermodynamics, and heat capacity

Now let us consider a *thermally insulated* system whose volume V may be changed by force – see, for example, Fig. 1. Such a system is different from the fully closed one, because its energy E may be changed by the external force's work – see Eq. (1):

$$dE = d\mathcal{W} = -PdV. \quad (1.14)$$

Let the volume change be so slow ($dV/dt \rightarrow 0$) that the system is virtually at equilibrium at any instant. Such a slow process is called *reversible*, and in the particular case of a thermally insulated system, it is also called *adiabatic*. If the pressure P (or any generalized external force \mathcal{F}_j) is deterministic, i.e. is a predetermined function of time, independent of the state of the system under analysis, it may be considered as coming from a fully ordered system, i.e. the one having zero entropy, with the total system (the system under our analysis plus the source of the force) completely closed. Since the entropy of the total closed system should stay constant (see the second of Eqs. (5) above), S of the system under analysis should stay constant on its own. Thus we arrive at a very important conclusion: at an adiabatic process, the entropy of a system cannot change. (Sometimes such a process is called *isentropic*.) This means that we may use Eq. (14) to write

$$P = -\left(\frac{\partial E}{\partial V}\right)_S. \quad (1.15)$$

Now let us consider a more general thermodynamic system that may also exchange thermal energy (“heat”) with its environment (Fig. 3).

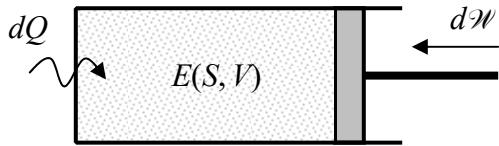

Fig. 1.3. An example of the thermodynamic process involving both the mechanical work by the environment, and the heat exchange with it.

For such a system, our previous conclusion about the entropy’s constancy is not valid, so that S , in equilibrium, may be a function of not only the system’s energy E , but also of its volume: $S = S(E, V)$. Let us consider this relation resolved for energy: $E = E(S, V)$, and write the general mathematical expression for the full differential of E as a function of these two independent arguments:

$$dE = \left(\frac{\partial E}{\partial S}\right)_V dS + \left(\frac{\partial E}{\partial V}\right)_S dV. \quad (1.16)$$

This formula, based on the stationary relation $E = E(S, V)$, is evidently valid not only in equilibrium but also for all very slow, reversible²¹ processes. Now, using Eqs. (9) and (15), we may rewrite Eq. (16) as

$$dE = TdS - PdV. \quad (1.17)$$

Energy:
differential

According to Eq. (1), the second term on the right-hand side of this equation is just the work of the external force, so that due to the conservation of energy,²² the first term has to be equal to the *heat* dQ transferred from the environment to the system (see Fig. 3):

$$dE = dQ + dW, \quad (1.18)$$

$$dQ = TdS. \quad (1.19)$$

1st law of
thermo-
dynamics

The last relation, divided by T and then integrated along an arbitrary (but reversible!) process,

$$S = \int \frac{dQ}{T} + \text{const}, \quad (1.20)$$

is sometimes used as an alternative definition of entropy S – provided that temperature is defined not by Eq. (9), but in some independent way. It is useful to recognize that entropy (like energy) may be defined

²¹ Let me emphasize again that any adiabatic process is reversible, but not vice versa.

²² Such conservation, expressed by Eqs. (18)-(19), is commonly called the *1st law of thermodynamics*. While it (in contrast with the 2nd law) does not present any new law of nature, and in particular was already used de-facto to write the first of Eqs. (5) and also Eq. (14), such a grand name was absolutely justified in the 19th century when the mechanical nature of the internal energy (the thermal motion) was not at all clear. In this context, the names of three scientists, Benjamin Thompson (who gave, in 1799, convincing arguments that heat cannot be anything but a form of particle motion), Julius Robert von Mayer (who conjectured the conservation of the sum of the thermal and macroscopic mechanical energies in 1841), and James Prescott Joule (who proved this conservation experimentally two years later), have to be reverently mentioned.

to an arbitrary constant, which does not affect any other thermodynamic observables. The common convention is to take

$$S \rightarrow 0, \quad \text{at } T \rightarrow 0. \quad (1.21)$$

This condition is sometimes called the “3rd law of thermodynamics”, but it is important to realize that this is just a convention rather than a real law.²³ Indeed, the convention corresponds well to the notion of the full order at $T = 0$ in some systems (e.g., separate atoms or perfect crystals), but creates ambiguity for other systems, e.g., amorphous solids (like the usual glasses) that may remain highly disordered for “astronomic” times, even at $T \rightarrow 0$.

Now let us discuss the notion of *heat capacity* that, by definition, is the ratio dQ/dT , where dQ is the amount of heat that should be given to a system to raise its temperature by a small amount dT .²⁴ (This notion is important because the heat capacity may be most readily measured experimentally.) The heat capacity depends, naturally, on whether the heat dQ goes only into an increase of the internal energy dE of the system (as it does if its volume V is constant), or also into the mechanical work ($-dW$) performed by the system at its expansion – as it happens, for example, if the pressure P , rather than the volume V , is fixed (the so-called *isobaric* process – see Fig. 4).

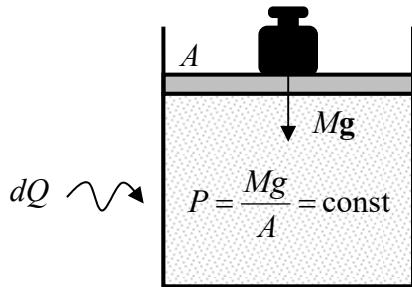

Fig. 1.4. The simplest example of the isobaric process.

Hence we should discuss at least two different quantities,²⁵ the *heat capacity at fixed volume*,

$$C_V \equiv \left(\frac{\partial Q}{\partial T} \right)_V \quad (1.22)$$

Heat capacity: definitions

and the *heat capacity at fixed pressure*

$$C_P \equiv \left(\frac{\partial Q}{\partial T} \right)_P, \quad (1.23)$$

²³Actually, the 3rd law (also called the *Nernst theorem*) as postulated by Walter Hermann Nernst in 1912 was different – and really meaningful: “It is impossible for any procedure to lead to the isotherm $T = 0$ in a finite number of steps.” I will discuss this theorem at the end of Sec. 6.

²⁴By this definition, the full heat capacity of a system is an extensive variable, but it may be used to form such intensive variables as the heat capacity per particle, called the *specific heat capacity*, or just the *specific heat*. (Please note that the last terms are rather ambiguous: they are used for the heat capacity per unit mass, per unit volume, and sometimes even for the heat capacity of the system as the whole, so that some caution is in order.)

²⁵Dividing both sides of Eq. (19) by dT , we get the general relation $dQ/dT = TdS/dT$, which may be used to rewrite the definitions (22) and (23) in the following forms:

$$C_V = T \left(\frac{\partial S}{\partial T} \right)_V, \quad C_P = T \left(\frac{\partial S}{\partial T} \right)_P,$$

more convenient for some applications.

and expect that for all “normal” (mechanically stable) systems, $C_P \geq C_V$. The difference between C_P and C_V is rather minor for most liquids and solids, but may be very substantial for gases – see Sec. 4.

1.4. Thermodynamic potentials

Since for a fixed volume, $d\mathcal{W} = -PdV = 0$, and Eq. (18) yields $dQ = dE$, we may rewrite Eq. (22) in another convenient form

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V . \quad (1.24)$$

so that to calculate C_V from a certain statistical-physics model, we only need to calculate E as a function of temperature and volume. If we want to obtain a similarly convenient expression for C_P , the best way is to introduce a new notion of so-called *thermodynamic potentials* – whose introduction and effective use is perhaps one of the most impressive techniques of thermodynamics. For that, let us combine Eqs. (1) and (18) to write the 1st law of thermodynamics in its most common form

$$dQ = dE + PdV. \quad (1.25)$$

At an isobaric process (Fig. 4), i.e. at $P = \text{const}$, this expression is reduced to

$$(dQ)_P = dE_P + d(PV)_P = d(E + PV)_P. \quad (1.26)$$

Thus, if we introduce a new function with the dimensionality of energy:²⁶

$$H \equiv E + PV, \quad (1.27)$$

Enthalpy:
definition

called *enthalpy* (or, sometimes, the “heat function” or the “heat contents”),²⁷ we may rewrite Eq. (23) as

$$C_P = \left(\frac{\partial H}{\partial T} \right)_P . \quad (1.28)$$

Comparing Eqs. (28) and (24) we see that for the heat capacity, the enthalpy H plays the same role at fixed pressure as the internal energy E plays at fixed volume.

Now let us explore properties of the enthalpy at an *arbitrary* reversible process, i.e. lifting the restriction $P = \text{const}$, but keeping the definition (27). Differentiating this equality, we get

$$dH = dE + PdV + VdP. \quad (1.29)$$

Plugging into this relation Eq. (17) for dE , we see that the terms $\pm PdV$ cancel, yielding a very simple expression

$$dH = TdS + VdP, \quad (1.30)$$

Enthalpy:
differential

whose right-hand side differs from Eq. (17) only by the swap of P and V in the second term, with the simultaneous change of its sign. Formula (30) shows that if H has been found (say, experimentally

²⁶ From the point of view of mathematics, Eq. (27) is a particular case of the so-called *Legendre transformations*.

²⁷ This function (as well as the Gibbs free energy G , see below), had been introduced in 1875 by J. Gibbs, though the term “enthalpy” was coined (much later) by H. Onnes.

measured or calculated for a certain microscopic model) as a function of the entropy S and the pressure P of a system, we can calculate its temperature T and volume V by simple partial differentiation:

$$T = \left(\frac{\partial H}{\partial S} \right)_P, \quad V = \left(\frac{\partial H}{\partial P} \right)_S. \quad (1.31)$$

The comparison of the first of these relations with Eq. (9) shows that not only for the heat capacity but for temperature as well, enthalpy plays the same role at fixed pressure, as played by internal energy at fixed volume.

This success immediately raises the question of whether we could develop this idea further on, by defining other useful thermodynamic potentials – the variables with the dimensionality of energy that would have similar properties – first of all, a potential that would enable a similar swap of T and S in its full differential, in comparison with Eq. (30). We already know that an adiabatic process is the reversible process with fixed entropy, inviting analysis of a reversible process with fixed temperature. Such an *isothermal process* may be implemented, for example, by placing the system under consideration into thermal contact with a much larger system (called either the *heat bath*, or “heat reservoir”, or “thermostat”) that remains in thermodynamic equilibrium at all times – see Fig. 5.

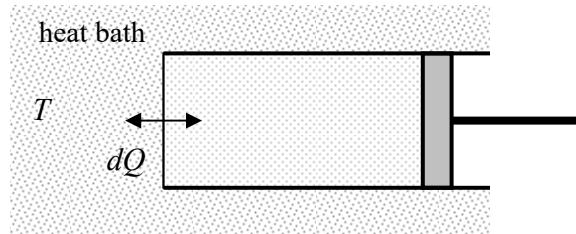

Fig. 1.5. The simplest example of the isothermal process.

Due to its very large size, the heat bath temperature T does not depend on what is being done with our system, and if the change is being done sufficiently slowly (i.e. reversibly), that this temperature is also the temperature of our system – see Eq. (8) and its discussion. Let us calculate the elementary mechanical work $d\mathcal{W}$ (1) at such a reversible isothermal process. According to the general Eq. (18), $d\mathcal{W} = dE - dQ$. Plugging dQ from Eq. (19) into this equality, for $T = \text{const}$ we get

$$(d\mathcal{W})_T = dE - TdS = d(E - TS) \equiv dF, \quad (1.32)$$

where the following combination,

Free energy:
definition

$$F \equiv E - TS, \quad (1.33)$$

is called the *free energy* (or the “Helmholtz free energy”, or just the “Helmholtz energy”²⁸). Just as we have done for the enthalpy, let us establish properties of this new thermodynamic potential for an arbitrarily small, reversible (now not necessarily isothermal!) variation of variables, while keeping the definition (33). Differentiating this relation and then using Eq. (17), we get

Free energy:
differential

$$dF = -SdT - PdV. \quad (1.34)$$

²⁸ It was named after Hermann von Helmholtz (1821-1894). The last of the listed terms for F was recommended by the most recent (1988) IUPAC’s decision, but I will use the first term, which prevails in physics literature. The origin of the adjective “free” stems from Eq. (32): F is may be interpreted as the internal energy’s part that is “free” to be transferred to the mechanical work, at the (most common) reversible, isothermal process.

Thus, if we know the function $F(T, V)$, we can calculate S and P by simple differentiation:

$$S = -\left(\frac{\partial F}{\partial T}\right)_V, \quad P = -\left(\frac{\partial F}{\partial V}\right)_T. \quad (1.35)$$

Now we may notice that the system of all partial derivatives may be made full and symmetric if we introduce one more thermodynamic potential. Indeed, we have already seen that each of the three already introduced thermodynamic potentials (E , H , and F) has an especially simple full differential if it is considered as a function of its two *canonical* arguments: one of the “thermal variables” (either S or T) and one of the “mechanical variables” (either P or V):²⁹

$$E = E(S, V); \quad H = H(S, P); \quad F = F(T, V). \quad (1.36)$$

In this list of pairs of four arguments, only one pair is missing: $\{T, P\}$. The thermodynamic function of this pair, which gives the two remaining variables (S and V) by simple differentiation, is called the *Gibbs energy* (or sometimes the “Gibbs free energy”): $G = G(T, P)$. The way to define it in a symmetric way is evident from the so-called *circular diagram* shown in Fig. 6.

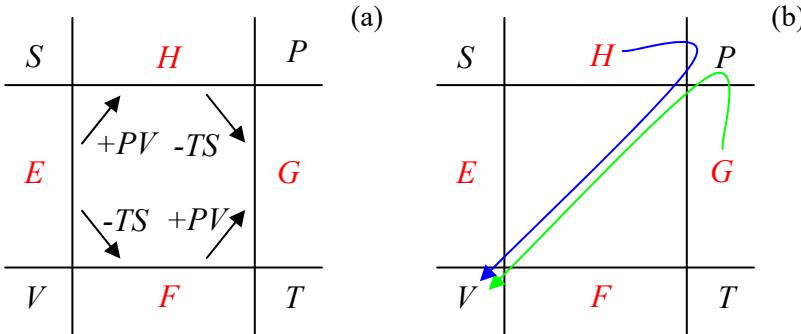

Fig. 1.6. (a) The circular diagram and (b) an example of its use for variable calculation. The thermodynamic potentials are typeset in red, each flanked with its two canonical arguments.

In this diagram, each thermodynamic potential is placed between its two canonical arguments – see Eq. (36). The left two arrows in Fig. 6a show the way the potentials H and F have been obtained from energy E – see Eqs. (27) and (33). This diagram hints that G has to be defined as shown by either of the two right arrows on that panel, i.e. as

$$G \equiv F + PV \equiv H - TS \equiv E - TS + PV. \quad (1.37)$$

Gibbs energy:
definition

In order to verify this idea, let us calculate the full differential of this new thermodynamic potential, using, e.g., the first form of Eq. (37) together with Eq. (34):

$$dG = dF + d(PV) = (-SdT - PdV) + (PdV + VdP) \equiv -SdT + VdP, \quad (1.38)$$

Gibbs energy:
differential

so that if we know the function $G(T, P)$, we can indeed readily calculate both entropy and volume:

$$S = -\left(\frac{\partial G}{\partial T}\right)_P, \quad V = \left(\frac{\partial G}{\partial P}\right)_T. \quad (1.39)$$

²⁹ Note the similarity of this situation with that in analytical mechanics (see, e.g., CM Chapters 2 and 10): the Lagrangian function may be used to derive the equations of motion if it is expressed as a function of generalized coordinates and their *velocities*, while to use the Hamiltonian function in a similar way, it has to be expressed as a function of the generalized coordinates and the corresponding *momenta*.

The circular diagram completed in this way is a good mnemonic tool for describing Eqs. (9), (15), (31), (35), and (39), which express thermodynamic variables as partial derivatives of the thermodynamic potentials. Indeed, the variable in any corner of the diagram may be found as a partial derivative of any of two potentials that are not its immediate neighbors, over the variable in the opposite corner. For example, the green line in Fig. 6b corresponds to the second of Eqs. (39), while the blue line, to the second of Eqs. (31). At this procedure, all the derivatives giving the variables of the upper row (S and P) have to be taken with negative signs, while those giving the variables of the bottom row (V and T), with positive signs.³⁰

Now I have to justify the collective name “thermodynamic potentials” used for E , H , F , and G . For that, let us consider an *irreversible* process, for example, a direct thermal contact of two bodies with different initial temperatures. As was discussed in Sec. 2, at such a process, the entropy may grow even without the external heat flow: $dS \geq 0$ at $dQ = 0$ – see Eq. (12). This means that at a more general process with $dQ \neq 0$, the entropy may grow faster than predicted by Eq. (19), which has been derived for a reversible process, so that

$$dS \geq \frac{dQ}{T}, \quad (1.40)$$

with the equality approached in the reversible limit. Plugging Eq. (40) into Eq. (18) (which, being just the energy conservation law, remains valid for irreversible processes as well), we get

$$dE \leq TdS - PdV. \quad (1.41)$$

We can use this relation to have a look at the behavior of other thermodynamic potentials in irreversible situations, still keeping their definitions given by Eqs. (27), (33), and (37). Let us start from the (very common) case when both the temperature T and the volume V of a system are kept constant. If the process is reversible, then according to Eq. (34), the full time derivative of the free energy F would equal zero. Eq. (41) says that at an irreversible process, this is not necessarily so: if $dT = dV = 0$, then

$$\frac{dF}{dt} = \frac{d}{dt}(E - TS)_T = \frac{dE}{dt} - T \frac{dS}{dt} \leq 0. \quad (1.42)$$

Hence, in the general (irreversible) situation, F can only decrease, but not increase in time. This means that F eventually approaches its minimum value $F(T, S)$, given by the equations of reversible thermodynamics. To re-phrase this important conclusion, in the case $T = \text{const}$, $V = \text{const}$, the free energy F , i.e. the difference $E - TS$, plays the role of the potential energy in the classical mechanics of dissipative processes: its minimum corresponds to the (in the case of F , thermodynamic) equilibrium of the system. This is one of the key results of thermodynamics, and I invite the reader to give it some thought. One of its possible handwaving interpretations of this fact is that the heat bath with fixed $T > 0$, i.e. with a substantial thermal agitation of its components, “wants” to impose thermal disorder in the system immersed into it, by “rewarding” it with lower F for any increase of disorder.

³⁰ There is also a wealth of other relations between thermodynamic variables that may be represented as second derivatives of the thermodynamic potentials, including four *Maxwell relations* such as $(\partial S/\partial V)_T = (\partial P/\partial T)_V$, etc. (They may be readily recovered from the well-known property of a function of two independent arguments, say, $f(x, y)$: $\partial(\partial f/\partial x)/\partial y = \partial(\partial f/\partial y)/\partial x$.) In this chapter, I will list only the thermodynamic relations that will be used later in the course; a more complete list may be found, e.g., in Sec. 16 of the book by L. Landau and E. Lifshitz, *Statistical Physics, Part 1*, 3rd ed., Pergamon, 1980 (and its later re-printings).

Repeating the calculation for a different case, $T = \text{const}$, $P = \text{const}$, it is easy to see that in this case the same role is played by the Gibbs energy:

$$\frac{dG}{dt} \equiv \frac{d}{dt}(E - TS + PV) = \frac{dE}{dt} - T \frac{dS}{dt} + P \frac{dV}{dt} \leq (T \frac{dS}{dt} - P \frac{dV}{dt}) - T \frac{dS}{dt} + P \frac{dV}{dt} \equiv 0, \quad (1.43)$$

so that the thermal equilibrium now corresponds to the minimum of G rather than F .

For the two remaining thermodynamic potentials, E and H , the calculations similar to Eqs. (42) and (43) make less sense because that would require keeping $S = \text{const}$ (with $V = \text{const}$ for E , and $P = \text{const}$ for H) for an irreversible process, but it is usually hard to prevent the entropy from growing if initially it had been lower than its equilibrium value, at least on the long-term basis.³¹ Thus the circular diagram is not so symmetric after all: G and F are somewhat more useful for most practical calculations than E and H .

Note that the difference $G - F = PV$ between the two “more useful” potentials has very little to do with thermodynamics at all because this difference exists (although is not much advertised) in classical mechanics as well.³² Indeed, the difference may be generalized as $G - F = -\mathcal{F}q$, where q is a generalized coordinate, and \mathcal{F} is the corresponding generalized force. The minimum of F corresponds to the equilibrium of an autonomous system (with $\mathcal{F} = 0$), while the equilibrium position of the same system under the action of external force \mathcal{F} is given by the minimum of G . Thus the external force “wants” the system to subdue to its effect, “rewarding” it with lower G .

Moreover, the difference between F and G becomes a bit ambiguous (approach-dependent) when the product $\mathcal{F}q$ may be partitioned into single-particle components – just as it is done in Eqs. (2b) and (3b) for the electric and magnetic fields. Here the applied field may be taken into account on the microscopic level, including its effect directly into the energy ε_k of each particle. In this case, the field contributes to the total internal energy E directly, and hence the thermodynamic equilibrium (at $T = \text{const}$) is described as the minimum of F . (We may say that in this case $F = G$, unless a difference between these thermodynamic potentials is created by the actual mechanical pressure P .) However, in some cases, typically for condensed systems, with their strong interparticle interactions, the easier (and sometimes the only one practicable³³) way to account for the field is on the macroscopic level, taking $G = F - \mathcal{F}q$. In this case, the same equilibrium state is described as the minimum of G . (Several examples of this dichotomy will be given later in this course.) Whatever the choice, one should mind not take the same field effect into account twice.

³¹ There are a few practicable systems, notably including the so-called *adiabatic magnetic refrigerators* (to be discussed in Chapter 2), where the unintentional growth of S is so slow that the condition $S = \text{const}$ may be closely approached.

³² It is convenient to describe it as the difference between the “usual” (internal) potential energy U of the system to its “Gibbs potential energy” U_G – see CM Sec. 1.4. For the readers who skipped that discussion: my pet example is the usual elastic spring with $U = kx^2/2$, under the effect of an external force \mathcal{F} , whose equilibrium position ($x_0 = \mathcal{F}/k$) evidently corresponds to the minimum of $U_G = U - \mathcal{F}x$, rather than just U .

³³ An example of such an extreme situation is the case when an external magnetic field \mathcal{H} is applied to a superconductor in its so-called *intermediate state*, in which the sample partitions into domains of the “normal” phase with $\mathcal{B} = \mu_0 \mathcal{H}$, and the superconducting phase with $\mathcal{B} = 0$. In this case, the field is effectively applied to the interfaces between the domains, very similarly to the mechanical pressure applied to a gas portion via a piston – see Fig. 1 again.

One more important conceptual question I would like to discuss here is why usually statistical physics pursues the calculation of thermodynamic potentials, rather than just of a relation between P , V , and T . (Such relation is called the *equation of state* of the system.) Let us explore this issue on the particular but important example of an *ideal classical gas* in thermodynamic equilibrium, for which the equation of state should be well known to the reader from undergraduate physics:³⁴

Ideal gas:
equation
of state

$$PV = NT, \quad (1.44)$$

where N is the number of particles in volume V . (In Chapter 3, we will derive Eq. (44) from statistics.) Let us try to use it for the calculation of all thermodynamic potentials, and all other thermodynamic variables discussed above. We may start, for example, from the calculation of the free energy F . Indeed, integrating the second of Eqs. (35) with the pressure calculated from Eq. (44), $P = NT/V$, we get

$$F = -\int PdV \Big|_{T=\text{const}} = -NT \int \frac{dV}{V} \equiv -NT \int \frac{d(V/N)}{(V/N)} = -NT \ln \frac{V}{N} + Nf(T), \quad (1.45)$$

where V has been divided by N in both instances just to represent F as a manifestly extensive variable, in this uniform system proportional to N . The integration “constant” $f(T)$ is some function of temperature, which cannot be recovered from the equation of state. This function affects all other thermodynamic potentials, and the entropy as well. Indeed, using the first of Eqs. (35) together with Eq. (45), we get

$$S = -\left(\frac{\partial F}{\partial T}\right)_V = N \left[\ln \frac{V}{N} - \frac{df(T)}{dT} \right], \quad (1.46)$$

and now may combine Eqs. (33) with (46) to calculate the (internal) energy of the gas,³⁵

$$E = F + TS = \left[-NT \ln \frac{V}{N} + Nf(T) \right] + T \left[N \ln \frac{V}{N} - N \frac{df(T)}{dT} \right] \equiv N \left[f(T) - T \frac{df(T)}{dT} \right], \quad (1.47)$$

then use Eqs. (27), (44) and (47) to calculate its enthalpy,

$$H = E + PV = E + NT = N \left[f(T) - T \frac{df(T)}{dT} + T \right], \quad (1.48)$$

and, finally, plug Eqs. (44) and (45) into Eq. (37) to calculate the Gibbs energy

$$G = F + PV = N \left[-T \ln \frac{V}{N} + f(T) + T \right]. \quad (1.49)$$

³⁴ The long history of the gradual discovery of this relation includes the very early (circa 1662) work by R. Boyle and R. Townely, followed by contributions from H. Power, E. Mariotte, J. Charles, J. Dalton, and J. Gay-Lussac. It was fully formulated by Benoît Paul Émile Clapeyron in 1834, in the form $PV = nRT_K$, where n is the number of moles in the gas sample, and $R \approx 8.31 \text{ J/mole}\cdot\text{K}$ is the so-called *gas constant*. This form is equivalent to Eq. (44), taking into account that $R \equiv k_B N_A$, where $N_A = 6.022\ 140\ 76 \times 10^{23} \text{ mole}^{-1}$ is the *Avogadro number*, i.e. the number of molecules per mole. (By the mole’s definition, N_A is just the reciprocal mass, in grams, of the 1/12th part of the ¹²C atom, which is close to the mass of one proton or neutron – see *Appendix CA: Selected Physical Constants*.) Historically, this equation of state was the main argument for the introduction of the absolute temperature T , because only with it, the equation acquires the spectacularly simple form (44).

³⁵ Note that Eq. (47), in particular, describes a very important property of the ideal classical gas: its energy depends only on temperature (and the number of particles), but not on volume or pressure.

One might ask whether the function $f(T)$ is physically significant, or it is something like the inconsequential, arbitrary constant – like the one that may be always added to the potential energy in non-relativistic mechanics. In order to address this issue, let us calculate, from Eqs. (24) and (28), both heat capacities, which are evidently measurable quantities:

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = -NT \frac{d^2 f}{dT^2}, \quad (1.50)$$

$$C_P = \left(\frac{\partial H}{\partial T} \right)_P = N \left(-T \frac{d^2 f}{dT^2} + 1 \right) = C_V + N. \quad (1.51)$$

We see that the function $f(T)$, or at least its second derivative, is measurable.³⁶ (In Chapter 3, we will calculate this function for two simple “microscopic” models of the ideal classical gas.) The meaning of this function is evident from the physical picture of the ideal gas: the pressure P exerted on the walls of the containing volume is produced only by the translational motion of the gas molecules, while their internal energy E (and hence other thermodynamic potentials) may be also contributed by the internal dynamics of the molecules – their rotations, vibrations, etc. Thus, the equation of state does *not* give us the full thermodynamic description of a system, while the thermodynamic potentials do.

1.5. Systems with a variable number of particles

Now we have to consider one more important case: when the number N of particles in a system is not rigidly fixed, but may change as a result of a thermodynamic process. A typical example of such a system is a gas sample separated from the environment by a penetrable partition – see Fig. 7.³⁷

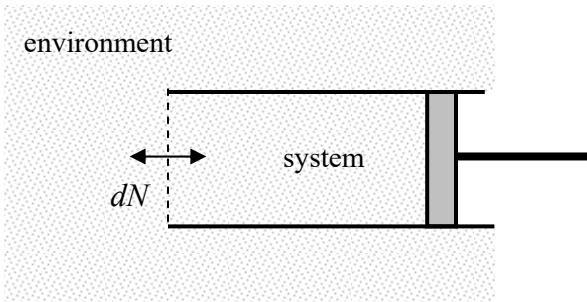

Fig. 1.7. An example of a system with a variable number of particles.

Let us analyze this situation for the simplest case when all the particles are similar. (In Sec. 4.1, this analysis will be extended to systems with particles of several sorts). In this case, we may consider N as an independent thermodynamic variable whose variation may change the energy E of the system, so that (for a slow, reversible process) Eq. (17) should be now generalized as

$$dE = TdS - PdV + \mu dN, \quad (1.52)$$

Chemical potential:
definition

³⁶ Note, however, that the difference $C_P - C_V = N$ is independent of $f(T)$. (If the temperature is measured in kelvins, this relation takes a more familiar form $C_P - C_V = nR$.) It is straightforward (and hence left for the reader’s exercise) to show that the difference $C_P - C_V$ of *any* system is fully determined by its equation of state.

³⁷ Another important example is a gas in a contact with the open-surface liquid of similar molecules.

where μ is a new function of state, called the *chemical potential*.³⁸ Keeping the definitions of other thermodynamic potentials, given by Eqs. (27), (33), and (37), intact, we see that the expressions for their differentials should be generalized as

$$dH = TdS + VdP + \mu dN, \quad (1.53a)$$

$$dF = -SdT - PdV + \mu dN, \quad (1.53b)$$

$$dG = -SdT + VdP + \mu dN, \quad (1.53c)$$

so that the chemical potential may be calculated as either of the following partial derivatives:³⁹

$$\mu = \left(\frac{\partial E}{\partial N} \right)_{S,V} = \left(\frac{\partial H}{\partial N} \right)_{S,P} = \left(\frac{\partial F}{\partial N} \right)_{T,V} = \left(\frac{\partial G}{\partial N} \right)_{T,P}. \quad (1.54)$$

Despite the formal similarity of all Eqs. (54), one of them is more consequential than the others. Indeed, the Gibbs energy G is the only thermodynamic potential that is a function of two *intensive* parameters, T and P . However, as all thermodynamic potentials, G has to be *extensive*, so that in a system of similar particles it has to be proportional to N :

$$G = Ng, \quad (1.55)$$

where g is some function of T and P . Plugging this expression into the last of Eqs. (54), we see that μ equals exactly this function, so that

$$\boxed{\mu = \frac{G}{N}}, \quad (1.56)$$

i.e. the chemical potential is just the Gibbs energy per particle.

In order to demonstrate how vital the notion of chemical potential may be, let us consider the situation (parallel to that shown in Fig. 2) when a system consists of two parts, with equal pressure and temperature, that can exchange particles at a relatively slow rate (much slower than the speed of the internal relaxation of each part). Then we can write two equations similar to Eqs. (5):

$$N = N_1 + N_2, \quad G = G_1 + G_2, \quad (1.57)$$

where $N = \text{const}$, and Eq. (56) may be used to describe each component of G :

$$G = \mu_1 N_1 + \mu_2 N_2. \quad (1.58)$$

Plugging the N_2 expressed from the first of Eqs. (57), $N_2 = N - N_1$, into Eq. (58), we see that

$$\frac{dG}{dN_1} = \mu_1 - \mu_2, \quad (1.59)$$

so that the minimum of G is achieved at $\mu_1 = \mu_2$. Hence, in the conditions of fixed temperature and pressure, i.e. when G is the appropriate thermodynamic potential, the chemical potentials of the system parts should be equal – the so-called *chemical equilibrium*.

³⁸ This name, of a historic origin, is misleading: as evident from Eq. (52), μ has a clear *physical* sense of the average energy cost of adding one more particle to the system of $N \gg 1$ particles.

³⁹ Note that strictly speaking, Eqs. (9), (15), (31), (35), and (39) should be now generalized by adding another lower index, N , to the corresponding derivatives; I will just imply this.

Finally, later in the course, we will also run into several cases when the volume V of a system, its temperature T , and the chemical potential μ are all fixed. (The last condition may be readily implemented by allowing the system of our interest to exchange particles with an environment so large that its μ stays constant.) The thermodynamic potential appropriate for this case may be obtained by subtraction of the product μN from the free energy F , resulting in the so-called *grand thermodynamic* (or “Landau”) *potential*:

$$\Omega \equiv F - \mu N = F - \frac{G}{N} N \equiv F - G = -PV. \quad (1.60)$$

Grand potential: definition

Indeed, for a reversible process, the full differential of this potential is

$$d\Omega = dF - d(\mu N) = (-SdT - PdV + \mu dN) - (\mu dN + Nd\mu) = -SdT - PdV - Nd\mu, \quad (1.61)$$

Grand potential: differential

so that if Ω has been calculated as a function of T , V , and μ , other thermodynamic variables may be found as

$$S = -\left(\frac{\partial\Omega}{\partial T}\right)_{V,\mu}, \quad P = -\left(\frac{\partial\Omega}{\partial V}\right)_{T,\mu}, \quad N = -\left(\frac{\partial\Omega}{\partial\mu}\right)_{T,V}. \quad (1.62)$$

Now acting exactly as we have done for other potentials, it is straightforward to prove that an irreversible process with fixed T , V , and μ , provides $d\Omega/dt \leq 0$, so that system’s equilibrium indeed corresponds to the minimum of the grand potential Ω . We will repeatedly use this fact in this course.

1.6. Thermal machines

In order to complete this brief review of thermodynamics, I cannot completely pass the topic of *thermal machines* – not because it will be used much in this course, but mostly because of its practical and historic significance.⁴⁰ Figure 8a shows the generic scheme of a thermal machine that may perform mechanical work on its environment (in our notation, equal to $-\mathcal{W}$) during each cycle of the expansion/compression of some “working gas”, by transferring different amounts of heat from a high-temperature heat bath (Q_H) and to the low-temperature bath (Q_L).

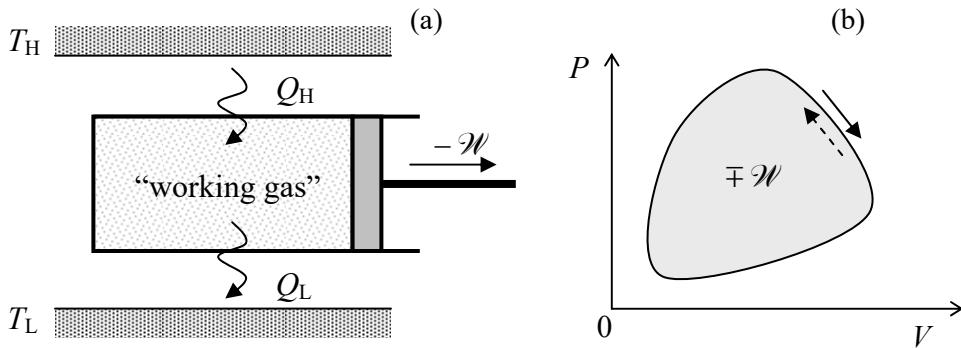

Fig. 1.8. (a) The simplest implementation of a thermal machine, and (b) the graphic representation of the mechanical work it performs. On panel (b), the solid arrow indicates the heat engine cycle direction, while the dashed arrow, the refrigerator cycle direction.

⁴⁰ The whole field of thermodynamics was spurred by the famous 1824 work by Nicolas Léonard Sadi Carnot, in which he, in particular, gave an alternative, indirect form of the 2nd law of thermodynamics – see below.

One relation between the three amounts Q_H , Q_L , and \mathcal{W} is immediately given by the energy conservation (i.e. by the 1st law of thermodynamics):

$$Q_H - Q_L = -\mathcal{W}. \quad (1.63)$$

From Eq. (1), the mechanical work during the cycle may be calculated as

$$-\mathcal{W} = \oint P dV, \quad (1.64)$$

and hence represented by the area circumvented by the state-representing point on the $[P, V]$ plane – see Fig. 8b. Note that the sign of this circular integral depends on the direction of the point's rotation; in particular, the work ($-\mathcal{W}$) done by the working gas is positive at its clockwise rotation (pertinent to *heat engines*) and negative in the opposite case (implemented in *refrigerators* and *heat pumps* – see below). Evidently, the work depends on the exact form of the cycle, which in turn may depend not only on T_H and T_L , but also on the working gas' properties.

An exception from this rule is the famous *Carnot cycle*, consisting of two isothermal and two adiabatic processes (all reversible!). In its heat engine's form, the cycle may start, for example, from an isothermic expansion of the working gas in contact with the hot bath (i.e. at $T = T_H$). It is followed by its additional adiabatic expansion (with the gas being disconnected from both heat baths) until its temperature drops to T_L . Then an isothermal compression of the gas is performed in its contact with the cold bath (at $T = T_L$), followed by its additional adiabatic compression to raise T to T_H again, after which the cycle is repeated again and again. Note that during this cycle the working gas is never in contact with both heat baths simultaneously, thus avoiding the irreversible heat transfer between them. The cycle's shape on the $[V, P]$ plane (Fig. 9a) depends on the exact properties of the working gas and may be rather complicated. However, since the system's entropy is constant at any adiabatic process, the Carnot cycle's shape on the $[S, T]$ plane is always rectangular – see Fig. 9b.

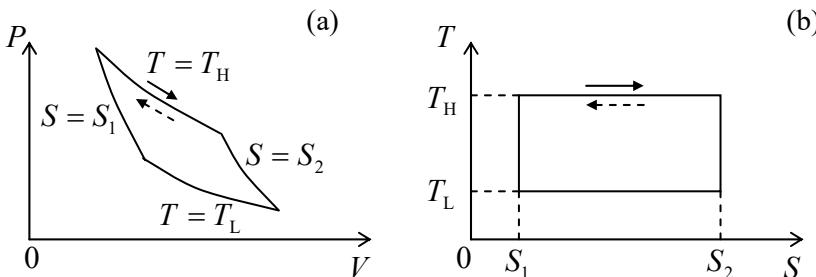

Fig. 1.9. Representation of the Carnot cycle: (a) on the $[V, P]$ plane (schematically), and (b) on the $[S, T]$ plane. The meaning of the arrows is the same as in Fig. 8.

Since during each isotherm, the working gas is brought into thermal contact only with the corresponding heat bath, i.e. its temperature is constant, the relation (19), $dQ = TdS$, may be immediately integrated to yield

$$Q_H = T_H(S_2 - S_1), \quad Q_L = T_L(S_2 - S_1). \quad (1.65)$$

Hence the ratio of these two heat flows is completely determined by their temperature ratio:

$$\frac{Q_H}{Q_L} = \frac{T_H}{T_L}, \quad (1.66)$$

regardless of the working gas properties. Formulas (63) and (66) are sufficient to find the ratio of the work ($-\mathcal{W}$) to any of Q_H and Q_L . For example, the main figure-of-merit of a thermal machine used as a heat engine ($Q_H > 0, Q_L > 0, -\mathcal{W} = |\mathcal{W}| > 0$), is its *efficiency*

$$\eta \equiv \frac{|\mathcal{W}|}{Q_H} = \frac{Q_H - Q_L}{Q_H} \equiv 1 - \frac{Q_L}{Q_H} \leq 1. \quad (1.67)$$

Heat
engine's
efficiency:
definition

For the Carnot cycle, this definition, together with Eq. (66), immediately yield the famous relation⁴¹

$$\eta_{\text{Carnot}} = 1 - \frac{T_L}{T_H}, \quad (1.68)$$

Carnot
cycle's
efficiency

which shows that at a given T_L (that is typically the ambient temperature ~ 300 K), the efficiency may be increased, ultimately to 1, by raising the temperature T_H of the heat source.⁴²

The unique nature of the Carnot cycle (see Fig. 9b again) makes its efficiency (68) the upper limit for any heat engine.⁴³ Indeed, in this cycle, the transfer of heat between any heat bath and the working gas is performed reversibly, when their temperatures are equal. (If this is not so, some heat might flow from a hotter to colder bath without performing any work.) In particular, it shows that $\eta_{\max} = 0$ at $T_H = T_L$, i.e., no heat engine can perform mechanical work in the absence of temperature gradients.⁴⁴

On the other hand, if the cycle is reversed (see the dashed arrows in Figs. 8 and 9), the same thermal machine may serve as a *refrigerator*, providing heat removal from the low-temperature bath ($Q_L < 0$) at the cost of consuming external mechanical work: $\mathcal{W} > 0$. This reversal does not affect the basic relation (63), which now may be used to calculate the relevant figure-of-merit, called the *cooling coefficient of performance* (COP_{cooling}):

$$\text{COP}_{\text{cooling}} \equiv \frac{|Q_L|}{\mathcal{W}} = \frac{Q_L}{Q_H - Q_L}. \quad (1.69)$$

Notice that this coefficient may be above unity; in particular, for the Carnot cycle we may use Eq. (66) (which is also unaffected by the cycle reversal) to get

$$(\text{COP}_{\text{cooling}})_{\text{Carnot}} = \frac{T_L}{T_H - T_L}, \quad (1.70)$$

⁴¹ Curiously, S. Carnot derived his key result still believing that heat is some specific fluid (“caloric”), whose flow is driven by the temperature difference, rather than just a form of particle motion.

⁴² Semi-quantitatively, such trend is valid also for other, less efficient but more practicable heat engine cycles – see Problems 13-16. This trend is the leading reason why internal combustion engines, with T_H of the order of 1,500 K, are more efficient than steam engines, with the difference $T_H - T_L$ of at most a few hundred K.

⁴³ In some alternative axiomatic systems of thermodynamics, this fact is postulated and serves the role of the 2nd law. This is why it is under persisting (dominantly, theoretical) attacks by suggestions of more efficient heat engines – recently, mostly of quantum systems using sophisticated protocols such as the so-called *shortcut-to-adiabaticity* – see, e.g., the recent paper by O. Abah and E. Lutz, *Europhysics Lett.* **118**, 40005 (2017), and references therein. To the best of my knowledge, reliable analyses of all the suggestions put forward so far have confirmed that the Carnot efficiency (68) is the highest possible even in quantum systems.

⁴⁴ Such a hypothetical heat engine, which would violate the 2nd law of thermodynamics, is called the “perpetual motion machine of the 2nd kind” – in contrast to any (also hypothetical) “perpetual motion machine of the 1st kind” that would violate the 1st law, i.e., the energy conservation.

so that this value is larger than 1 at $T_H < 2T_L$, and even may be much larger than that when the temperature difference $(T_H - T_L)$ sustained by the refrigerator, tends to zero. For example, in a typical air-conditioning system, this difference is of the order of 10 K, while $T_L \sim 300$ K, so that $(T_H - T_L) \sim T_L/30$, i.e. the Carnot value of $\text{COP}_{\text{cooling}}$ is as high as ~ 30 . (In the state-of-the-art commercial HVAC systems it is within the range of 3 to 4.) This is why the term “cooling efficiency”, used in some textbooks instead of $(\text{COP})_{\text{cooling}}$, may be misleading.

Since in the reversed cycle $Q_H = -\mathcal{W} + Q_L < 0$, i.e. the system provides heat flow into the high-temperature heat bath, it may be used as a *heat pump* for heating purposes. The figure-of-merit appropriate for this application is different from Eq. (69):

$$\text{COP}_{\text{heating}} \equiv \frac{|Q_H|}{\mathcal{W}} = \frac{Q_H}{Q_H - Q_L}, \quad (1.71)$$

so that for the Carnot cycle, using Eq. (66) again, we get

$$(\text{COP}_{\text{heating}})_{\text{Carnot}} = \frac{T_H}{T_H - T_L}. \quad (1.72)$$

Note that this COP is *always* larger than 1, meaning that the Carnot heat pump is always more efficient than the direct conversion of work into heat (when $Q_H = -\mathcal{W}$, so that $\text{COP}_{\text{heating}} = 1$), though practical electricity-driven heat pumps are substantially more complex, and hence more expensive than simple electric heaters. Such heat pumps, with the typical $\text{COP}_{\text{heating}}$ values around 4 in summer and 2 in winter, are frequently used for heating large buildings.

Finally, note that according to Eq. (70), the $\text{COP}_{\text{cooling}}$ of the Carnot cycle tends to zero at $T_L \rightarrow 0$, making it impossible to reach the absolute zero of temperature, and hence illustrating the meaningful (Nernst's) formulation of the 3rd law of thermodynamics, cited in Sec. 3. Indeed, let us prescribe a finite but very large heat capacity $C(T)$ to the low-temperature bath, and use the definition of this variable to write the following expression for the relatively small change of its temperature as a result of dn similar refrigeration cycles:

$$C(T_L)dT_L = Q_L dn. \quad (1.73)$$

Together with Eq. (66), this relation yields

$$\frac{C(T_L)dT_L}{T_L} = -\frac{|Q_H|}{T_H} dn. \quad (1.74)$$

If $T_L \rightarrow 0$, so that $T_H \gg T_L$ and $|Q_H| \approx -\mathcal{W} = \text{const}$, the right-hand side of this equation does not depend on T_L , so that if we integrate it over many ($n \gg 1$) cycles, getting the following simple relation between the initial and final values of T_L :

$$\int_{T_{\text{ini}}}^{T_{\text{fin}}} \frac{C(T)dT}{T} = -\frac{|Q_H|}{T_H} n. \quad (1.75)$$

For example, if $C(T)$ is a constant, Eq. (75) yields an exponential law,

$$T_{\text{fin}} = T_{\text{ini}} \exp \left\{ -\frac{|Q_H|}{CT_H} n \right\}, \quad (1.76)$$

with the absolute zero of temperature not reached as any finite n . Even for an arbitrary function $C(T)$ that does not vanish at $T \rightarrow 0$, Eq. (74) proves the Nernst theorem, because dn diverges at $T_L \rightarrow 0$.⁴⁵

1.7. Exercise problems

1.1. Two bodies, with temperature-independent heat capacities C_1 and C_2 , and different initial temperatures T_1 and T_2 , are placed into a weak thermal contact. Calculate the change of the total entropy of the system before it reaches the thermal equilibrium.

1.2. A gas portion has the following properties:

- (i) its heat capacity $C_V = aT^b$, and
- (ii) the work \mathcal{W}_T needed for its isothermal compression from V_2 to V_1 equals $cT\ln(V_2/V_1)$,

where a , b , and c are some constants. Find the equation of state of the gas, and calculate the temperature dependence of its entropy S and thermodynamic potentials E , H , F , G , and Ω .

1.3. A closed volume with an ideal classical gas of similar molecules is separated with a partition in such a way that the number N of molecules in each part is the same, but their volumes are different. The gas is initially in thermal equilibrium, and its pressure in one part is P_1 , and in the other part, P_2 . Calculate the change of entropy resulting from a fast removal of the partition, and analyze the result.

1.4. An ideal classical gas of N particles is initially confined to volume V , and is in thermal equilibrium with a heat bath of temperature T . Then the gas is allowed to expand to volume $V' > V$ in one of the following ways:

- (i) The expansion is slow, so that due to the sustained thermal contact with the heat bath, the gas temperature remains equal to T .
- (ii) The partition separating the volumes V and $(V' - V)$ is removed very fast, allowing the gas to expand rapidly.

For each process, calculate the eventual changes of pressure, temperature, energy, and entropy of the gas at its expansion.

1.5. For an ideal classical gas with temperature-independent specific heat, derive the relation between P and V at an adiabatic expansion/compression.

1.6. Calculate the speed and the wave impedance of acoustic waves propagating in an ideal classical gas with temperature-independent specific heat, in the limits when the propagation may be treated as:

- (i) an isothermal process, and
- (ii) an adiabatic process.

⁴⁵ Note that for such metastable systems as glasses the situation may be more complicated. (For a detailed discussion of this issue see, e.g., J. Wilks, *The Third Law of Thermodynamics*, Oxford U. Press, 1961.) Fortunately, this issue does not affect other aspects of statistical physics – at least those to be discussed in this course.

Which of these limits is achieved at higher wave frequencies?

1.7. As will be discussed in Sec. 3.5, the so-called “hardball” models of classical particle interaction yield the following equation of state of a gas of such particles:

$$P = T\varphi(n),$$

where $n = N/V$ is the particle density, and the function $\varphi(n)$ is generally different from that ($\varphi_{\text{ideal}}(n) = n$) of the ideal gas, but still independent of temperature. For such a gas, with temperature-independent c_V , calculate:

- (i) the energy of the gas, and
- (ii) its pressure as a function of n at the adiabatic compression.

1.8. For an arbitrary thermodynamic system with a fixed number of particles, prove the following four *Maxwell relations* (already mentioned in Sec. 4):

$$\begin{aligned} \text{(i)}: \left(\frac{\partial S}{\partial V}\right)_T &= \left(\frac{\partial P}{\partial T}\right)_V, & \text{(ii)}: \left(\frac{\partial V}{\partial S}\right)_P &= \left(\frac{\partial T}{\partial P}\right)_S, \\ \text{(iii)}: \left(\frac{\partial S}{\partial P}\right)_T &= -\left(\frac{\partial V}{\partial T}\right)_P, & \text{(iv)}: \left(\frac{\partial P}{\partial S}\right)_V &= -\left(\frac{\partial T}{\partial V}\right)_S, \end{aligned}$$

and also the following relation:

$$\left(\frac{\partial E}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V - P.$$

1.9. Express the heat capacity difference, $C_P - C_V$, via the equation of state $P = P(V, T)$ of the system.

1.10. Prove that the *isothermal compressibility*⁴⁶

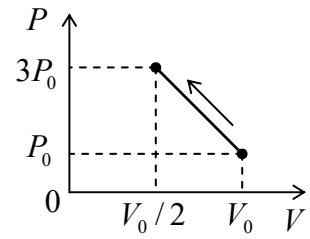

$$\kappa_T \equiv -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_{T,N}$$

in a single-phase system may be expressed in two different ways:

$$\kappa_T = \frac{V^2}{N^2}\left(\frac{\partial^2 P}{\partial \mu^2}\right)_T = \frac{V}{N^2}\left(\frac{\partial N}{\partial \mu}\right)_{T,V}.$$

1.11. A reversible process, performed with a fixed portion of an ideal classical gas, may be represented on the $[V, P]$ plane with the straight line shown in the figure on the right. Find the point at which the heat flow into/out of the gas changes its direction.

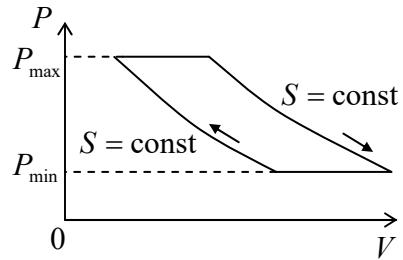

1.12. Two bodies have equal, temperature-independent heat capacities

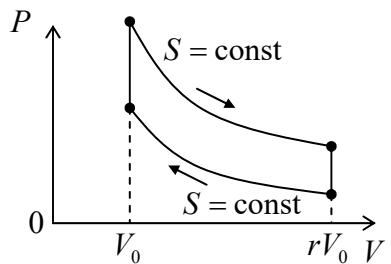

⁴⁶ Note that the compressibility is just the reciprocal bulk modulus, $\kappa = 1/K$ – see, e.g., CM Sec. 7.3.

C , but different temperatures, T_1 and T_2 . Calculate the maximum mechanical work obtainable from this system, using a heat engine.

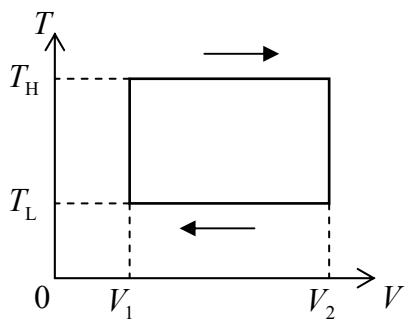

1.13. Express the efficiency η of a heat engine that uses the so-called *Joule cycle*, consisting of two adiabatic and two isobaric processes (see the figure on the right), via the minimum and maximum values of pressure, and compare the result with η_{Carnot} . Assume an ideal classical working gas with temperature-independent C_P and C_V .

1.14. Calculate the efficiency of a heat engine using the *Otto cycle*,⁴⁷ which consists of two adiabatic and two isochoric (constant-volume) reversible processes – see the figure on the right. Explore how the efficiency depends on the ratio $r \equiv V_{\max}/V_{\min}$, and compare it with the Carnot cycle's efficiency. Assume an ideal classical working gas with temperature-independent heat capacity.

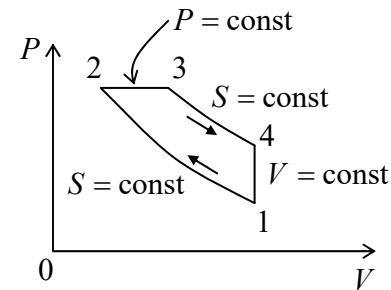

1.15. A heat engine's cycle consists of two isothermal ($T = \text{const}$) and two isochoric ($V = \text{const}$) reversible processes – see the figure on the right.⁴⁸

(i) Assuming that the working gas is an ideal classical gas of N particles, calculate the mechanical work performed by the engine during one cycle.

(ii) Are the specified conditions sufficient to calculate the engine's efficiency? (Justify your answer.)

1.16. The *Diesel cycle* (an approximate model of the Diesel internal combustion engine's operation) consists of two adiabatic processes, one isochoric process, and one isobaric process – see the figure on the right. Assuming an ideal working gas with temperature-independent C_V and C_P , express the efficiency η of the heat engine using this cycle via the gas temperature values in its transitional states corresponding to the corners of the cycle diagram.

⁴⁷ This name stems from the fact that the cycle is an approximate model of operation of the four-stroke internal combustion engine, which was improved and made practicable (though not invented!) by N. Otto in 1876.

⁴⁸ The reversed cycle of this type is a reasonable approximation for the operation of the *Stirling* and *Gifford-McMahon* (GM) refrigerators, broadly used for *cryocooling* – for a recent review see, e.g., A. de Waele, *J. Low Temp. Phys.* **164**, 179 (2011).

Chapter 2. Principles of Physical Statistics

This chapter is the keystone of this course. It starts with a brief discussion of such basic notions of statistical physics as statistical ensembles, probability, and ergodicity. Then the so-called microcanonical distribution postulate is formulated, simultaneously with the statistical definition of the entropy. This allows a derivation of the famous Gibbs (“canonical”) distribution – the most frequently used tool of statistical physics. Then we will discuss one more, “grand canonical” distribution, which is more convenient for some tasks. In particular, it is immediately used for the derivation of the most important Boltzmann, Fermi-Dirac, and Bose-Einstein statistics of independent particles, which will be repeatedly utilized in the following chapters.

2.1. Statistical ensembles and probability

As has been already discussed in Sec. 1.1, statistical physics deals with situations when either unknown initial conditions, or system’s complexity, or the laws of its motion (as in the case of quantum mechanics) do not allow a definite prediction of measurement results. The main formalism for the analysis of such systems is the probability theory, so let me start with a very brief review of its basic concepts, using an informal “physical” language – less rigorous but (hopefully) more transparent than standard mathematical treatments,¹ and quite sufficient for our purposes.

Consider $N \gg 1$ independent similar experiments carried out with *apparently* similar systems (i.e. systems with identical *macroscopic* parameters such as volume, pressure, etc.), but still giving, by any of the reasons listed above, different results of measurements. Such a collection of experiments, together with a fixed method of result processing, is a good example of a *statistical ensemble*. Let us start from the case when the experiments may have M different *discrete* outcomes, and the number of experiments giving the corresponding different results is N_1, N_2, \dots, N_M , so that

$$\sum_{m=1}^M N_m = N. \quad (2.1)$$

The *probability* of each outcome, for the given statistical ensemble, is then defined as

Probability

$$W_m \equiv \lim_{N \rightarrow \infty} \frac{N_m}{N}. \quad (2.2)$$

Though this definition is so close to our everyday experience that it is almost self-evident, a few remarks may still be relevant.

First, the probabilities W_m depend on the exact statistical ensemble they are defined for, notably including the method of result processing. As the simplest example, consider throwing the standard cubic-shaped dice many times. For the ensemble of all thrown and counted dice, the probability of each outcome (say, “1”) is $1/6$. However, nothing prevents us from defining another statistical ensemble of dice-throwing experiments in which all outcomes “1” are discounted. Evidently, the probability of

¹ For the reader interested in a more rigorous approach, I can recommend, for example, Chapter 18 of the handbook by G. Korn and T. Korn – see MA Sec. 16(ii).

finding outcomes “1” in this modified (but legitimate) ensemble is 0, while for all other five outcomes (“2” to “6”), it is $1/5$ rather than $1/6$.

Second, a statistical ensemble does not necessarily require N similar physical systems, e.g., N distinct dice. It is intuitively clear that tossing the same die N times constitutes an ensemble with similar statistical properties. More generally, a set of N experiments with the same system gives a statistical ensemble equivalent to the set of experiments with N different systems, provided that the experiments are kept independent, i.e. that outcomes of past experiments do not affect those of the experiments to follow. Moreover, for many physical systems of interest, no special preparation of each experiment is necessary, and N experiments separated by sufficiently long time intervals, form a “good” statistical ensemble – the property called *ergodicity*.²

Third, the reference to infinite N in Eq. (2) does not strip the notion of probability from its practical relevance. Indeed, it is easy to prove (see Chapter 5) that, at very general conditions, at finite but sufficiently large N , the numbers N_m are approaching their *average* (or *expectation*) values³

$$\langle N_m \rangle \equiv W_m N, \quad (2.3)$$

with the relative deviations decreasing as $\sim 1/\langle N_m \rangle^{1/2}$, i.e. as $1/N^{1/2}$.

Now let me list those properties of probabilities that we will immediately need. First, dividing both sides of Eq. (1) by N and following the limit $N \rightarrow \infty$, we get the well-known *normalization condition*

$$\sum_{m=1}^M W_m = 1; \quad (2.4)$$

just remember that it is true only if each experiment definitely yields one of the outcomes N_1, N_2, \dots, N_M .

Second, if we have an additive function of the results,

$$f = \frac{1}{N} \sum_{m=1}^M N_m f_m, \quad (2.5)$$

where f_m are some definite (deterministic) coefficients, the *statistical average* (also called the *expectation value*) of the function is naturally defined as

² The most popular counter-example is an energy-conserving system. Consider, for example, a system of particles placed in a potential that is a quadratic form of its coordinates. The theory of oscillations tells us (see, e.g., CM Sec. 6.2) that this system is equivalent to a set of non-interacting harmonic oscillators. Each of these oscillators conserves its own initial energy E_j forever, so that the statistics of N measurements of one such system may differ from that of N different systems with a random distribution of E_j , even if the total energy of the system, $E = \sum_j E_j$, is the same. Such non-ergodicity, however, is a rather feeble phenomenon and is readily destroyed by any of many mechanisms, such as weak interaction with the environment (leading, in particular, to oscillation damping), potential anharmonicity (see, e.g., CM Chapter 5), and chaos (CM Chapter 9), all of them strongly enhanced by increasing the number of particles in the system, i.e. the number of its degrees of freedom. This is why an overwhelming part of real-life systems are ergodic; for the readers interested in non-ergodic exotics, I can recommend the monograph by V. Arnold and A. Avez, *Ergodic Problems of Classical Mechanics*, Addison-Wesley, 1989.

³ Here, and everywhere in this series, angle brackets $\langle \dots \rangle$ mean averaging over a statistical ensemble, which is generally different from averaging over time – as it will be the case in quite a few examples considered below.

$$\langle f \rangle \equiv \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{m=1}^M \langle N_m \rangle f_m, \quad (2.6)$$

so that using Eq. (3) we get

Expectation
value via
probabilities

$$\langle f \rangle = \sum_{m=1}^M W_m f_m. \quad (2.7)$$

Notice that Eq. (3) may be considered as the particular form of this general result, when all $f_m = 1$.

Next, the spectrum of possible experimental outcomes is frequently continuous for all practical purposes. (Think, for example, about the set of positions of the marks left by bullets fired into a target from afar.) The above formulas may be readily generalized to this case; let us start from the simplest situation when all different outcomes may be described by just one continuous scalar variable q – which replaces the discrete index m in Eqs. (1)-(7). The basic relation for this case is the self-evident fact that the probability dW of having an outcome within a small interval dq near some point q is proportional to the magnitude of that interval:

$$dW = w(q)dq, \quad (2.8)$$

where $w(q)$ is some function of q , which does not depend on dq . This function is called *probability density*. Now all the above formulas may be recast by replacing the probabilities W_m with the products (8), and the summation over m , with the integration over q . In particular, instead of Eq. (4) the normalization condition now becomes

$$\int w(q)dq = 1, \quad (2.9)$$

where the integration should be extended over the whole range of possible values of q . Similarly, instead of the discrete values f_m participating in Eq. (5), it is natural to consider a function $f(q)$. Then instead of Eq. (7), the expectation value of the function may be calculated as

$$\langle f \rangle = \int w(q)f(q)dq. \quad (2.10)$$

Expectation
value via
probability
density

It is also straightforward to generalize these formulas to the case of more variables. For example, the state of a classical particle with three degrees of freedom may be fully described by the probability density w defined in the 6D space of its generalized radius-vector \mathbf{q} and momentum \mathbf{p} . As a result, the expectation value of a function of these variables may be expressed as a 6D integral

$$\langle f \rangle = \int w(\mathbf{q}, \mathbf{p})f(\mathbf{q}, \mathbf{p})d^3qd^3p. \quad (2.11)$$

Some systems considered in this course consist of components whose quantum properties cannot be ignored, so let us discuss how $\langle f \rangle$ should be calculated in this case. If by f_m we mean measurement results, then Eq. (7) (and its generalizations) remains valid, but since these numbers themselves may be affected by the intrinsic quantum-mechanical uncertainty, it may make sense to have a bit deeper look into this situation. Quantum mechanics tells us⁴ that the most general expression for the expectation value of an observable f in a certain ensemble of macroscopically similar systems is

$$\langle f \rangle = \sum_{m,m'} W_{mm'} f_{m'm} \equiv \text{Tr}(Wf). \quad (2.12)$$

⁴ See, e.g., QM Sec. 7.1.

Here $f_{mm'}$ are the matrix elements of the quantum-mechanical operator \hat{f} corresponding to the observable f , in a full basis of orthonormal states m ,

$$f_{mm'} = \langle m | \hat{f} | m' \rangle, \quad (2.13)$$

while the coefficients $W_{mm'}$ are the elements of the so-called *density matrix* W , which represents, in the same basis, the *density operator* \hat{W} describing properties of this ensemble. Eq. (12) is evidently more general than Eq. (7), and is reduced to it only if the density matrix is diagonal:

$$W_{mm'} = W_m \delta_{mm'} \quad (2.14)$$

(where $\delta_{mm'}$ is the Kronecker symbol), when the diagonal elements W_m play the role of probabilities of the corresponding states.

Thus formally, the largest difference between the quantum and classical description is the presence, in Eq. (12), of the off-diagonal elements of the density matrix. They have the largest values in the *pure* (also called “coherent”) ensemble, in which the state of the system may be described with *state vectors*, e.g., the *ket-vector*

$$|\alpha\rangle = \sum_m \alpha_m |m\rangle, \quad (2.15)$$

where α_m are some (generally, complex) coefficients. In this case, the density matrix elements are merely

$$W_{mm'} = \alpha_m^* \alpha_{m'}, \quad (2.16)$$

so that the off-diagonal elements are of the same order as the diagonal elements. For example, in the very important particular case of a *two-level system*, the pure-state density matrix is

$$W = \begin{pmatrix} \alpha_1^* \alpha_1 & \alpha_1^* \alpha_2 \\ \alpha_2^* \alpha_1 & \alpha_2^* \alpha_2 \end{pmatrix}, \quad (2.17)$$

so that the product of its off-diagonal components is as large as that of the diagonal components.

In the most important basis of stationary states, i.e. the eigenstates of the system’s time-independent Hamiltonian, the coefficients α_m oscillate in time as⁵

$$\alpha_m(t) = \alpha_m(0) \exp\left\{-i \frac{E_m}{\hbar} t\right\} \equiv |\alpha_m| \exp\left\{-i \frac{E_m}{\hbar} t + i\varphi_m\right\}, \quad (2.18)$$

where E_m are the corresponding eigenenergies, and φ_m are constant phase shifts. This means that while the diagonal terms of the density matrix (16) remain constant, its off-diagonal components are oscillating functions of time:

$$W_{mm'} = \alpha_{m'}^* \alpha_m = |\alpha_{m'} \alpha_m| \exp\left\{i \frac{E_m - E_{m'}}{\hbar} t\right\} \exp\{i(\varphi_{m'} - \varphi_m)\}. \quad (2.19)$$

⁵ Here I use the Schrödinger picture of quantum dynamics, in which the matrix elements $f_{nn'}$ representing quantum-mechanical operators, do not evolve in time. The final results of this discussion do not depend on the particular picture – see, e.g., QM Sec. 4.6.

Due to the extreme smallness of the Planck constant (on the human scale of things), minuscule random perturbations of eigenenergies are equivalent to substantial random changes of the phase multipliers, so that the time average of any off-diagonal matrix element tends to zero. Moreover, even if our statistical ensemble consists of systems with exactly the same E_m , but different values φ_m (which are typically hard to control at the initial preparation of the system), the average values of all $W_{mm'}$ (with $m \neq m'$) vanish again.

This is why, besides some very special cases, typical statistical ensembles of quantum particles are far from being pure, and in most cases (certainly including the thermodynamic equilibrium), a good approximation for their description is given by the opposite limit of the so-called *classical mixture*, in which all off-diagonal matrix elements of the density matrix equal zero, and its diagonal elements W_{mm} are merely the probabilities W_m of the corresponding eigenstates. In this case, for the observables compatible with energy, Eq. (12) is reduced to Eq. (7), with f_m being the eigenvalues of the variable f , so that we may base our further discussion on this key relation and its continuous extensions (10)-(11).

2.2. Microcanonical ensemble and distribution

Now we move to the now-standard approach to statistical mechanics, based on the three statistical ensembles introduced in the 1870s by Josiah Willard Gibbs.⁶ The most basic of them is the so-called *microcanonical statistical ensemble*⁷ defined as a set of macroscopically similar closed (isolated) systems with *virtually* the same total energy E . Since in quantum mechanics the energy of a closed system is quantized, in order to make the forthcoming discussion suitable for quantum systems as well, it is convenient to include to the ensemble all systems with energies E_m within a relatively narrow interval $\Delta E \ll E$ (see Fig. 1) that is nevertheless much larger than the average distance δE between the energy levels, so that the number M of different quantum states within the interval ΔE is large, $M \gg 1$. Such choice of ΔE is only possible if $\delta E \ll E$; however, the reader should not worry too much about this condition, because the most important applications of the microcanonical ensemble are for very large systems (and/or very high energies) when the energy spectrum is very dense.⁸

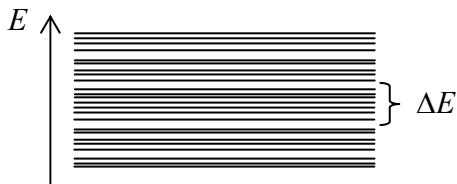

Fig. 2.1. A very schematic image of the microcanonical ensemble. (Actually, the ensemble deals with quantum states rather than energy levels. An energy level may be degenerate, i.e. correspond to several states.)

This ensemble serves as the basis for the formulation of the postulate which is most frequently called the *microcanonical distribution* (or, more adequately, “the main statistical postulate” or “the main

⁶ Personally, I believe that the genius of J. Gibbs, praised by Albert Einstein as the “greatest mind in the American history”, is still insufficiently recognized, and agree with R. Millikan that Gibbs “did for statistical mechanics and thermodynamics what [...] Maxwell did for electrodynamics”.

⁷ The terms “microcanonical”, as well as “canonical” (see Sec. 4 below) are apparently due to Gibbs and I was unable to find out his motivation for the former name. (“Canonical” in the sense of “standard” or “common” is quite appropriate, but why “micro”? Perhaps to reflect the smallness of ΔE ?)

⁸ Formally, the main result of this section, Eq. (20), is valid for any M (including $M = 1$); it is just less informative for small M – and trivial for $M = 1$.

statistical hypothesis"): *in the thermodynamic equilibrium of a microcanonical ensemble, all its states have equal probabilities,*

$$W_m = \frac{1}{M} = \text{const.} \quad (2.20)$$

Micro-canonical distribution

Though in some constructs of statistical mechanics this equality is derived from other axioms, which look more plausible to their authors, I believe that Eq. (20) may be taken as the starting point of the statistical physics, supported "just" by the compliance of all its corollaries with experimental observations.

Note that the postulate (20) is closely related to the macroscopic irreversibility of the systems that are microscopically virtually reversible (closed): if such a system was initially in a certain state, its time evolution with just minuscule interactions with the environment (which is necessary for reaching the thermodynamic equilibrium) eventually leads to the uniform distribution of its probability among all states with essentially the same energy. Each of these states is not "better" than the initial one; rather, in a macroscopic system, there are just so many of these states that the chance to find the system in the initial state is practically nil – again, think about the ink drop diffusion into a glass of water.⁹

Now let us find a suitable definition of the entropy S of a microcanonical ensemble's member – for now, in the thermodynamic equilibrium only. This was done in 1877 by another giant of statistical physics, Ludwig Eduard Boltzmann – on the basis of the prior work by James Clerk Maxwell on the kinetic theory of gases – see Sec. 3.1 below. In the present-day terminology, since S is a measure of *disorder*, it should be related to the amount of information¹⁰ *lost* when the system went irreversibly from the full order to the full disorder, i.e. from one definite state to the microcanonical distribution (20). In an even more convenient formulation, this is the amount of information necessary to find the exact state of your system in a microcanonical ensemble.

In the information theory, the amount of information necessary to make a definite choice between two options with equal probabilities (Fig. 2a) is defined as

$$I(2) \equiv \log_2 2 = 1. \quad (2.21)$$

This unit of information is called a *bit*.

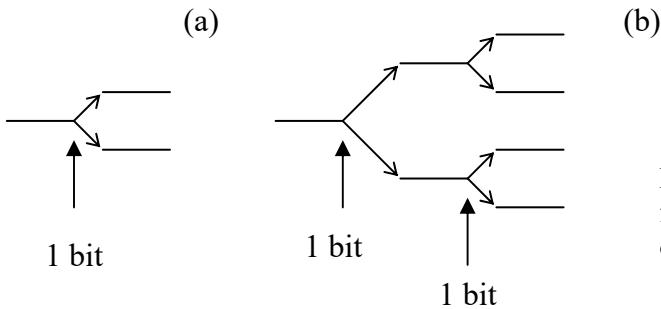

Fig. 2.2. "Logarithmic trees" of binary decisions for choosing between (a) $M = 2$, and (b) $M = 4$ opportunities with equal probabilities.

⁹ Though I have to move on, let me note that the microcanonical distribution (20) is a very nontrivial postulate, and my advice to the reader is to find some time to give additional thought to this keystone of the whole building of statistical mechanics.

¹⁰ I will rely on the reader's common sense and intuitive understanding of what information is, because even in the formal information theory, this notion is essentially postulated – see, e.g., the wonderfully clear text by J. Pierce, *An Introduction to Information Theory*, Dover, 1980.

Now, if we need to make a choice between four equally probable opportunities, it can be made in two similar steps (Fig. 2b), each requiring one bit of information, so that the total amount of information necessary for the choice is

$$I(4) = 2I(2) = 2 \equiv \log_2 4. \quad (2.22)$$

An obvious extension of this process to the choice between $M = 2^m$ states gives

$$I(M) = mI(2) = m \equiv \log_2 M. \quad (2.23)$$

This measure, if extended naturally to any integer M is quite suitable for the definition of entropy at equilibrium, with the only difference that, following tradition, the binary logarithm is replaced with the natural one:¹¹

$$S \equiv \ln M. \quad (2.24a)$$

Using Eq. (20), we may recast this definition in its most frequently used form

$$S = \ln \frac{1}{W_m} \equiv -\ln W_m. \quad (2.24b)$$

(Again, please note that Eq. (24) is valid in thermodynamic equilibrium only!)

Note that Eq. (24) satisfies the major properties of the entropy discussed in thermodynamics. First, it is a unique characteristic of the disorder. Indeed, according to Eq. (20), M (at fixed ΔE) is the only possible measure characterizing the microcanonical distribution, and so is its unique function $\ln M$. This function also satisfies another thermodynamic requirement to the entropy, of being an extensive variable. Indeed, for several independent systems, the joint probability of a certain state is just a product of the partial probabilities, and hence, according to Eq. (24), their entropies just add up.

Now let us see whether Eqs. (20) and (24) are compatible with the 2nd law of thermodynamics. For that, we need to generalize Eq. (24) for S to an arbitrary state of the system (generally, out of thermodynamic equilibrium), with an arbitrary set of state probabilities W_m . Let us first recognize that M in Eq. (24) is just the number of possible ways to commit a particular system to a certain state m ($m = 1, 2, \dots, M$), in a statistical ensemble where each state is equally probable. Now let us consider a more general ensemble, still consisting of a large number $N \gg 1$ of similar systems, but with a certain number $N_m = W_m N \gg 1$ of systems in each of M states, with the factors W_m not necessarily equal. In this case, the evident generalization of Eq. (24) is that the entropy S_N of the whole ensemble is

$$S_N \equiv \ln M(N_1, N_2, \dots), \quad (2.25)$$

where $M(N_1, N_2, \dots)$ is the number of ways to commit a particular system to a certain state m while keeping all numbers N_m fixed. This number $M(N_1, N_2, \dots)$ is clearly equal to the number of ways to distribute N distinct balls between M different boxes, with the fixed number N_m of balls in each box, but

¹¹ This is of course just the change of a constant factor: $S(M) = \ln M = \ln 2 \times \log_2 M = \ln 2 \times I(M) \approx 0.693 I(M)$. A review of Chapter 1 shows that nothing in thermodynamics prevents us from choosing such a constant coefficient arbitrarily, with the corresponding change of the temperature scale – see Eq. (1.9). In particular, in the SI units, where Eq. (24b) becomes $S = -k_B \ln W_m$, one bit of information corresponds to the entropy change $\Delta S = k_B \ln 2 \approx 0.693 k_B \approx 0.965 \times 10^{-23}$ J/K. By the way, the formula “ $S = k \log W$ ” is engraved on L. Boltzmann’s tombstone in Vienna.

in no particular order within it. Comparing this description with the definition of the so-called *multinomial coefficients*,¹² we get

$$M(N_1, N_2, \dots) = {}^N C_{N_1, N_2, \dots, N_M} \equiv \frac{N!}{N_1! N_2! \dots N_M!}, \quad \text{with } N = \sum_{m=1}^M N_m. \quad (2.26)$$

To simplify the resulting expression for S_N , we can use the famous *Stirling formula*, in its crudest, de Moivre's form,¹³ whose accuracy is suitable for most purposes of statistical physics:

$$\ln(N!)_{N \rightarrow \infty} \rightarrow N(\ln N - 1). \quad (2.27)$$

When applied to our current problem, this formula gives the following average entropy per system,¹⁴

$$\begin{aligned} S \equiv \frac{S_N}{N} &= \frac{1}{N} \left[\ln(N!) - \sum_{m=1}^M \ln(N_m!) \right]_{N_m \rightarrow \infty} \rightarrow \frac{1}{N} \left[N(\ln N - 1) - \sum_{m=1}^M N_m (\ln N_m - 1) \right] \\ &\equiv -\sum_{m=1}^M \frac{N_m}{N} \ln \frac{N_m}{N}, \end{aligned} \quad (2.28)$$

and since this result is only valid in the limit $N_m \rightarrow \infty$ anyway, we may use Eq. (2) to represent it as

$$S = -\sum_{m=1}^M W_m \ln W_m = \sum_{m=1}^M W_m \ln \frac{1}{W_m}. \quad (2.29)$$

Entropy
out of
equilibrium

This extremely important result¹⁵ may be interpreted as the average of the entropy values given by Eq. (24), weighed with specific probabilities W_m per the general formula (7).¹⁶

Now let us find what distribution of probabilities W_m provides the largest value of the entropy (29). The answer is almost evident from a good glance at Eq. (29). For example, if for a subgroup of $M' \leq M$ states the coefficients W_m are constant and equal to $1/M'$, so that $W_m = 0$ for all other states, all M' non-zero terms in the sum (29) are equal to each other, so that

$$S = M' \frac{1}{M'} \ln M' \equiv \ln M', \quad (2.30)$$

and the closer M' to its maximum value M the larger S . Hence, the maximum of S is reached at the uniform distribution given by Eq. (24).

¹² See, e.g., MA Eq. (2.3). Despite the intimidating name, Eq. (26) may be very simply derived. Indeed, $N!$ is just the number of all possible permutations of N balls, i.e. the ways to place them in *certain* positions – say, inside M boxes. Now to take into account that the particular order of the balls in each box is not important, that number should be divided by all numbers $N_m!$ of possible permutations of balls within each box – that's it.

¹³ See, e.g., MA Eq. (2.10).

¹⁴ Strictly speaking, I should use the notation $\langle S \rangle$ here. However, following the style accepted in thermodynamics, I will drop the averaging signs until we will really need them to avoid confusion. Again, this shorthand is not too bad because the relative fluctuations of entropy (as those of any macroscopic variable) are very small at $N \gg 1$.

¹⁵ With the replacement of $\ln W_m$ with $\log_2 W_m$ (i.e. division of both sides by $\ln 2$), Eq. (29) becomes the famous *Shannon* (or “Boltzmann-Shannon”) *formula* for the average information I per symbol in a long communication string using M different symbols, with probability W_m each.

¹⁶ In some textbooks, this interpretation is even accepted as the derivation of Eq. (29); however, it is evidently less strict than the one outlined above.

In order to prove this important fact more strictly, let us find the maximum of the function given by Eq. (29). If its arguments W_1, W_2, \dots, W_M were completely independent, this could be done by finding the point (in the M -dimensional space of the coefficients W_m) where all partial derivatives $\partial S/\partial W_m$ equal zero. However, since the probabilities are constrained by the condition (4), the differentiation has to be carried out more carefully, taking into account this interdependence:

$$\left[\frac{\partial}{\partial W_m} S(W_1, W_2, \dots) \right]_{\text{cond}} = \frac{\partial S}{\partial W_m} + \sum_{m' \neq m} \frac{\partial S}{\partial W_{m'}} \frac{\partial W_{m'}}{\partial W_m}. \quad (2.31)$$

At the maximum of the function S , all such expressions should be equal to zero simultaneously. This condition yields $\partial S/\partial W_m = \lambda$, where the so-called *Lagrange multiplier* λ is independent of m . Indeed, at such point Eq. (31) becomes

$$\left[\frac{\partial}{\partial W_m} S(W_1, W_2, \dots) \right]_{\text{cond}} = \lambda + \sum_{m' \neq m} \lambda \frac{\partial W_{m'}}{\partial W_m} \equiv \lambda \left(\frac{\partial W_m}{\partial W_m} + \sum_{m' \neq m} \frac{\partial W_{m'}}{\partial W_m} \right) \equiv \lambda \frac{\partial}{\partial W_m} (1) = 0. \quad (2.32)$$

For our particular expression (29), the condition $\partial S/\partial W_m = \lambda$ yields

$$\frac{\partial S}{\partial W_m} \equiv \frac{d}{d W_m} [-W_m \ln W_m] \equiv -\ln W_m - 1 = \lambda. \quad (2.33)$$

The last equality holds for all m (and hence the entropy reaches its maximum value) only if W_m is independent on m . Thus the entropy (29) indeed reaches its maximum value (24) at equilibrium.

To summarize, we see that the statistical definition (24) of entropy does fit all the requirements imposed on this variable by thermodynamics. In particular, we have been able to *prove* the 2nd law of thermodynamics using that definition together with the fundamental postulate (20).

Now let me discuss one possible point of discomfort with that definition: the values of M , and hence W_m , depend on the accepted energy interval ΔE of the microcanonical ensemble, for whose choice no exact guidance is offered. However, if the interval ΔE contains many states, $M \gg 1$, as was assumed before, then with a very small relative error (vanishing in the limit $M \rightarrow \infty$), M may be represented as

$$M = g(E)\Delta E, \quad (2.34)$$

where $g(E)$ is the *density of states* of the system:

$$g(E) \equiv \frac{d\Sigma(E)}{dE}, \quad (2.35)$$

$\Sigma(E)$ being the total number of states with energies *below* E . (Note that the average interval δE between energy levels, mentioned at the beginning of this section, is just $\Delta E/M = 1/g(E)$.) Plugging Eq. (34) into Eq. (24), we get

$$S = \ln M = \ln g(E) + \ln \Delta E, \quad (2.36)$$

so that the only effect of a particular choice of ΔE is an offset of the entropy by a constant, and in Chapter 1 we have seen that such constant shift does not affect any measurable quantity. Of course, Eq. (34), and hence Eq. (36) are only precise in the limit when the density of states $g(E)$ is so large that the range available for the appropriate choice of ΔE :

$$g^{-1}(E) \ll \Delta E \ll E, \quad (2.37)$$

is sufficiently broad: $g(E)E = E/\delta E \gg 1$.

In order to get some feeling of the functions $g(E)$ and $S(E)$ and the feasibility of the condition (37), and also to see whether the microcanonical distribution may be directly used for calculations of thermodynamic variables in particular systems, let us apply it to a microcanonical ensemble of many sets of $N \gg 1$ independent, similar harmonic oscillators with frequency ω . (Please note that the requirement of a virtually fixed energy is applied, in this case, to the total energy E_N of each set of oscillators, rather to energy E of a single oscillator – which may be virtually arbitrary, though certainly much less than $E_N \sim NE \gg E$.) Basic quantum mechanics tells us¹⁷ that the eigenenergies of such an oscillator form a discrete, equidistant spectrum:

$$E_m = \hbar\omega \left(m + \frac{1}{2} \right), \quad \text{where } m = 0, 1, 2, \dots \quad (2.38)$$

If ω is kept constant, the ground-state energy $\hbar\omega/2$ does not contribute to any thermodynamic properties of the system,¹⁸ so that for the sake of simplicity we may take that point as the energy origin, and replace Eq. (38) with $E_m = m\hbar\omega$. Let us carry out an approximate analysis of the system for the case when its average energy per oscillator,

$$E = \frac{E_N}{N}, \quad (2.39)$$

is much larger than the energy quantum $\hbar\omega$.

For one oscillator, the number of states with energy ε_1 below a certain value $E_1 \gg \hbar\omega$ is evidently $\Sigma(E_1) \approx E_1/\hbar\omega \equiv (E_1/\hbar\omega)/1!$ (Fig. 3a). For two oscillators, all possible values of the total energy ($\varepsilon_1 + \varepsilon_2$) below some level E_2 correspond to the points of a 2D square grid within the right triangle shown in Fig. 3b, giving $\Sigma(E_2) \approx (1/2)(E_2/\hbar\omega)^2 \equiv (E_2/\hbar\omega)^2/2!$. For three oscillators, the possible values of the total energy ($\varepsilon_1 + \varepsilon_2 + \varepsilon_3$) correspond to those points of the 3D cubic grid, that fit inside the right pyramid shown in Fig. 3c, giving $\Sigma(E_3) \approx (1/3)[(1/2)(E_3/\hbar\omega)^3] \equiv (E_3/\hbar\omega)^3/3!$, etc.

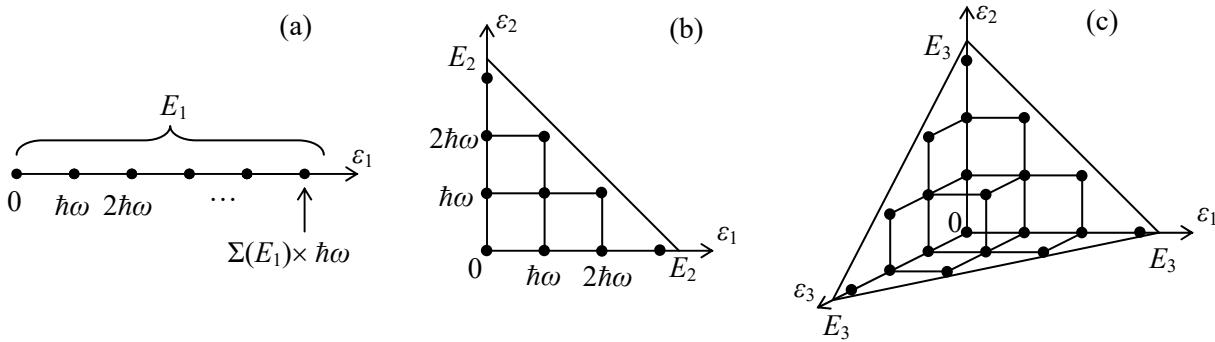

Fig. 2.3. Calculating functions $\Sigma(E_N)$ for systems of (a) one, (b) two, and (c) three harmonic oscillators.

¹⁷ See, e.g., QM Secs. 2.9 and 5.4.

¹⁸ Let me hope that the reader knows that the ground-state energy *is* experimentally measurable – for example, using the famous *Casimir effect* – see, e.g., QM Sec. 9.1. (In Sec. 5.5 below I will briefly discuss another method of experimental observation of that energy.)

An evident generalization of these formulas to arbitrary N gives the number of states¹⁹

$$\Sigma(E_N) \approx \frac{1}{N!} \left(\frac{E_N}{\hbar\omega} \right)^N. \quad (2.40)$$

Differentiating this expression over the energy, we get

$$g(E_N) \equiv \frac{d\Sigma(E_N)}{dE_N} = \frac{1}{(N-1)!} \frac{E_N^{N-1}}{(\hbar\omega)^N}, \quad (2.41)$$

so that

$$S_N(E_N) = \ln g(E_N) + \text{const} = -\ln[(N-1)!] + (N-1)\ln E_N - N\ln(\hbar\omega) + \text{const}. \quad (2.42)$$

For $N \gg 1$ we can ignore the difference between N and $(N-1)$ in both instances, and use the Stirling formula (27) to simplify this result as

$$S_N(E) - \text{const} \approx N \left(\ln \frac{E_N}{N\hbar\omega} + 1 \right) \approx N \left(\ln \frac{E}{\hbar\omega} \right) \equiv \ln \left[\left(\frac{E}{\hbar\omega} \right)^N \right]. \quad (2.43)$$

(The second, approximate step is only valid at very high $E/\hbar\omega$ ratios, when the logarithm in Eq. (43) is substantially larger than 1.) Returning for a second to the density of states, we see that in the limit $N \rightarrow \infty$, it is exponentially large:

$$g(E_N) = e^{S_N} \approx \left(\frac{E}{\hbar\omega} \right)^N, \quad (2.44)$$

so that the conditions (37) may be indeed satisfied within a very broad range of ΔE .

Now we can use Eq. (43) to find all thermodynamic properties of the system, though only in the limit $E \gg \hbar\omega$. Indeed, according to thermodynamics, if the system's volume and the number of particles in it are fixed, the derivative dS/dE is nothing else than the reciprocal temperature in thermal equilibrium – see Eq. (1.9). In our current case, we imply that the harmonic oscillators are distinct, for example by their spatial positions. Hence, even if we can speak of some volume of the system, it is certainly fixed.²⁰ Differentiating Eq. (43) over energy E , we get

$$\frac{1}{T} \equiv \frac{dS_N}{dE_N} = \frac{N}{E_N} = \frac{1}{E}. \quad (2.45)$$

Classical oscillator:
average energy

Reading this result backward, we see that the average energy E of a harmonic oscillator equals T (i.e. $k_B T_K$ is SI units). At this point, the first-time student of thermodynamics should be very much relieved to see that the counter-intuitive thermodynamic definition (1.9) of temperature does indeed correspond to what we all have known about this notion from our kindergarten physics courses.

The result (45) may be readily generalized. Indeed, in quantum mechanics, a harmonic oscillator with eigenfrequency ω may be described by the Hamiltonian operator

¹⁹ The coefficient $1/N!$ in this formula has the geometrical meaning of the (hyper)volume of the N -dimensional right pyramid with unit sides.

²⁰ For the same reason, the notion of pressure P in such a system is not clearly defined, and neither are any thermodynamic potentials but E and F .

$$\hat{H} = \frac{\hat{p}^2}{2m} + \frac{\kappa\hat{q}^2}{2}, \quad (2.46)$$

where q is some generalized coordinate, p is the corresponding generalized momentum, m is oscillator's mass,²¹ and κ is the spring constant, so that $\omega = (\kappa/m)^{1/2}$. Since in the thermodynamic equilibrium the density matrix is always diagonal in the basis of stationary states m (see Sec. 1 above), the quantum-mechanical averages of the kinetic and potential energies may be found from Eq. (7):

$$\left\langle \frac{p^2}{2m} \right\rangle = \sum_{m=0}^{\infty} W_m \langle m | \frac{\hat{p}^2}{2m} | m \rangle, \quad \left\langle \frac{\kappa q^2}{2} \right\rangle = \sum_{m=0}^{\infty} W_m \langle m | \frac{\kappa \hat{q}^2}{2} | m \rangle, \quad (2.47)$$

where W_m is the probability to occupy the m^{th} energy level, and bra- and ket-vectors describe the stationary state corresponding to that level.²² However, both classical and quantum mechanics teach us that for any m , the bra-ket expressions under the sums in Eqs. (47), which represent the average kinetic and mechanical energies of the oscillator on its m^{th} energy level, are equal to each other, and hence each of them is equal to $E_m/2$. Hence, even though we do not know the probability distribution W_m yet (it will be calculated in Sec. 5 below), we may conclude that in the “classical limit” $T \gg \hbar\omega$,

$$\left\langle \frac{p^2}{2m} \right\rangle = \left\langle \frac{\kappa q^2}{2} \right\rangle = \frac{T}{2}. \quad (2.48)$$

Equipartition theorem

Now let us consider a system with an arbitrary number of degrees of freedom, described by a more general Hamiltonian:²³

$$\hat{H} = \sum_j \hat{H}_j, \quad \text{with } \hat{H}_j = \frac{\hat{p}_j^2}{2m_j} + \frac{\kappa_j \hat{q}_j^2}{2}, \quad (2.49)$$

with (generally, different) frequencies $\omega_j = (\kappa_j/m_j)^{1/2}$. Since the “modes” (effective harmonic oscillators) contributing to this Hamiltonian, are independent, the result (48) is valid for each of the modes. This is the famous *equipartition theorem*: at thermal equilibrium with $T \gg \hbar\omega_j$, the average energy of each so-called *half-degree of freedom* (which is defined as any variable, either p_j or q_j , giving a quadratic contribution to the system's Hamiltonian), is equal to $T/2$.²⁴ In particular, for each of three Cartesian component contributions to the kinetic energy of a free-moving particle, this theorem is valid for *any* temperature, because such components may be considered as 1D harmonic oscillators with vanishing potential energy, i.e. $\omega_j = 0$, so that condition $T \gg \hbar\omega_j$ is fulfilled at any temperature.

²¹ I am using this fancy font for the mass to avoid any chance of its confusion with the state number.

²² Note again that while we have committed the energy E_N of N oscillators to be fixed (to apply Eq. (36), valid only for a microcanonical ensemble at thermodynamic equilibrium), the single oscillator's energy E in our analysis may be arbitrary – within the limits $\hbar\omega \ll E \leq E_N \sim NT$.

²³ As a reminder, the Hamiltonian of any system whose classical Lagrangian function is an arbitrary quadratic form of its generalized coordinates and the corresponding generalized velocities, may be brought to the form (49) by an appropriate choice of “normal coordinates” q_j which are certain linear combinations of the original coordinates – see, e.g., CM Sec. 6.2.

²⁴ This also means that in the classical limit, the heat capacity of a system is equal to one-half of the number of its half-degrees of freedom (in the SI units, multiplied by k_B).

I believe that this case study of harmonic oscillator systems was a fair illustration of both the strengths and the weaknesses of the microcanonical ensemble approach.²⁵ On one hand, we could readily calculate virtually everything we wanted in the classical limit $T \gg \hbar\omega$, but calculations for an arbitrary $T \sim \hbar\omega$, though possible, are rather unpleasant because for that, all vertical steps of the function $\Sigma(E_N)$ have to be carefully counted. In Sec. 4, we will see that other statistical ensembles are much more convenient for such calculations.

Let me conclude this section with a short notice on deterministic classical systems with just a few degrees of freedom (and even simpler mathematical objects called “maps”) that may exhibit essentially disordered behavior, called the *deterministic chaos*.²⁶ Such chaotic system may be approximately characterized by an entropy defined similarly to Eq. (29), where W_m are the probabilities to find it in different small regions of phase space, at well-separated small time intervals. On the other hand, one can use an expression slightly more general than Eq. (29) to define the so-called *Kolmogorov* (or “Kolmogorov-Sinai”) *entropy K* that characterizes the speed of loss of the information about the initial state of the system, and hence what is called the “chaos depth”. In the definition of K , the sum over m is replaced with the summation over all possible permutations $\{m\} = m_0, m_1, \dots, m_{N-1}$ of small space regions, and W_m is replaced with $W_{\{m\}}$, the probability of finding the system in the corresponding regions m at time moment t_m , with $t_m = m\tau$, in the limit $\tau \rightarrow 0$, with $N\tau = \text{const}$. For chaos in the simplest objects, 1D maps, K is equal to the Lyapunov exponent $\lambda > 0$.²⁷ For systems of higher dimensionality, which are characterized by several Lyapunov exponents λ , the Kolmogorov entropy is equal to the phase-space average of the sum of all positive λ . These facts provide a much more practicable way of (typically, numerical) calculation of the Kolmogorov entropy than the direct use of its definition.²⁸

2.3. Maxwell’s Demon, information, and computation

Before proceeding to other statistical distributions, I would like to make a detour to address one more popular concern about Eq. (24) – the direct relation between entropy and information. Some physicists are still uneasy with entropy being nothing else than the (deficit of) information, though to the best of my knowledge, nobody has yet been able to suggest any experimentally verifiable difference between these two notions. Let me give one example of their direct relation.²⁹ Consider a cylinder containing just one molecule (considered as a point particle), and separated into two halves by a movable partition with a door that may be opened and closed at will, at no energy cost – see Fig. 4a. If the door is open and the system is in thermodynamic equilibrium, we do not know on which side of the partition the molecule is. Here the disorder, i.e. the entropy has the largest value, and there is no way to get, from a large ensemble of such systems in equilibrium, any useful mechanical energy.

²⁵ The reader is strongly urged to solve Problem 2, whose task is to do a similar calculation for another key (“two-level”) physical system, and compare the results.

²⁶ See, e.g., CM Chapter 9 and literature therein.

²⁷ For the definition of λ , see, e.g., CM Eq. (9.9).

²⁸ For more discussion, see, e.g., either Sec. 6.2 of the monograph H. G. Schuster and W. Just, *Deterministic Chaos*, 4th ed., Wiley-VHS, 2005, or the monograph by Arnold and Avez, cited in Sec. 1.

²⁹ This system is frequently called the *Szilard engine*, after L. Szilard who published its detailed theoretical discussion in 1929, but is essentially a straightforward extension of the thought experiment suggested by J. Maxwell as early as 1867.

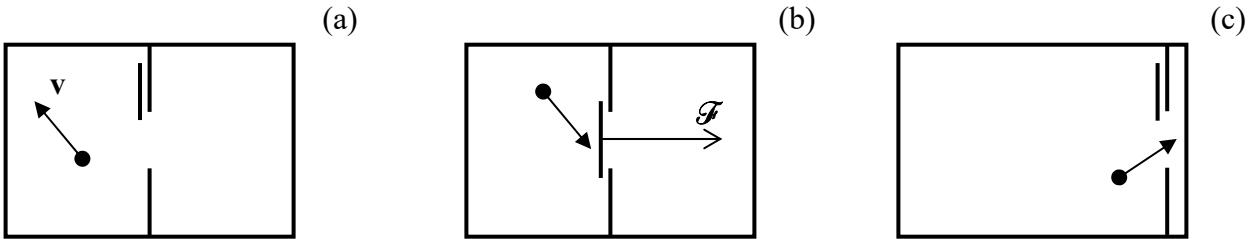

Fig. 2.4. The Szilard engine: a cylinder with a single molecule and a movable partition: (a) before and (b) after closing the door, and (c) after opening the door at the end of the expansion stage.

Now, let us consider that we know (as instructed by, in Lord Kelvin's formulation, an omniscient *Maxwell's Demon*) on which side of the partition the molecule is currently located. Then we may close the door, trapping the molecule, so that its repeated impacts on the partition create, on average, a pressure force \mathcal{F} directed toward the empty part of the volume (in Fig. 4b, the right one). Now we can get from the molecule some mechanical work, say by allowing the force \mathcal{F} to move the partition to the right, and picking up the resulting mechanical energy by some deterministic (zero-entropy) external mechanism. After the partition has been moved to the right end of the volume, we can open the door again (Fig. 4c), equalizing the molecule's average pressure on both sides of the partition, and then slowly move the partition back to the middle of the volume – without its resistance, i.e. without doing any substantial work. With the continuing help by the Maxwell's Demon, we can repeat the cycle again and again, and hence make the system perform unlimited mechanical work, fed “only” by the molecule's thermal motion, and the information about its position – thus implementing the perpetual motion machine of the 2nd kind – see Sec. 1.6. The fact that such heat engines do not exist means that getting any *new* information, at non-zero temperature (i.e. at a substantial thermal agitation of particles) has a non-zero energy cost.

In order to evaluate this cost, let us calculate the maximum work per cycle that can be made by the Szilard engine (Fig. 4), assuming that it is constantly in the thermal equilibrium with a heat bath of temperature T . Formula (21) tells us that the information supplied by the demon (on what exactly half of the volume contains the molecule) is exactly one bit, $I(2) = 1$. According to Eq. (24), this means that by getting this information we are changing the entropy of our system by

$$\Delta S_I = -\ln 2. \quad (2.50)$$

Now, it would be a mistake to plug this (negative) entropy change into Eq. (1.19). First, that relation is only valid for slow, reversible processes. Moreover (and more importantly), this equation, as well as its irreversible version (1.41), is only valid for a fixed statistical ensemble. The change ΔS_I does not belong to this category and may be formally described by the change of the statistical ensemble – from the one consisting of all similar systems (experiments) with an unknown location of the molecule, to a new ensemble consisting of the systems with the molecule in its certain (in Fig. 4, left) half.³⁰

Now let us consider a slow expansion of the “gas” after the door had been closed. At this stage, we do not need the Demon's help any longer (i.e. the statistical ensemble may be fixed), and can indeed use the relation (1.19). At the assumed isothermal conditions ($T = \text{const}$), this relation may be integrated

³⁰ This procedure of the *statistical ensemble re-definition* is the central point of the connection between physics and information theory, and is crucial in particular for any (or rather any meaningful :-) discussion of measurements in quantum mechanics – see, e.g., QM Secs. 2.5 and 10.1.

over the whole expansion process, getting $\Delta Q = T\Delta S$. At the final position shown in Fig. 4c, the system's entropy should be the same as initially, i.e. before the door had been opened, because we again do not know where in the volume the molecule is. This means that the entropy was replenished, during the reversible expansion, from the heat bath, by $\Delta S = -\Delta S_I = +\ln 2$, so that $\Delta Q = T\Delta S = T\ln 2$. Since by the end of the whole cycle the internal energy E of the system is the same as before, all this heat could have gone into the mechanical energy obtained during the expansion. Thus the maximum obtained work per cycle (i.e. for each obtained information bit) is $T\ln 2$ ($k_B T_K \ln 2$ in the SI units), about 4×10^{-21} Joule at room temperature. This is exactly the energy cost of getting one bit of *new* information about a system at temperature T . The smallness of that amount on the everyday human scale has left the Szilard engine an academic theoretical exercise for almost a century. However, recently several such devices, of various physical nature, were implemented experimentally (with the Demon's role played by an instrument measuring the position of the particle without a substantial effect on its motion), and the relation $\Delta Q = T\ln 2$ was proved, with a gradually increasing precision.³¹

Actually, discussion of another issue closely related to Maxwell's Demon, namely of energy consumption at numerical calculations, was started earlier, in the 1960s. It was motivated by the exponential (*Moore's-law*) progress of the digital integrated circuits, which has led in particular, to a fast reduction of the energy ΔE "spent" (turned into heat) per one binary logic operation. In the recent generations of semiconductor digital integrated circuits, the typical ΔE is still above 10^{-17} J, i.e. still exceeds the room-temperature value of $T\ln 2 \approx 4 \times 10^{-21}$ J by several orders of magnitude. Still, some engineers believe that thermodynamics imposes this important lower limit on ΔE and hence presents an insurmountable obstacle to the future progress of computation. Unfortunately, in the 2000s this delusion resulted in a substantial and unjustified shift of electron device research resources toward using "non-charge degrees of freedom" such as spin (as if they do not obey the general laws of statistical physics!), so that the issue deserves at least a brief discussion.

Let me believe that the reader of these notes understands that, in contrast to naïve popular talk, computers *do not create* any new information; all they can do is reshaping ("processing") the input information, *losing* most of it on the go. Indeed, any digital computation algorithm may be decomposed into simple, binary logical operations, each of them performed by a circuit called the *logic gate*. Some of these gates (e.g., the logical NOT performed by inverters, as well as memory READ and WRITE operations) do not change the amount of information in the computer. On the other hand, such *information-irreversible* logic gates as two-input NAND (or NOR, or XOR, etc.) erase one bit at each operation, because they turn two input bits into one output bit – see Fig. 5a.

In 1961, Rolf Landauer argued that each logic operation should turn into heat at least energy

$$\Delta E_{\min} = T \ln 2 \equiv k_B T_K \ln 2 . \quad (2.51)$$

Irreversible computation:
energy cost

This result may be illustrated with the Szilard engine (Fig. 4), operated in a reversed cycle. At the first stage, with the door closed, it uses external mechanical work $\Delta E = T\ln 2$ to reduce the volume in that the molecule is confined, from V to $V/2$, pumping heat $\Delta Q = \Delta E$ into the heat bath. To model a logically irreversible logic gate, let us now open the door in the partition, and thus lose one bit of information about the molecule's position. Then we will never get the work $T\ln 2$ back, because moving the partition

³¹ See, for example, A. Bérut *et al.*, *Nature* **483**, 187 (2012); J. Koski *et al.*, *PNAS USA* **111**, 13786 (2014); Y. Jun *et al.*, *Phys. Rev. Lett.* **113**, 190601 (2014); J. Peterson *et al.*, *Proc. Roy. Soc. A* **472**, 20150813 (2016).

back to the right, with the door open, takes place at zero average pressure. Hence, Eq. (51) gives a fundamental limit for energy loss (per bit) at the logically irreversible computation.

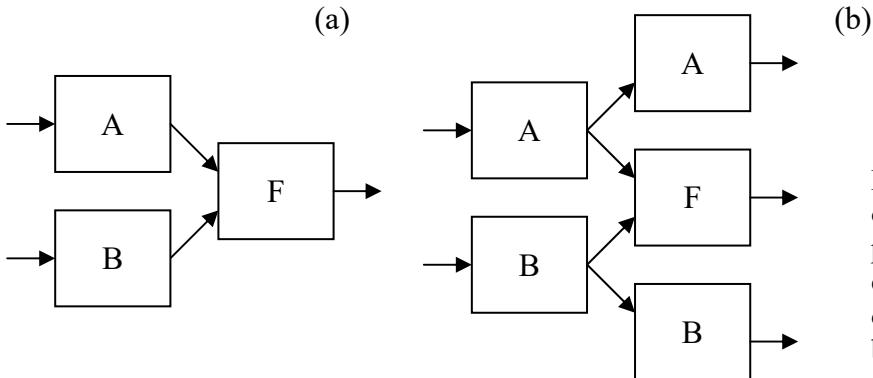

Fig. 2.5. Simple examples of (a) irreversible and (b) potentially reversible logic circuits. Each rectangle denotes a circuit storing one bit of information.

However, in 1973 Charles Bennett came up with convincing arguments that it is possible to avoid such energy loss by using only operations that are *reversible* not only physically, but also logically.³² For that, one has to avoid any loss of information, i.e. any erasure of intermediate results, for example in the way shown in Fig. 5b.³³ At the end of all calculations, after the result has been copied into memory, the intermediate results may be “rolled back” through reversible gates to be eventually merged into a copy of input data, again without erasing a single bit. The minimal energy dissipation at such reversible calculation tends to zero as the operation speed is decreased, so that the average energy loss per bit may be less than the perceived “fundamental thermodynamic limit” (51). The price to pay for this ultralow dissipation is a very high complexity of the hardware necessary for the storage of all intermediate results. However, using irreversible gates sparsely, it may be possible to reduce the complexity dramatically, so that in the future such *mostly* reversible computation may be able to reduce energy consumption in practical digital electronics.³⁴

Before we leave Maxwell’s Demon behind, let me use it to revisit, for one more time, the relation between the reversibility of the classical and quantum mechanics of Hamiltonian systems and the irreversibility possible in thermodynamics and statistical physics. In the gedanken experiment shown in Fig. 4, the laws of mechanics governing the motion of the molecule are reversible at all times. Still, at partition’s motion to the right, driven by molecular impacts, the entropy grows, because the molecule picks up the heat $\Delta Q > 0$, and hence the entropy $\Delta S = \Delta Q/T > 0$, from the heat bath. The physical mechanism of this irreversible entropy (read: disorder) growth is the interaction of the molecule with uncontrollable components of the heat bath, and the resulting loss of information about the motion of the molecule. Philosophically, such emergence of irreversibility in large systems is a strong argument against *reductionism* – a naïve belief that knowing the exact laws of Nature at the lowest, most fundamental level of its complexity, we can readily understand all phenomena on the higher levels of its

³² C. Bennett, *IBM J. Res. Devel.* **17**, 525 (1973); see also C. Bennett, *Int. J. Theor. Phys.* **21**, 905 (1982).

³³ For that, all gates have to be *physically reversible*, with no static power consumption. Such logic devices do exist, though they are still not very practicable – see, e.g., K. Likharev, *Int. J. Theor. Phys.* **21**, 311 (1982). (Another reason for citing, rather reluctantly, my own paper is that it also gave constructive proof that the reversible computation may also beat the perceived “fundamental quantum limit”, $\Delta E \Delta t > \hbar$, where Δt is the time of the binary logic operation.)

³⁴ Many currently explored schemes of *quantum computing* are also reversible – see, e.g., QM Sec. 8.5 and references therein.

organization. In reality, the macroscopic irreversibility of large systems is a good example³⁵ of a new law (in this case, the 2nd law of thermodynamics) that becomes relevant on a substantially new, higher level of complexity – without defying the lower-level laws. Without such new laws, very little of the higher-level organization of Nature may be understood.

2.4. Canonical ensemble and the Gibbs distribution

As was shown in Sec. 2 (see also a few problems of the list given in the end of this chapter), the microcanonical distribution may be directly used for solving some simple problems. However, its further development, also due to J. Gibbs, turns out to be much more convenient for calculations.

Let us consider a statistical ensemble of macroscopically similar systems, each in thermal equilibrium with a heat bath of the same temperature T (Fig. 6a). Such an ensemble is called *canonical*.

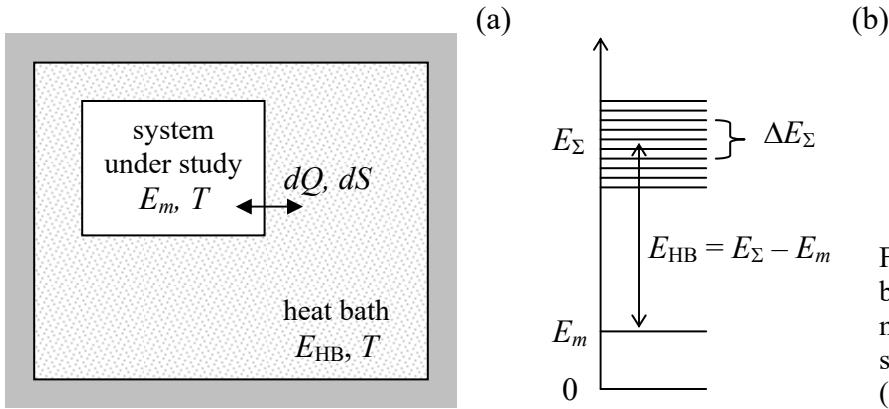

Fig. 2.6. (a) A system in a heat bath (i.e. a canonical ensemble's member) and (b) the energy spectrum of the composite system (including the heat bath).

It is intuitively evident that if the heat bath is sufficiently large, any thermodynamic variables characterizing the system under study should not depend on the *heat bath's* environment. In particular, we may assume that the heat bath is thermally insulated, so that the total energy E_Σ of the *composite* system, consisting of the system of our interest plus the heat bath, does not change in time. For example, if the system of our interest is in a certain (say, m^{th}) quantum state, then the sum

$$E_\Sigma = E_m + E_{\text{HB}} \quad (2.52)$$

is time-independent. Now let us partition the considered *canonical* ensemble of such systems into much smaller sub-ensembles, each being a *microcanonical* ensemble of composite systems whose total, time-independent energies E_Σ are the same – as was discussed in Sec. 2, within a certain small energy interval $\Delta E_\Sigma \ll E_\Sigma$ – see Fig. 6b. Due to the very large size of each heat bath in comparison with that of the system under study, the heat bath's density of states g_{HB} is very high, and ΔE_Σ may be selected so that

$$\frac{1}{g_{\text{HB}}} \ll \Delta E_\Sigma \ll |E_m - E_{m'}| \ll E_{\text{HB}}, \quad (2.53)$$

where m and m' are any states of the system of our interest.

³⁵ Another famous example is Charles Darwin's theory of biological evolution.

According to the microcanonical distribution, the probabilities to find the composite system, within each of these microcanonical sub-ensembles, in any state are equal. Still, the heat bath energies $E_{\text{HB}} = E_{\Sigma} - E_m$ (Fig. 6b) of the members of this sub-ensemble may be different – due to the difference in E_m . The probability $W(E_m)$ to find the system of our interest (within the selected sub-ensemble) in a state with energy E_m is proportional to the number ΔM of the corresponding heat baths in the sub-ensemble. As Fig. 6b shows, in this case we may write $\Delta M = g_{\text{HB}}(E_{\text{HB}})\Delta E_{\Sigma}$. As a result, within the microcanonical sub-ensemble with the total energy E_{Σ} ,

$$W_m \propto \Delta M = g_{\text{HB}}(E_{\text{HB}})\Delta E_{\Sigma} = g_{\text{HB}}(E_{\Sigma} - E_m)\Delta E_{\Sigma}. \quad (2.54)$$

Let us simplify this expression further, using the Taylor expansion with respect to relatively small $E_m \ll E_{\Sigma}$. However, here we should be careful. As we have seen in Sec. 2, the density of states of a large system is an extremely fast growing function of energy, so that if we applied the Taylor expansion directly to Eq. (54), the Taylor series would converge for very small E_m only. A much broader applicability range may be obtained by taking logarithms of both parts of Eq. (54) first:

$$\ln W_m = \text{const} + \ln[g_{\text{HB}}(E_{\Sigma} - E_m)] + \ln \Delta E_{\Sigma} = \text{const} + S_{\text{HB}}(E_{\Sigma} - E_m), \quad (2.55)$$

where the last equality results from the application of Eq. (36) to the heat bath, and $\ln \Delta E_{\Sigma}$ has been incorporated into the (inconsequential) constant. Now, we can Taylor-expand the (much more smooth) function of energy on the right-hand side, and limit ourselves to the two leading terms of the series:

$$\ln W_m \approx \text{const} + S_{\text{HB}} \Big|_{E_m=0} - \frac{dS_{\text{HB}}}{dE_{\text{HB}}} \Big|_{E_m=0} E_m. \quad (2.56)$$

But according to Eq. (1.9), the derivative participating in this expression is nothing else than the reciprocal temperature of the heat bath, which (due to the large bath size) does not depend on whether E_m is equal to zero or not. Since our system of interest is in the thermal equilibrium with the bath, this is also the temperature T of the system – see Eq. (1.8). Hence Eq. (56) is merely

$$\ln W_m = \text{const} - \frac{E_m}{T}. \quad (2.57)$$

This equality describes a substantial decrease of W_m as E_m is increased by $\sim T$, and hence our linear approximation (56) is virtually exact as soon as E_{HB} is much larger than T – the condition that is rather easy to satisfy, because as we have seen in Sec. 2, the average energy per one degree of freedom of the system of the heat bath is also of the order of T , so that its total energy is much larger because of its much larger size.

Now we should be careful again because so far Eq. (57) was only derived for a sub-ensemble with a certain fixed E_{Σ} . However, since the second term on the right-hand side of Eq. (57) includes only E_m and T , which are independent of E_{Σ} , this relation, perhaps with different constant terms, is valid for all sub-ensembles of the canonical ensemble, and hence for that ensemble as the whole. Hence for the total probability to find our system of interest in a state with energy E_m , in the canonical ensemble with temperature T , we can write

$$W_m = \text{const} \times \exp \left\{ -\frac{E_m}{T} \right\} \equiv \frac{1}{Z} \exp \left\{ -\frac{E_m}{T} \right\}. \quad (2.58)$$

Gibbs
distribution

. This is the famous *Gibbs distribution*,³⁶ sometimes called the “canonical distribution”, which is arguably the summit of statistical physics,³⁷ because it may be used for a straightforward (or at least conceptually straightforward :-) calculation of all statistical and thermodynamic variables of a vast range of systems.

Before illustrating this, let us first calculate the coefficient Z participating in Eq. (58) for the general case. Requiring, per Eq. (4), the sum of all W_m to be equal 1, we get

$$\text{Statistical sum} \quad Z = \sum_m \exp\left\{-\frac{E_m}{T}\right\}, \quad (2.59)$$

where the summation is formally extended to all quantum states of the system, though in practical calculations, the sum may be truncated to include only the states that are noticeably occupied. The apparently humble normalization coefficient Z turns out to be so important for applications that it has a special name – or actually, two names: either the *statistical sum* or the *partition function* of the system. To appreciate the importance of Z , let us use the general expression (29) for entropy to calculate it for the particular case of the canonical ensemble, i.e. the Gibbs distribution (58) of the probabilities W_n :

$$S = -\sum_m W_m \ln W_m = \frac{\ln Z}{Z} \sum_m \exp\left\{-\frac{E_m}{T}\right\} + \frac{1}{ZT} \sum_m E_m \exp\left\{-\frac{E_m}{T}\right\}. \quad (2.60)$$

On the other hand, according to the general rule (7), the thermodynamic (i.e. ensemble-averaged) value E of the internal energy of the system is

$$E = \sum_m W_m E_m = \frac{1}{Z} \sum_m E_m \exp\left\{-\frac{E_m}{T}\right\}, \quad (2.61a)$$

so that the second term on the right-hand side of Eq. (60) is just E/T , while the first term equals $\ln Z$, due to Eq. (59). (By the way, using the notion of *reciprocal temperature* $\beta \equiv 1/T$, with the account of Eq. (59), Eq. (61a) may be also rewritten as

$$E = -\frac{\partial(\ln Z)}{\partial\beta}. \quad (2.61b)$$

This formula is very convenient for calculations if our prime interest is the average internal energy E rather than F or W_n .) With these substitutions, Eq. (60) yields a very simple relation between the statistical sum and the entropy of the system:

$$S = \frac{E}{T} + \ln Z. \quad (2.62)$$

Now using Eq. (1.33), we see that Eq. (62) gives a straightforward way to calculate the free energy F of the system from nothing other than its statistical sum (and temperature):

³⁶ The temperature dependence of the type $\exp\{-\text{const}/T\}$, especially when showing up in rates of certain events, e.g., chemical reactions, is also frequently called the *Arrhenius law* – after chemist S. Arrhenius who has noticed this law in numerous experimental data. In all cases I am aware of, the Gibbs distribution is the underlying reason of the Arrhenius law. (We will see several examples of that later in this course.)

³⁷ This is the opinion of many physicists, including Richard Feynman – who climbs on this “summit” already on the first page of his brilliant book *Statistical Mechanics*, CRC Press, 1998. (This is a collection of lectures on a few diverse, mostly advanced topics of statistical physics, rather than its systematic course, so that it can hardly be used as the first textbook on the subject. However, I can highly recommend its first chapter to all my readers.)

$$F \equiv E - TS = -T \ln Z. \quad (2.63) \quad F \text{ from } Z$$

The relations (61b) and (63) play the key role in the connection of statistics to thermodynamics, because they enable the calculation, from Z alone, of the thermodynamic potentials of the system in equilibrium, and hence of all other variables of interest, using the general thermodynamic relations – see especially the circular diagram shown in Fig. 1.6, and its discussion in Sec. 1.4. Let me only note that to calculate the pressure P , e.g., from the second of Eqs. (1.35), we would need to know the explicit dependence of F , and hence of the statistical sum Z on the system's volume V . This would require the calculation, by appropriate methods of either classical or quantum mechanics, of the dependence of the eigenenergies E_m on the volume. Numerous examples of such calculations will be given later in the course.

Before proceeding to first such examples, let us notice that Eqs. (59) and (63) may be readily combined to give an elegant equality,

$$\exp\left\{-\frac{F}{T}\right\} = \sum_m \exp\left\{-\frac{E_m}{T}\right\}. \quad (2.64)$$

This equality, together with Eq. (59), enables us to rewrite the Gibbs distribution (58) in another form:

$$W_m = \exp\left\{\frac{F - E_m}{T}\right\}, \quad (2.65)$$

more convenient for some applications. In particular, this expression shows that since all probabilities W_m are below 1, F is always *lower* than the lowest energy level. Also, Eq. (65) clearly shows that the probabilities W_m do not depend on the energy reference, i. e. on an arbitrary constant added to all E_m – and hence to E and F .

2.5. Harmonic oscillator statistics

The last property may be immediately used in our first example of the Gibbs distribution application to a particular, but very important system – the harmonic oscillator, for a much more general case than was done in Sec. 2, namely for an arbitrary relation between T and $\hbar\omega$.³⁸ Let us consider a canonical ensemble of similar oscillators, each in a contact with a heat bath of temperature T . Selecting the ground-state energy $\hbar\omega/2$ for the origin of E , the oscillator eigenenergies (38) become $E_m = m\hbar\omega$ (with $m = 0, 1, \dots$), so that the Gibbs distribution (58) for probabilities of these states is

$$W_m = \frac{1}{Z} \exp\left\{-\frac{E_m}{T}\right\} = \frac{1}{Z} \exp\left\{-\frac{m\hbar\omega}{T}\right\}, \quad (2.66)$$

with the following statistical sum:

$$Z = \sum_{m=0}^{\infty} \exp\left\{-\frac{m\hbar\omega}{T}\right\} \equiv \sum_{m=0}^{\infty} \lambda^m, \quad \text{where } \lambda \equiv \exp\left\{-\frac{\hbar\omega}{T}\right\} \leq 1. \quad (2.67)$$

This is just the well-known infinite geometric progression (the “geometric series”),³⁹ with the sum

³⁸ The task of making a similar (and even simpler) calculation for another key quantum-mechanical object, the two-level system, is left for the reader's exercise.

³⁹ See, e.g., MA Eq. (2.8b).

so that Eq. (66) yields

$$Z = \frac{1}{1-\lambda} \equiv \frac{1}{1-e^{-\hbar\omega/T}}, \quad (2.68)$$

$$W_m = (1-e^{-\hbar\omega/T}) e^{-m\hbar\omega/T}. \quad (2.69)$$

Figure 7a shows W_m for several lower energy levels, as functions of temperature, or rather of the $T/\hbar\omega$ ratio. The plots show that the probability to find the oscillator in each particular state (except for the ground one, with $m = 0$) vanishes in both low- and high-temperature limits, and reaches its maximum value $W_m \sim 0.3/m$ at $T \sim m\hbar\omega$, so that the contribution $m\hbar\omega W_m$ of each excited level to the average oscillator energy E is always smaller than $\hbar\omega$.

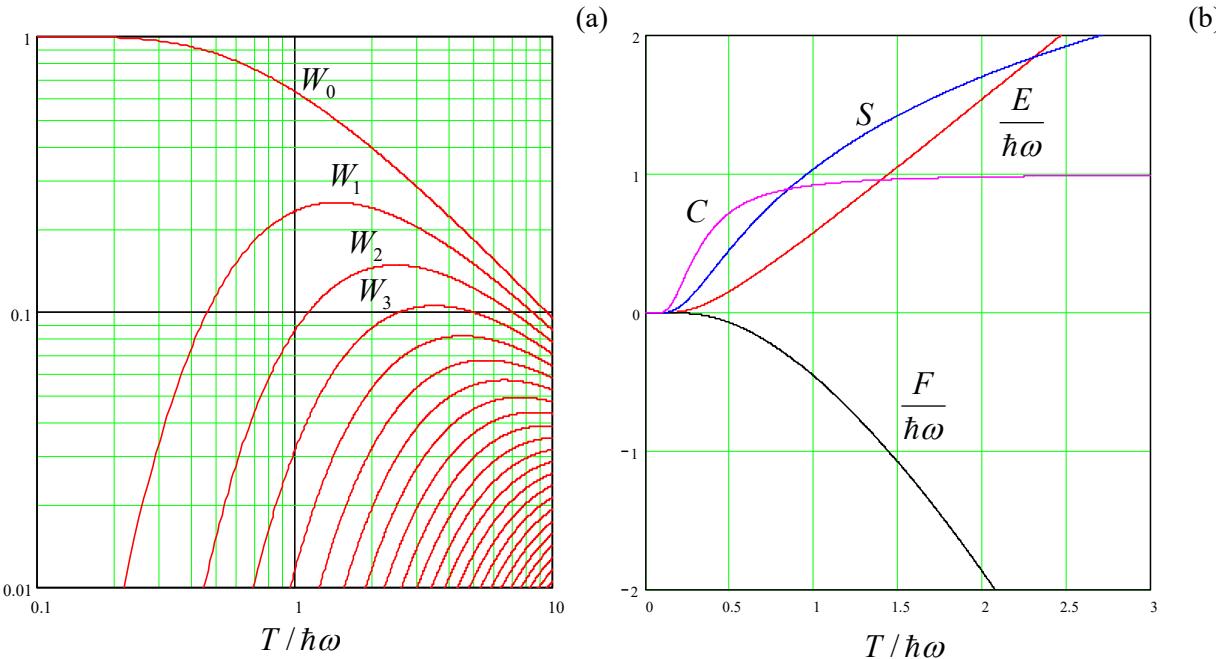

Fig. 2.7. Statistical and thermodynamic parameters of a harmonic oscillator, as functions of temperature.

This average energy may be calculated in either of two ways: either using Eq. (61a) directly:

$$E = \sum_{m=0}^{\infty} E_m W_m = (1 - e^{-\hbar\omega/T}) \sum_{m=0}^{\infty} m\hbar\omega e^{-m\hbar\omega/T}, \quad (2.70)$$

or (simpler) using Eq. (61b), as

$$E = -\frac{\partial}{\partial \beta} \ln Z = \frac{\partial}{\partial \beta} \ln(1 - \exp\{-\beta\hbar\omega\}), \quad \text{where } \beta \equiv \frac{1}{T}. \quad (2.71)$$

Both methods give (of course) the same result,⁴⁰

⁴⁰ It was first obtained in 1924 by S. Bose and is sometimes called the *Bose distribution* – a particular case of the *Bose-Einstein distribution* to be discussed in Sec. 8 below.

$$E = E(\omega, T) = \hbar\omega \frac{1}{e^{\hbar\omega/T} - 1}, \quad (2.72)$$

Quantum oscillator:
average energy

which is valid for arbitrary temperature and plays a key role in many fundamental problems of physics. The red line in Fig. 7b shows this result as a function of the normalized temperature. At relatively low temperatures, $T \ll \hbar\omega$, the oscillator is predominantly in its lowest (ground) state, and its energy (on top of the constant zero-point energy $\hbar\omega/2$, which was used in our calculation as the reference) is exponentially small: $E \approx \hbar\omega \exp\{-\hbar\omega/T\} \ll T, \hbar\omega$. On the other hand, in the high-temperature limit, the energy tends to T . This is exactly the result (a particular case of the equipartition theorem) that was obtained in Sec. 2 from the microcanonical distribution. Please note how much simpler is the calculation using the Gibbs distribution, even for an arbitrary ratio $T/\hbar\omega$.

To complete the discussion of the thermodynamic properties of the harmonic oscillator, we can calculate its free energy using Eq. (63):

$$F = T \ln \frac{1}{Z} = T \ln \left(1 - e^{-\hbar\omega/T} \right). \quad (2.73)$$

Now the entropy may be found from thermodynamics: either from the first of Eqs. (1.35), $S = -(\partial F / \partial T)_V$, or (even more easily) from Eq. (1.33): $S = (E - F)/T$. Both relations give, of course, the same result:

$$S = \frac{\hbar\omega}{T} \frac{1}{e^{\hbar\omega/T} - 1} - \ln \left(1 - e^{-\hbar\omega/T} \right). \quad (2.74)$$

Finally, since in the general case the dependence of the oscillator properties (essentially, of ω) on volume V is not specified, such variables as P , μ , G , W , and Ω are not defined, and what remains is to calculate the average heat capacity C per one oscillator:

$$C = \frac{\partial E}{\partial T} = \left(\frac{\hbar\omega}{T} \right)^2 \frac{e^{\hbar\omega/T}}{(e^{\hbar\omega/T} - 1)^2} \equiv \left[\frac{\hbar\omega/2T}{\sinh(\hbar\omega/2T)} \right]^2. \quad (2.75)$$

The calculated thermodynamic variables are plotted in Fig. 7b. In the low-temperature limit ($T \ll \hbar\omega$), they all tend to zero. On the other hand, in the high-temperature limit ($T \gg \hbar\omega$), $F \rightarrow -T \ln(T/\hbar\omega) \rightarrow -\infty$, $S \rightarrow \ln(T/\hbar\omega) \rightarrow +\infty$, and $C \rightarrow 1$ (in the SI units, $C \rightarrow k_B$). Note that the last limit is the direct corollary of the equipartition theorem: each of the two “half-degrees of freedom” of the oscillator gives, in the classical limit, the same contribution $C = \frac{1}{2}$ into its heat capacity.

Now let us use Eq. (69) to discuss the statistics of the quantum oscillator described by Hamiltonian (46), in the coordinate representation. Again using the density matrix’ diagonality in thermodynamic equilibrium, we may use a relation similar to Eqs. (47) to calculate the probability density to find the oscillator at coordinate q :

$$w(q) = \sum_{m=0}^{\infty} W_m w_m(q) = \sum_{m=0}^{\infty} W_m |\psi_m(q)|^2 = \left(1 - e^{-\hbar\omega/T} \right) \sum_{m=0}^{\infty} e^{-m\hbar\omega/T} |\psi_m(q)|^2, \quad (2.76)$$

where $\psi_m(q)$ is the normalized eigenfunction of the m^{th} stationary state of the oscillator. Since each $\psi_m(q)$ is proportional to the Hermite polynomial⁴¹ that requires at least m elementary functions for its

⁴¹ See, e.g., QM Sec. 2.10.

representation, working out the sum in Eq. (76) is a bit tricky,⁴² but the final result is rather simple: $w(q)$ is just a normalized *Gaussian distribution* (the “bell curve”),

$$w(q) = \frac{1}{(2\pi)^{1/2} \delta q} \exp\left\{-\frac{q^2}{2(\delta q)^2}\right\}, \quad (2.77)$$

with $\langle q \rangle = 0$, and

$$\langle q^2 \rangle = (\delta q)^2 = \frac{\hbar}{2m\omega} \coth \frac{\hbar\omega}{2T}. \quad (2.78)$$

Since the function $\coth \xi$ tends to 1 at $\xi \rightarrow \infty$, and diverges as $1/\xi$ at $\xi \rightarrow 0$, Eq. (78) shows that the width δq of the coordinate distribution is nearly constant (and equal to that, $(\hbar/2m\omega)^{1/2}$, of the ground-state wavefunction ψ_0) at $T \ll \hbar\omega$, and grows as $(T/m\omega^2)^{1/2} \equiv (T/\kappa)^{1/2}$ at $T/\hbar\omega \rightarrow \infty$.

As a sanity check, we may use Eq. (78) to write the following expression,

$$U \equiv \left\langle \frac{\kappa q^2}{2} \right\rangle = \frac{\hbar\omega}{4} \coth \frac{\hbar\omega}{2T} \rightarrow \begin{cases} \hbar\omega/4, & \text{for } T \ll \hbar\omega, \\ T/2, & \text{for } \hbar\omega \ll T, \end{cases} \quad (2.79)$$

for the average potential energy of the oscillator. To comprehend this result, let us recall that Eq. (72) for the average full energy E was obtained by counting it from the ground state energy $\hbar\omega/2$ of the oscillator. If we add this reference energy to that result, we get

$$E = \frac{\hbar\omega}{e^{\hbar\omega/T} - 1} + \frac{\hbar\omega}{2} \equiv \frac{\hbar\omega}{2} \coth \frac{\hbar\omega}{2T}. \quad (2.80)$$

We see that for arbitrary temperature, $U = E/2$, as was already discussed in Sec. 2. This means that the average kinetic energy, equal to $E - U$, is also the same:⁴³

$$\left\langle \frac{p^2}{2m} \right\rangle = \left\langle \frac{\kappa q^2}{2} \right\rangle = \frac{E}{2} = \frac{\hbar\omega}{4} \coth \frac{\hbar\omega}{2T}. \quad (2.81)$$

In the classical limit $T \gg \hbar\omega$, both energies equal $T/2$, reproducing the equipartition theorem result (48).

2.6. Two important applications

The results of the previous section, especially Eq. (72), have innumerable applications in physics and related disciplines, but here I have time for a brief discussion of only two of them.

(i) Blackbody radiation. Let us consider a free-space volume V limited by non-absorbing (i.e. ideally reflecting) walls. Electrodynamics tells us⁴⁴ that the electromagnetic field in such a “cavity” may be represented as a sum of “modes” with the time evolution similar to that of the usual harmonic

⁴² The calculation may be found, e.g., in QM Sec. 7.2.

⁴³ As a reminder: the equality of these two averages, at arbitrary temperature, was proved already in Sec. 2.

⁴⁴ See, e.g., EM Sec. 7.8.

oscillator. If the volume V is large enough,⁴⁵ the number of these modes within a small range dk of the wavevector magnitude k is

$$dN = \frac{gV}{(2\pi)^3} d^3k = \frac{gV}{(2\pi)^3} 4\pi k^2 dk, \quad (2.82)$$

where for electromagnetic waves, the degeneracy factor g is equal to 2, due to their two different independent (e.g., linear) polarizations of waves with the same wave vector \mathbf{k} . With the linear, isotropic dispersion relation for waves in vacuum, $k = \omega/c$, Eq. (82) yields

$$dN = \frac{2V}{(2\pi)^3} 4\pi \frac{\omega^2 d\omega}{c^3} \equiv V \frac{\omega^2}{\pi^2 c^3} d\omega. \quad (2.83)$$

On the other hand, quantum mechanics says⁴⁶ that the energy of such a “field oscillator” is quantized per Eq. (38), so that at thermal equilibrium its average energy is described by Eq. (72). Plugging that result into Eq. (83), we see that the spectral density of the electromagnetic field’s energy, per unit volume, is

$$u(\omega) \equiv \frac{E}{V} \frac{dN}{d\omega} = \frac{\hbar\omega^3}{\pi^2 c^3} \frac{1}{e^{\hbar\omega/T} - 1}. \quad (2.84)$$

Planck's
radiation
law

This is the famous *Planck's blackbody radiation law*.⁴⁷ To understand why its common name mentions radiation, let us consider a small planar part, of area dA , of a surface that completely absorbs electromagnetic waves incident from any direction. (Such “perfect black body” approximation may be closely approached using special experimental structures, especially in limited frequency intervals.) Figure 8 shows that if the arriving wave was planar, with the incidence angle θ , then the power $d\mathcal{P}_\theta(\omega)$ absorbed by the surface of small area dA , within a small frequency interval $d\omega$, i.e. the energy incident at that area in unit time, would be equal to the radiation energy within the same frequency interval, contained inside an imaginary cylinder (shaded in Fig. 8) of height c , base area $dA\cos\theta$, and hence volume $dV = c dA\cos\theta$:

$$d\mathcal{P}_\theta(\omega) = u(\omega)d\omega dV = u(\omega)d\omega c dA\cos\theta. \quad (2.85)$$

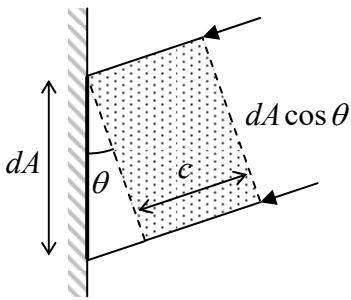

Fig. 2.8. Calculating the relation between $d\mathcal{P}(\omega)$ and $u(\omega)d\omega$.

⁴⁵ In our current context, the volume should be much larger than $(c\hbar/T)^3$, where $c \approx 3 \times 10^8$ m/s is the speed of light. For the room temperature ($T \approx k_B \times 300K \approx 4 \times 10^{-21}$ J), this lower bound is of the order of 10^{-16} m³.

⁴⁶ See, e.g., QM Sec. 9.1.

⁴⁷ Let me hope the reader knows that this law was first suggested in 1900 by Max Planck as an empirical fit for the experimental data on blackbody radiation, and this was the historic point at which the Planck constant \hbar (or rather $\hbar \equiv 2\pi\hbar$) was introduced – see, e.g., QM Sec. 1.1.

Since the thermally-induced field is isotropic, i.e. propagates equally in all directions, this result should be averaged over all solid angles within the polar angle interval $0 \leq \theta \leq \pi/2$:

$$\frac{d\mathcal{P}(\omega)}{dAd\omega} = \frac{1}{4\pi} \int \frac{d\mathcal{P}_\theta(\omega)}{dAd\omega} d\Omega = cu(\omega) \frac{1}{4\pi} \int_0^{\pi/2} \sin \theta d\theta \int_0^{2\pi} d\varphi \cos \theta = \frac{c}{4} u(\omega). \quad (2.86)$$

Hence the Planck's expression (84), multiplied by $c/4$, gives the power absorbed by such a “blackbody” surface. But at thermal equilibrium, this absorption has to be exactly balanced by the surface's own radiation, due to its non-zero temperature T .

I hope the reader is familiar with the main features of the Planck law (84), including its general shape (Fig. 9), with the low-frequency asymptote $u(\omega) \propto \omega^2$ (due to its historic significance bearing the special name of the *Rayleigh-Jeans law*), the exponential drop at high frequencies (the *Wien law*), and the resulting maximum of the function $u(\omega)$, reached at the frequency ω_{\max} with

$$\hbar\omega_{\max} \approx 2.82T, \quad (2.87)$$

i.e. at the wavelength $\lambda_{\max} = 2\pi/k_{\max} = 2\pi c/\omega_{\max} \approx 2.22 \text{ cm}/T$.

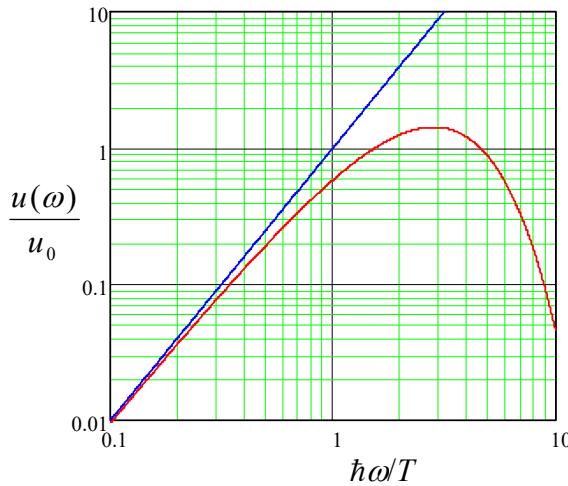

Fig. 2.9. The frequency dependence of the blackbody radiation density, normalized by $u_0 \equiv T^3/\pi^2\hbar^2c^3$, according to the Planck law (red line) and the Rayleigh-Jeans law (blue line).

Still, I cannot help mentioning a few important particular values: one corresponding to the visible light ($\lambda_{\max} \sim 500 \text{ nm}$) for the Sun's effective surface temperature $T_K \approx 6,000 \text{ K}$, and another one corresponding to the mid-infrared range ($\lambda_{\max} \sim 10 \mu\text{m}$) for the Earth's surface temperature $T_K \approx 300 \text{ K}$. The balance of these two radiations, absorbed and emitted by the Earth, determines its surface temperature and hence has the key importance for all life on our planet. This is why it is at the front and center of the current climate change discussions. As one more example, the cosmic microwave background (CMB) radiation, closely following the Planck law with $T_K = 2.725 \text{ K}$ (and hence having the maximum density at $\lambda_{\max} \approx 1.9 \text{ mm}$), and in particular its (very small) anisotropy, is a major source of data for modern cosmology.

Now let us calculate the total energy E of the blackbody radiation inside some volume V . It may be found from Eq. (84) by its integration over all frequencies:⁴⁸⁻⁴⁹

⁴⁸ The last step in Eq. (88) uses a table integral, equal to $\Gamma(4)\zeta(4) = (3!)(\pi^4/90) = \pi^4/15$ – see, e.g., MA Eq. (6.8b), with $s = 4$, and then MA Eqs. (6.7e), and (2.7b).

$$E = V \int_0^\infty u(\omega) d\omega = V \int_0^\infty \frac{\hbar\omega^3}{\pi^2 c^3} \frac{d\omega}{e^{\hbar\omega/T} - 1} = \frac{VT^4}{\pi^2 \hbar^3 c^3} \int_0^\infty \frac{\xi^3 d\xi}{e^{\xi} - 1} = V \frac{\pi^2}{15\hbar^3 c^3} T^4. \quad (2.88)$$

Using Eq. (86) to recast Eq. (88) into the total power radiated by a blackbody surface, we get the well-known *Stefan* (or “Stefan-Boltzmann”) law⁵⁰

$$\boxed{\frac{d\mathcal{P}}{dA} = \frac{\pi^2}{60\hbar^3 c^2} T^4 \equiv \sigma T_K^4,} \quad (2.89a) \quad \text{Stefan law}$$

where σ is the *Stefan-Boltzmann constant*

$$\boxed{\sigma \equiv \frac{\pi^2}{60\hbar^3 c^2} k_B^4 \approx 5.67 \times 10^{-8} \frac{\text{W}}{\text{m}^2 \text{K}^4}.} \quad (2.89b) \quad \text{Stefan-Boltzmann constant}$$

By this point, the thoughtful reader should have an important concern ready: Eq. (84) and hence Eq. (88) are based on Eq. (72) for the average energy of each oscillator, referred to its ground-state energy $\hbar\omega/2$. However, the radiation power should not depend on the energy origin; why have not we included the ground energy of each oscillator into the integration (88), as we have done in Eq. (80)? The answer is that usual radiation detectors only measure the *difference* between the power \mathcal{P}_{in} of the incident radiation (say, that of a blackbody surface with temperature T) and their own back-radiation power \mathcal{P}_{out} , corresponding to some effective temperature T_d of the detector – see Fig. 10. But however low T_d is, the temperature-independent contribution $\hbar\omega/2$ of the ground-state energy to the back radiation is always there. Hence, the term $\hbar\omega/2$ drops out from the balance, and cannot be detected – at least in this simple way. This is the reason why we had the right to ignore this contribution in Eq. (88) – very fortunately, because it would lead to the integral’s divergence at its upper limit. However, let me repeat that the ground-state energy of the electromagnetic field oscillators is physically real – and important – see Sec. 5.5 below.

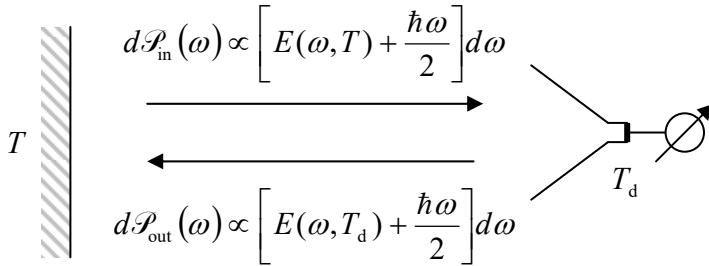

Fig. 2.10. The power balance at the electromagnetic radiation power measurement.

One more interesting result may be deduced from the free energy F of the electromagnetic radiation, which may be calculated by integration of Eq. (73) over all the modes, with the appropriate weight (83):

⁴⁹ Note that the heat capacity $C_V \equiv (\partial E / \partial T)_V$, following from Eq. (88), is proportional to T^3 at any temperature, and hence does not obey the trend $C_V \rightarrow \text{const}$ at $T \rightarrow \infty$. This is the result of the unlimited growth, with temperature, of the number of thermally-excited field oscillators with frequencies ω below T/\hbar .

⁵⁰ Its functional part ($E \propto T^4$) was deduced in 1879 by Joseph Stefan from earlier experiments by John Tyndall. Theoretically, it was proved in 1884 by L. Boltzmann, using a result derived earlier by Adolfo Bartoli from the Maxwell equations for the electromagnetic field – all well before Max Planck’s work.

$$F = \sum_{\omega} T \ln(1 - e^{-\hbar\omega/T}) \rightarrow \int_0^{\infty} T \ln(1 - e^{-\hbar\omega/T}) \frac{dN}{d\omega} d\omega = \int_0^{\infty} T \ln(1 - e^{-\hbar\omega/T}) \left(V \frac{\omega^2}{\pi^2 c^3} \right) d\omega. \quad (2.90)$$

Representing $\omega^2 d\omega$ as $d(\omega^3)/3$, we can readily work out this integral by parts, reducing it to a table integral similar to that in Eq. (88), and getting a surprisingly simple result:

$$F = -V \frac{\pi^2}{45\hbar^3 c^3} T^4 \equiv -\frac{E}{3}. \quad (2.91)$$

Now we can use the second of the general thermodynamic relations (1.35) to calculate the pressure exerted by the radiation on the walls of the containing volume V :⁵¹

$$P = -\left(\frac{\partial F}{\partial V}\right)_T = \frac{\pi^2}{45\hbar^3 c^3} T^4 = \frac{E}{3V}. \quad (2.92a)$$

Rewritten in the form,

Photon gas:
PV vs. E

$$PV = \frac{E}{3}, \quad (2.92b)$$

this result may be considered as the equation of state of the electromagnetic field, i.e. from the quantum-mechanical point of view, of the *photon gas*. Note that the equation of state (1.44) of the ideal classical gas may be represented in a similar form, but with a coefficient generally different from Eq. (92). Indeed, according to the equipartition theorem, for an ideal gas of non-relativistic particles whose internal degrees of freedom are in a fixed (say, ground) state, the temperature-dependent energy is that of the three translational “half-degrees of freedom”, $E = 3N(T/2)$. Expressing from here the product $NT = (2E/3)$, and plugging it into Eq. (1.44), we get a relation similar to Eq. (92), but with a twice larger factor before E . On the other hand, a *relativistic* treatment of the classical gas shows that Eq. (92) is valid for any gas in the ultra-relativistic limit, $T \gg mc^2$, where m is the rest mass of the gas’ particle. Evidently, photons (i.e. particles with $m = 0$) satisfy this condition at any energy.⁵²

Finally, let me note that Eq. (92) allows for the following interesting interpretation. The last of Eqs. (1.60), being applied to Eq. (92), shows that in this particular case the grand thermodynamic potential Ω equals $(-E/3)$, so that according to Eq. (91), it is equal to F . But according to the definition of Ω , i.e. the first of Eqs. (1.60), this means that the chemical potential of the electromagnetic field excitations (photons) vanishes:

$$\mu = \frac{F - \Omega}{N} = 0. \quad (2.93)$$

In Sec. 8 below, we will see that the same result follows from the comparison of Eq. (72) and the general Bose-Einstein distribution for arbitrary bosons. So, from the statistical point of view, photons may be considered as bosons with zero chemical potential.

(ii) Specific heat of solids. The heat capacity of solids is readily measurable, and in the early 1900s, its experimentally observed temperature dependence served as an important test for the then-

⁵¹ This formula may be also derived from the expression for the forces exerted by the electromagnetic radiation on the walls (see, e.g. EM Sec. 9.8), but the above calculation is much simpler.

⁵² Note that according to Eqs. (1.44), (88), and (92), the difference between the equations of state of the photon gas and an ideal gas of non-relativistic particles, expressed in the more usual form $P = P(V, T)$, is much more dramatic: $P \propto T^4 V^0$ vs. $P \propto T^1 V^1$.

emerging quantum theories. However, the theoretical calculation of C_V is not simple⁵³ – even for insulators, whose specific heat at realistic temperatures is due to thermally-induced vibrations of their crystal lattice alone.⁵⁴ Indeed, at relatively low frequencies, a solid may be treated as an elastic continuum. Such a continuum supports three different modes of mechanical waves with the same frequency ω , that all obey linear dispersion laws, $\omega = vk$, but the velocity $v = v_l$ for one of these modes (the *longitudinal sound*) is higher than that (v_t) of two other modes (the *transverse sound*).⁵⁵ At such frequencies, the wave mode density may be described by an evident generalization of Eq. (83):

$$dN = V \frac{1}{(2\pi)^3} \left(\frac{1}{v_l^3} + \frac{2}{v_t^3} \right) 4\pi\omega^2 d\omega. \quad (2.94a)$$

For what follows, it is convenient to rewrite this relation in a form similar to Eq. (83):

$$dN = \frac{3V}{(2\pi)^3} 4\pi \frac{\omega^2 d\omega}{v^3}, \quad \text{with } v \equiv \left[\frac{1}{3} \left(\frac{1}{v_l^3} + \frac{2}{v_t^3} \right) \right]^{-1/3}. \quad (2.94b)$$

However, the basic wave theory shows⁵⁶ that as the frequency ω of a sound wave in a periodic structure is increased so that its half-wavelength π/k approaches the crystal period d , the dispersion law $\omega(k)$ becomes nonlinear before the frequency reaches its maximum at $k = \pi/d$. To make things even more complex, 3D crystals are generally anisotropic, so that the dispersion law is different in different directions of the wave propagation. As a result, the exact statistics of thermally excited sound waves, and hence the heat capacity of crystals, is rather complex and specific for each particular crystal type.

In 1912, P. Debye suggested an approximate theory of the specific heat's temperature dependence, which is in a surprisingly good agreement with experiment for many insulators, including polycrystalline and amorphous materials. In his model, the linear (*acoustic*) dispersion law $\omega = vk$, with the effective sound velocity v defined by the second of Eqs. (94b), is assumed to be exact all the way up to some cutoff frequency ω_D , the same for all three wave modes. This *Debye frequency* may be defined by the requirement that the total number of acoustic modes, calculated within this model from Eq. (94b),

$$N = V \frac{1}{(2\pi)^3} \frac{3}{v^3} \int_0^{\omega_D} 4\pi\omega^2 d\omega = \frac{V\omega_D^3}{2\pi^2 v^3}, \quad (2.95)$$

is equal to the universal number $N = 3nV$ of the degrees of freedom (and hence of independent oscillation modes) in a 3D system of nV elastically coupled particles, where n is the atomic density of the crystal, i.e. the number of atoms per unit volume.⁵⁷ For this model, Eq. (72) immediately yields the following expression for the average energy and specific heat (in thermal equilibrium at temperature T):

$$E = V \frac{1}{(2\pi)^3} \frac{3}{v^3} \int_0^{\omega_D} \frac{\hbar\omega}{e^{\hbar\omega/T} - 1} 4\pi\omega^2 d\omega \equiv 3nVT D(x)_{x=T_D/T}, \quad (2.96)$$

⁵³ Due to a rather low temperature expansion of solids, the difference between their C_V and C_P is small.

⁵⁴ In good conductors (e.g., metals), specific heat is contributed (and at low temperatures, dominated) by free electrons – see Sec. 3.3 below.

⁵⁵ See, e.g., CM Sec. 7.7.

⁵⁶ See, e.g., CM Sec. 6.3, in particular Fig. 6.5 and its discussion.

⁵⁷ See, e.g., CM Sec. 6.2.

Debye
law

$$c_V \equiv \frac{C_V}{nV} = \frac{1}{nV} \left(\frac{\partial E}{\partial T} \right)_V = 3 \left[D(x) - x \frac{dD(x)}{dx} \right]_{x=T_D/T}, \quad (2.97)$$

where $T_D \equiv \hbar\omega_D$ is called the *Debye temperature*,⁵⁸ and

$$D(x) \equiv \frac{3}{x^3} \int_0^x \frac{\xi^3 d\xi}{e^{\xi} - 1} \rightarrow \begin{cases} 1, & \text{for } x \rightarrow 0, \\ \pi^4 / 5x^3, & \text{for } x \rightarrow \infty, \end{cases} \quad (2.98)$$

is the *Debye function*. Red lines in Fig. 11 show the temperature dependence of the specific heat c_V (per particle) within the Debye model. At high temperatures, it approaches a constant value of three, corresponding to the energy $E = 3nVT$, in agreement with the equipartition theorem for each of three degrees of freedom (i.e. six half-degrees of freedom) of each mode. (This value of c_V is known as the *Dulong-Petit law*.) In the opposite limit of low temperatures, the specific heat is much smaller:

$$c_V \approx \frac{12\pi^4}{5} \left(\frac{T}{T_D} \right)^3 \ll 1, \quad (2.99)$$

reflecting the reduction of the number of excited phonons with $\hbar\omega < T$ as the temperature is decreased.

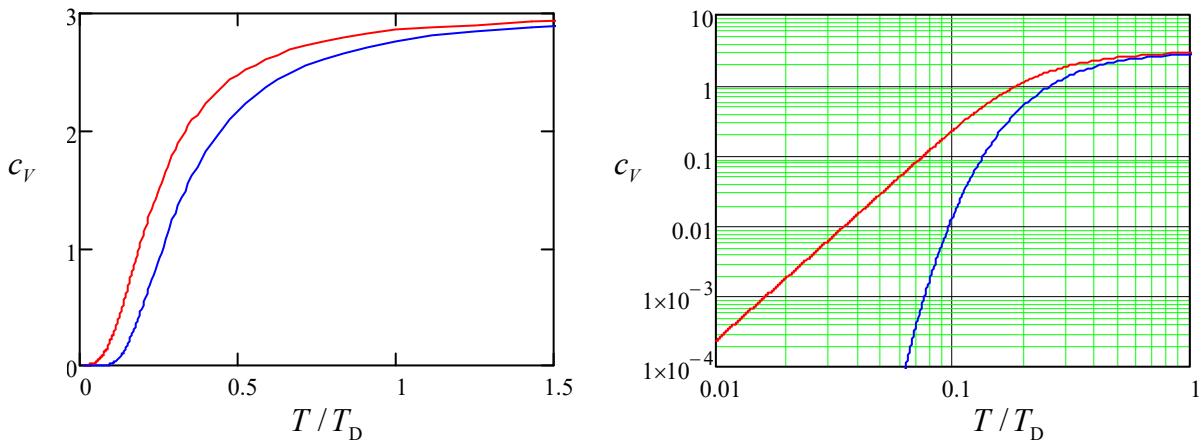

Fig. 2.11. The specific heat as a function of temperature in the Debye (red lines) and Einstein (blue lines) models.

As a historic curiosity, P. Debye's work followed one by A. Einstein, who had suggested (in 1907) a simpler model of crystal vibrations. In his model, all $3nV$ independent oscillatory modes of nV atoms of the crystal have approximately the same frequency, say ω_E , and Eq. (72) immediately yields

$$E = 3nV \frac{\hbar\omega_E}{e^{\hbar\omega_E/T} - 1}, \quad (2.100)$$

so that the specific heat is functionally similar to Eq. (75):

⁵⁸ In the SI units, the Debye temperature T_D is of the order of a few hundred K for most simple solids (e.g., ~430 K for aluminum and ~340 K for copper), with somewhat lower values for crystals with heavy atoms (~105 K for lead), and reaches its highest value ~2200 K for diamond, with its relatively light atoms and very stiff lattice.

$$c_V \equiv \frac{1}{nV} \left(\frac{\partial E}{\partial T} \right)_V = 3 \left[\frac{\hbar\omega_E / 2T}{\sinh(\hbar\omega_E / 2T)} \right]^2. \quad (2.101)$$

This dependence $c_V(T)$ is shown with blue lines in Fig. 11 (assuming, for the sake of simplicity, that $\hbar\omega_E = T_D$). At high temperatures, this result does satisfy the universal Dulong-Petit law ($c_V = 3$), but for $T \ll T_D$, Einstein's model predicts a much faster (exponential) drop of the specific heat as the temperature is reduced. (The difference between the Debye and Einstein models is not too spectacular on the linear scale, but in the log-log plot, shown on the right panel of Fig. 11, it is rather dramatic.⁵⁹⁾ The Debye model is in a much better agreement with experimental data for simple, monoatomic crystals, thus confirming the conceptual correctness of his wave-based approach.

Note, however, that when a genius such as Albert Einstein makes an error, there is usually some deep and important background under it. Indeed, crystals with the basic cell consisting of atoms of two or more types (such as NaCl, etc.), feature two or more separate branches of the dispersion law $\omega(k)$ – see, e.g., Fig. 12. While the lower, “acoustic” branch is virtually similar to those for monoatomic crystals and may be approximated by the Debye model, $\omega = v k$, reasonably well, the upper (“optical”⁶⁰⁾ branch does not approach $\omega = 0$ at any k . Moreover, for large values of the atomic mass ratio r , the optical branches are almost flat, with virtually k -independent frequencies ω_0 , which correspond to simple oscillations of each light atom between its heavy neighbors. For thermal excitations of such oscillations, and their contribution to the specific heat, Einstein's model (with $\omega_E = \omega_0$) gives a very good approximation, so that for such solids, the specific heat may be well described by a sum of the Debye and Einstein laws (97) and (101), with appropriate weights.

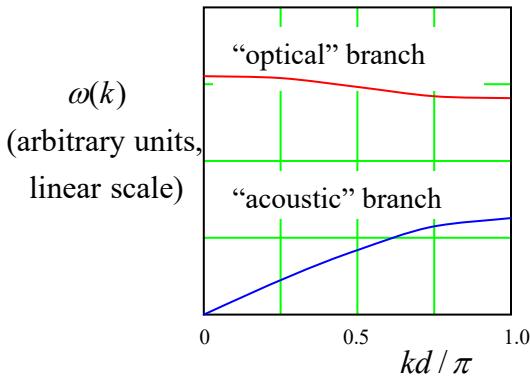

Fig. 2.12. The dispersion relation for mechanical waves in a simple 1D model of a solid, with similar interparticle distances d , but alternating particle masses, plotted for a particular mass ratio $r = 5$ – see CM Chapter 6.

2.7. Grand canonical ensemble and distribution

As we have seen, the Gibbs distribution is a very convenient way to calculate the statistical and thermodynamic properties of systems with a fixed number N of particles. However, for systems in which N may vary, another distribution is preferable for applications. Several examples of such situations (as

⁵⁹⁾ This is why there is the following general “rule of thumb” in quantitative sciences: if you plot your data on a linear rather than log scale, you better have a good excuse ready. (An example of a valid excuse: the variable you are plotting changes its sign within the range you want to exhibit.)

⁶⁰⁾ This term stems from the fact that at $k \rightarrow 0$, the mechanical waves corresponding to these branches have phase velocities $v_{ph} \equiv \omega(k)/k$ that are much higher than that of the acoustic waves, and may approach the speed of light. As a result, these waves can strongly interact with electromagnetic (practically, optical) waves of the same frequency, while acoustic waves cannot.

well as the basic thermodynamics of such systems) have already been discussed in Sec. 1.5. Perhaps even more importantly, statistical distributions for systems with variable N are also applicable to some ensembles of independent particles in certain single-particle states even if the number of the particles is fixed – see the next section.

With this motivation, let us consider what is called the *grand canonical ensemble* (Fig. 13). It is similar to the canonical ensemble discussed in Sec. 4 (see Fig. 6) in all aspects, besides that now the system under study and the heat bath (in this case more often called the *environment*) may exchange not only heat but also particles. In this ensemble, all environments are in both the thermal and chemical equilibrium, with their temperatures T and chemical potentials μ the same for all members.

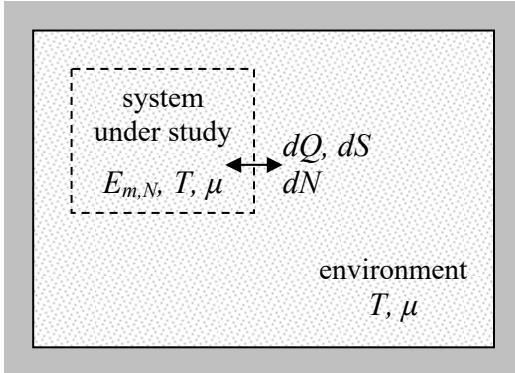

Fig. 2.13. A member of the grand canonical ensemble.

Let us assume that the system of interest is also in the chemical and thermal equilibrium with its environment. Then using exactly the same arguments as in Sec. 4 (including the specification of microcanonical sub-ensembles with fixed E_Σ and N_Σ), we may generalize Eq. (55), taking into account that the entropy S_{env} of the environment is now a function of not only its energy $E_{\text{env}} = E_\Sigma - E_{m,N}$,⁶¹ but also of the number of particles $N_{\text{env}} = N_\Sigma - N$, with E_Σ and N_Σ fixed:

$$\begin{aligned} \ln W_{m,N} &\propto \ln M = \ln g_{\text{env}}(E_\Sigma - E_{m,N}, N_\Sigma - N) + \ln \Delta E_\Sigma = S_{\text{env}}(E_\Sigma - E_{m,N}, N_\Sigma - N) + \text{const} \\ &\approx S_{\text{env}} \Big|_{E_\Sigma, N_\Sigma} - \frac{\partial S_{\text{env}}}{\partial E_{\text{env}}} \Big|_{E_\Sigma, N_\Sigma} E_{m,N} - \frac{\partial S_{\text{env}}}{\partial N_{\text{env}}} \Big|_{E_\Sigma, N_\Sigma} N + \text{const}. \end{aligned} \quad (2.102)$$

To simplify this relation, let us rewrite Eq. (1.52) in the following equivalent form:

$$dS = \frac{1}{T} dE + \frac{P}{T} dV - \frac{\mu}{T} dN. \quad (2.103)$$

Hence, if the entropy S of a system is expressed as a function of E , V , and N , then

$$\left(\frac{\partial S}{\partial E} \right)_{V,N} = \frac{1}{T}, \quad \left(\frac{\partial S}{\partial V} \right)_{E,N} = \frac{P}{T}, \quad \left(\frac{\partial S}{\partial N} \right)_{E,V} = -\frac{\mu}{T}. \quad (2.104)$$

Applying the first one and the last one of these relations to the last form of Eq. (102), and using the equality of the temperatures T and chemical potentials μ in the system under study and its environment, at equilibrium (as was discussed in Sec. 1.5), we get

⁶¹ The additional index in the new notation $E_{m,N}$ for the energy of the system of interest reflects the fact that its spectrum is generally dependent on the number N of particles in it.

$$\ln W_{m,N} = S_{\text{env}}(E_\Sigma, N_\Sigma) - \frac{1}{T} E_{m,N} + \frac{\mu}{T} N + \text{const.} \quad (2.105)$$

Again, exactly as at the derivation of the Gibbs distribution in Sec. 4, we may argue that since $E_{m,N}$, T , and μ do not depend on the choice of environment's size, i.e. on E_Σ and N_Σ , the probability $W_{m,N}$ for a system to have N particles and be in m^{th} quantum state in the whole grand canonical ensemble should also obey Eq. (105). As a result, we get the so-called *grand canonical distribution*:

$$W_{m,N} = \frac{1}{Z_G} \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\}. \quad (2.106)$$

Grand
canonical
distribution

Just as in the case of the Gibbs distribution, the constant Z_G (most often called the *grand statistical sum*, but sometimes the “grand partition function”) should be determined from the probability normalization condition, now with the summation of probabilities $W_{m,N}$ over all possible values of both m and N :

$$Z_G = \sum_{m,N} \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\}. \quad (2.107)$$

Grand
canonical
sum

Now, using the general Eq. (29) to calculate the entropy for the distribution (106) (exactly like we did it for the canonical ensemble), we get the following expression,

$$S = - \sum_{m,N} W_{m,N} \ln W_{m,N} = \frac{E}{T} - \frac{\mu \langle N \rangle}{T} + \ln Z_G, \quad (2.108)$$

which is evidently a generalization of Eq. (62).⁶² We see that now the grand thermodynamic potential Ω (rather than the free energy F) may be expressed directly via the normalization coefficient Z_G :

$$\Omega \equiv F - \mu \langle N \rangle = E - TS - \mu \langle N \rangle = T \ln \frac{1}{Z_G} = -T \ln \sum_{m,N} \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\}. \quad (2.109)$$

Ω from Z_G

Finally, solving the last equality for Z_G , and plugging the result back into Eq. (106), we can rewrite the grand canonical distribution in the form

$$W_{m,N} = \exp \left\{ \frac{\Omega + \mu N - E_{m,N}}{T} \right\}, \quad (2.110)$$

similar to Eq. (65) for the Gibbs distribution. Indeed, in the particular case when the number N of particles is fixed, $N = \langle N \rangle$, so that $\Omega + \mu N = \Omega + \mu \langle N \rangle \equiv F$, Eq. (110) is reduced to Eq. (65).

2.8. Systems of independent particles

Now let us apply the general statistical distributions discussed above to a simple but very important case when the system we are considering consists of many similar particles whose explicit (“direct”) interaction is negligible. As a result, each particular energy value $E_{m,N}$ of such a system may

⁶² The average number of particles $\langle N \rangle$ is exactly what was called N in thermodynamics (see Chapter 1), but I keep this explicit notation here to make a clear distinction between this average value of the variable, and its particular values participating in Eqs. (102)-(110).

be represented as a sum of energies ε_k of the particles, where the index k numbers single-particle states – rather than those of the whole system, as the index m does.

Let us start with the classical limit. In classical mechanics, the energy quantization effects are negligible, i.e. there is a formally infinite number of quantum states k within each finite energy interval. However, it is convenient to keep, for the time being, the discrete-state language, with the understanding that the average number $\langle N_k \rangle$ of particles in each of these states, usually called the *state occupancy*, is very small. In this case, we may apply the Gibbs distribution to the canonical ensemble of *single particles*, and hence use it with the substitution $E_m \rightarrow \varepsilon_k$, so that Eq. (58) becomes

$$\langle N_k \rangle = c \exp\left\{-\frac{\varepsilon_k}{T}\right\} \ll 1, \quad (2.111)$$

Boltzmann distribution

where the constant c should be found from the normalization condition:

$$\sum_k \langle N_k \rangle = 1. \quad (2.112)$$

This is the famous *Boltzmann distribution*.⁶³ Despite its formal similarity to the Gibbs distribution (58), let me emphasize the conceptual difference between these two important formulas. The Gibbs distribution describes the probability to find the *whole system* on one of its states with energy E_m , and it is *always* valid – more exactly, for a canonical ensemble of systems in thermodynamic equilibrium. On the other hand, the Boltzmann distribution describes the occupancy of an energy level of a *single particle*, and, as we will see in just a minute, is valid for quantum particles *only in the classical limit* $\langle N_k \rangle \ll 1$, even if they do not interact directly.

The last fact may be surprising, because it may seem that as soon as particles of the system are independent, nothing prevents us from using the Gibbs distribution to derive Eq. (111), regardless of the value of $\langle N_k \rangle$. This is indeed true if the particles are *distinguishable*, i.e. may be distinguished from each other – say by their fixed spatial positions, or by the states of certain internal degrees of freedom (say, spin), or by any other “pencil mark”. However, it is an experimental fact that elementary particles of each particular type (say, electrons) are *identical* to each other, i.e. cannot be “pencil-marked”.⁶⁴ For such particles we have to be more careful: even if they do not interact *explicitly*, there is still some *implicit* dependence in their behavior, which is especially evident for the so-called *fermions* (elementary particles with semi-integer spin): they obey the *Pauli exclusion principle* that forbids two identical particles to be in the same quantum state, even if they do not interact explicitly.⁶⁵

⁶³ The distribution was first suggested in 1877 by L. Boltzmann. For the particular case when ε is the kinetic energy of a free classical particle (and hence has a continuous spectrum), it is reduced to the *Maxwell distribution* (see Sec. 3.1 below), which was derived earlier – in 1860.

⁶⁴ This invites a natural question: what particles are “elementary enough” for their identity? For example, protons and neutrons have an internal structure, in some sense consisting of quarks and gluons; can they be considered elementary? Next, if protons and neutrons are elementary, are atoms? molecules? What about *really* large molecules (such as proteins)? viruses? The general answer to these questions, given by quantum mechanics (or rather experiment :-), is that any particles/systems, no matter how large and complex they are, are identical if they not only have the same internal structure but also are exactly in the same internal quantum state – for example, in the ground state of all their internal degrees of freedom.

⁶⁵ For a more detailed discussion of this issue, see, e.g., QM Sec. 8.1.

Note that the term “the same quantum state” carries a heavy meaning load here. For example, if two particles are confined to stay at different spatial positions (say, reliably locked in different boxes), they are *distinguishable* even if they are internally *identical*. Thus the Pauli principle, as well as other particle identity effects such as the Bose-Einstein condensation to be discussed in the next chapter, are important only when identical particles may move in the same spatial region. To emphasize this fact, it is common to use, instead of “identical”, a more precise (though grammatically rather unpleasant) adjective *indistinguishable*.

In order to take these effects into account, let us examine statistical properties of a system of many non-interacting but indistinguishable particles (at the first stage of calculation, either fermions or bosons) in equilibrium, applying the grand canonical distribution (109) to a very unusual grand canonical ensemble: a subset of particles in the same quantum state k (Fig. 14).

single-particle energy levels:

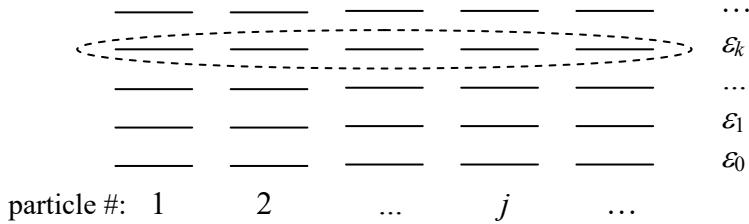

Fig. 2.14. The grand canonical ensemble of particles in the same quantum state with energy ε_k – schematically.

In this ensemble, the role of the environment may be played just by the set of particles in all other states $k' \neq k$, because due to infinitesimal interactions, the particles may gradually change their states. In the resulting equilibrium, the chemical potential μ and temperature T of the system should not depend on the state number k , though the grand thermodynamic potential Ω_k of the chosen particle subset may. Replacing N with N_k – the particular (not average!) number of particles in the selected k^{th} state, and the particular energy value $E_{m,N}$ with $\varepsilon_k N_k$, we reduce the final form of Eq. (109) to

$$\Omega_k = -T \ln \left(\sum_{N_k} \exp \left\{ \frac{\mu N_k - \varepsilon_k N_k}{T} \right\} \right) \equiv -T \ln \left[\sum_{N_k} \left(\exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \right)^{N_k} \right], \quad (2.113)$$

where the summation should be carried out over all possible values of N_k . For the final calculation of this sum, the elementary particle type is essential.

On one hand, for *fermions*, obeying the Pauli principle, the numbers N_k in Eq. (113) may take only two values, either 0 (the state k is unoccupied) or 1 (the state is occupied), and the summation gives

$$\Omega_k = -T \ln \left[\sum_{N_k=0,1} \left(\exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \right)^{N_k} \right] \equiv -T \ln \left(1 + \exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \right). \quad (2.114)$$

Now the state occupancy may be calculated from the last of Eqs. (1.62) – in this case, with the (average) N replaced with $\langle N_k \rangle$:

$$\langle N_k \rangle = - \left(\frac{\partial \Omega_k}{\partial \mu} \right)_{T,V} = \frac{1}{e^{(\varepsilon_k - \mu)/T} + 1}. \quad (2.115)$$

Fermi-
Dirac
distribution

This is the famous *Fermi-Dirac distribution*, derived in 1926 independently by Enrico Fermi and Paul Dirac.

On the other hand, *bosons* do not obey the Pauli principle, and for them the numbers N_k can take any non-negative integer values. In this case, Eq. (113) turns into the following equality:

$$\Omega_k = -T \ln \left[\sum_{N_k=0}^{\infty} \left(\exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \right)^{N_k} \right] \equiv -T \ln \sum_{N_k=0}^{\infty} \lambda^{N_k}, \quad \text{with } \lambda \equiv \exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\}. \quad (2.116)$$

This sum is just the usual geometric series, which converges if $\lambda < 1$, giving

$$\Omega_k = -T \ln \frac{1}{1-\lambda} \equiv T \ln \left(1 - \exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \right), \quad \text{for } \mu < \varepsilon_k. \quad (2.117)$$

In this case, the average occupancy, again calculated using Eq. (1.62) with N replaced with $\langle N_k \rangle$, obeys the *Bose-Einstein distribution*,

$$\langle N_k \rangle = - \left(\frac{\partial \Omega_k}{\partial \mu} \right)_{T,V} = \frac{1}{e^{(\varepsilon_k - \mu)/T} - 1}, \quad \text{for } \mu < \varepsilon_k, \quad (2.118)$$

which was derived in 1924 by Satyendra Nath Bose (for the particular case $\mu = 0$) and generalized in 1925 by Albert Einstein for an arbitrary chemical potential. In particular, comparing Eq. (118) with Eq. (72), we see that harmonic oscillator's *excitations*,⁶⁶ each with energy $\hbar\omega$, may be considered as bosons, with the chemical potential equal to zero. As a reminder, we have already obtained this equality ($\mu = 0$) in a different way – see Eq. (93). Its physical interpretation is that the oscillator excitations may be created inside the system, so that there is no energy cost μ of moving them into the system under consideration from its environment.

The simple form of Eqs. (115) and (118), and their similarity (besides “only” the difference of the signs before the unity in their denominators), is one of the most beautiful results of physics. This similarity, however, should not disguise the fact that the energy dependences of the occupancies $\langle N_k \rangle$ given by these two formulas are very different – see their linear and semi-log plots in Fig. 15.

In the Fermi-Dirac statistics, the level occupancy is not only finite, but below 1 at any energy, while in the Bose-Einstein it may be above 1, and diverges at $\varepsilon_k \rightarrow \mu$. However, as the temperature is increased, it eventually becomes much larger than the difference $(\varepsilon_k - \mu)$. In this limit, $\langle N_k \rangle \ll 1$, both quantum distributions coincide with each other, as well as with the classical Boltzmann distribution (111) with $c = \exp \{ \mu/T \}$:

$$\langle N_k \rangle \rightarrow \exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\}, \quad \text{for } \langle N_k \rangle \rightarrow 0. \quad (2.119)$$

This distribution (also shown in Fig. 15) may be, therefore, understood also as the high-temperature limit for indistinguishable particles of both sorts.

Bose-Einstein distribution

Boltzmann distribution:
identical particles

⁶⁶ As the reader certainly knows, for the electromagnetic field oscillators, such excitations are called *photons*; for mechanical oscillation modes, *phonons*. It is important, however, not to confuse these mode *excitations* with the oscillators as such, and be very careful in prescribing to them certain spatial locations – see, e.g., QM Sec. 9.1.

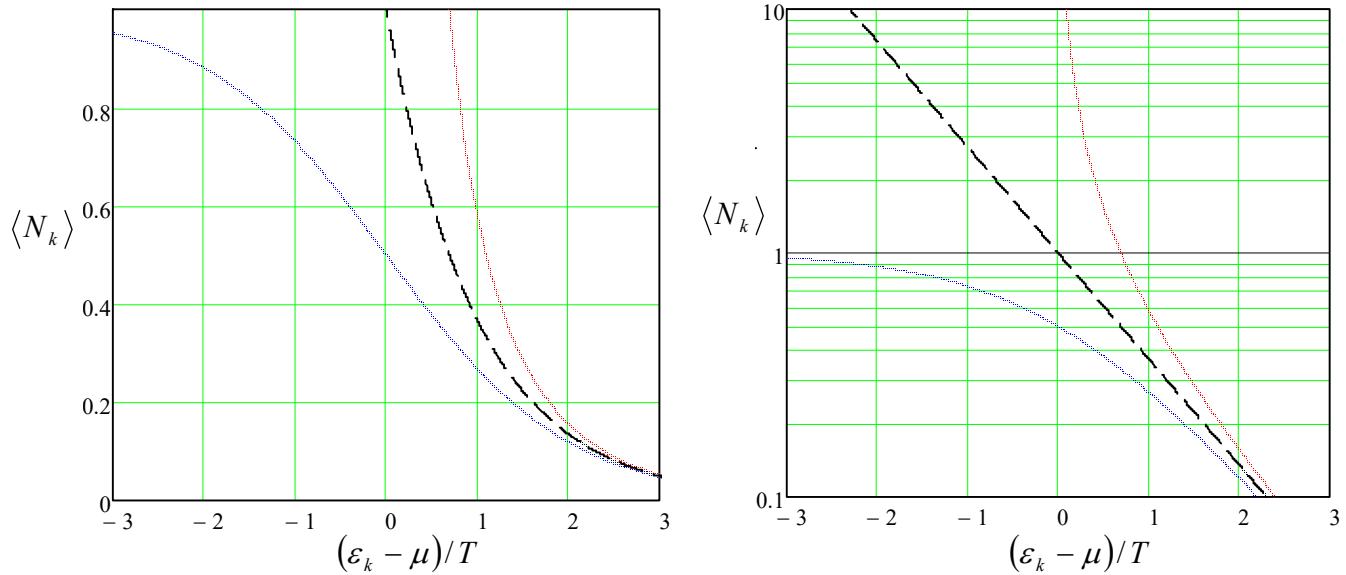

Fig. 2.15. The Fermi-Dirac (blue line), Bose-Einstein (red line), and Boltzmann (dashed line) distributions for indistinguishable quantum particles. (The last distribution is valid only asymptotically, at $\langle N_k \rangle \ll 1$.)

A natural question now is how to find the chemical potential μ participating in Eqs. (115), (118), and (119). In the grand canonical ensemble as such (Fig. 13), with the number of particles variable, the value of μ is imposed by the system's environment. However, both the Fermi-Dirac and Bose-Einstein distributions are also *approximately* applicable (in thermal equilibrium) to systems with a *fixed but very large* number N of particles. In these conditions, the role of the environment for some subset of $N' \ll N$ particles is essentially played by the remaining $N - N'$ particles. In this case, μ may be found by the calculation of $\langle N \rangle$ from the corresponding probability distribution, and then requiring it to be equal to the genuine number of particles in the system. In the next section, we will perform such calculations for several particular systems.

For that and other applications, it will be convenient for us to have ready formulas for the entropy S of a general (i.e. not necessarily equilibrium) state of systems of independent Fermi or Bose particles, expressed not as a function of W_m of the whole system, as in Eq. (29), but via the occupancy numbers $\langle N_k \rangle$. For that, let us consider an ensemble of *composite systems*, each consisting of $M \gg 1$ similar but distinct *component systems*, numbered by index $m = 1, 2, \dots, M$, with independent (i.e. not directly interacting) particles. We will assume that though in each of M component systems the number $N_k^{(m)}$ of particles in their k^{th} quantum state may be different (Fig. 16), their total number $N_k^{(\Sigma)}$ in the composite system is fixed. As a result, the total energy of the composite system is fixed as well,

$$\sum_{m=1}^M N_k^{(m)} = N_k^{(\Sigma)} = \text{const}, \quad E_k = \sum_{m=1}^M N_k^{(m)} \varepsilon_k = N_k^{(\Sigma)} \varepsilon_k = \text{const}, \quad (2.120)$$

so that an ensemble of many such composite systems (with the same k), in equilibrium, is microcanonical.

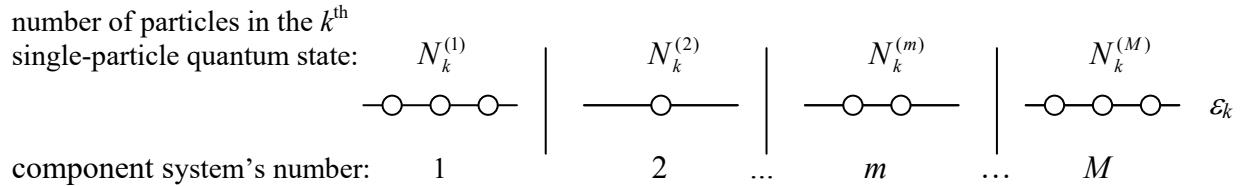

Fig. 2.16. A composite system of $N_k^{(\Sigma)}$ particles in the k^{th} quantum state, distributed between M component systems.

According to Eq. (24a), the average entropy S_k per component system in this microcanonical ensemble may be calculated as

$$S_k = \lim_{M \rightarrow \infty} \frac{\ln M_k}{M}, \quad (2.121)$$

where M_k is the number of possible different ways such a composite system (with fixed $N_k^{(\Sigma)}$) may be implemented. Let us start the calculation of M_k for Fermi particles – for which the Pauli principle is valid. Here the level occupancies $N_k^{(m)}$ may be only equal to either 0 or 1, so that the distribution problem is solvable only if $N_k^{(\Sigma)} \leq M$, and evidently equivalent to the choice of $N_k^{(\Sigma)}$ balls (in *arbitrary* order) from the total number of M *distinct* balls. Comparing this formulation with the definition of the binomial coefficient,⁶⁷ we immediately get

$$M_k = {}^M C_{N_k^{(\Sigma)}} = \frac{M!}{(M - N_k^{(\Sigma)})! N_k^{(\Sigma)}!}. \quad (2.122)$$

From here, using the Stirling formula (again, in its simplest form (27)), we get

Fermions:
entropy

$$S_k = -\langle N_k \rangle \ln \langle N_k \rangle - (1 - \langle N_k \rangle) \ln (1 - \langle N_k \rangle), \quad (2.123)$$

where

$$\langle N_k \rangle \equiv \lim_{M \rightarrow \infty} \frac{N_k^{(\Sigma)}}{M} \quad (2.124)$$

is exactly the average occupancy of the k^{th} single-particle state in each system, which was discussed earlier in this section. Since for a Fermi system, $\langle N_k \rangle$ is always somewhere between 0 and 1, its entropy (123) is always positive.

In the Bose case, where the Pauli principle is not valid, the number $N_k^{(m)}$ of particles on the k^{th} energy level in each of the systems is an arbitrary (non-negative) integer. Let us consider $N_k^{(\Sigma)}$ particles and $(M - 1)$ partitions (shown by vertical lines in Fig. 16) between M systems as $(M - 1 + N_k^{(\Sigma)})$ mathematical objects ordered along one axis. Each specific location of the partitions evidently fixes all $N_k^{(m)}$. Hence M_k may be calculated as the number of possible ways to distribute the $(M - 1)$ indistinguishable partitions among these $(M - 1 + N_k^{(\Sigma)})$ ordered objects, i.e. as the following binomial coefficient:⁶⁸

⁶⁷ See, e.g., MA Eq. (2.2).

⁶⁸ See also MA Eq. (2.4).

$$M_k = {}^{M+N_k-1}C_{M-1} = \frac{(M-1+N_k^{(\Sigma)})!}{(M-1)!N_k^{(\Sigma)}!}. \quad (2.125)$$

Applying the Stirling formula (27) again, we get the following result,

$$S_k = -\langle N_k \rangle \ln \langle N_k \rangle + (1 + \langle N_k \rangle) \ln (1 + \langle N_k \rangle), \quad (2.126)$$
Bosons:
entropy

which again differs from the Fermi case (123) “only” by the signs in the second term, and is valid for any positive $\langle N_k \rangle$.

Expressions (123) and (126) are valid for an arbitrary (possibly non-equilibrium) case; they may be also used for an alternative derivation of the Fermi-Dirac (115) and Bose-Einstein (118) distributions, which are valid only in equilibrium. For that, we may use the method of Lagrange multipliers, requiring (just like it was done in Sec. 2) the total entropy of a system of N independent, similar particles,

$$S = \sum_k S_k, \quad (2.127)$$

considered as a function of state occupancies $\langle N_k \rangle$, to attain its maximum, under the conditions of the fixed total number of particles N and total energy E :

$$\sum_k \langle N_k \rangle = N = \text{const}, \quad \sum_k \langle N_k \rangle \varepsilon_k = E = \text{const}. \quad (2.128)$$

The completion of this calculation is left for the reader’s exercise.

In the classical limit, when the average occupancies $\langle N_k \rangle$ of all states are small, the Fermi and Bose expressions for S_k tend to the same limit

$$S_k = -\langle N_k \rangle \ln \langle N_k \rangle, \quad \text{for } \langle N_k \rangle \ll 1. \quad (2.129)$$
Boltzmann
entropy

This expression, frequently referred to as the *Boltzmann* (or “classical”) *entropy*, might be also obtained, for arbitrary $\langle N_k \rangle$, directly from the functionally similar Eq. (29), by considering an ensemble of systems, each consisting of just one classical particle, so that $E_m \rightarrow \varepsilon_k$ and $W_m \rightarrow \langle N_k \rangle$. Let me emphasize again that for indistinguishable particles, such identification is generally (i.e. at $\langle N_k \rangle \sim 1$) illegitimate even if the particles do not interact explicitly. As we will see in the next chapter, indistinguishability may affect the statistical properties of identical particles even in the classical limit.

2.9. Exercise problems

2.1. A famous example of macroscopic irreversibility was suggested in 1907 by P. Ehrenfest. Two dogs share $2N \gg 1$ fleas. Each flea may jump onto another dog, and the rate Γ of such events (i.e. the probability of jumping per unit time) does not depend either on time or on the location of other fleas. Find the time evolution of the average number of fleas on a dog, and of the flea-related part of the total dogs’ entropy (at arbitrary initial conditions), and prove that the entropy can only grow.⁶⁹

⁶⁹ This is essentially a simpler (and funnier :-) version of the particle scattering model used by L. Boltzmann to prove his famous *H-theorem* (1872). Besides the historic significance of that theorem, the model used in it (see Sec. 6.2 below) is as cartoonish, and not more general.

2.2. Use the microcanonical distribution to calculate thermodynamic properties (including the entropy, all relevant thermodynamic potentials, and the heat capacity), of a two-level system in thermodynamic equilibrium with its environment, at temperature T that is comparable with the energy gap Δ . For each variable, sketch its temperature dependence, and find its asymptotic values (or trends) in the low-temperature and high-temperature limits.

Hint: The two-level system is any quantum system with just two different stationary states, whose energies (say, E_0 and E_1) are separated by a gap $\Delta \equiv E_1 - E_0$. Its most popular (but by no means the only!) example is the spin- $\frac{1}{2}$ of a particle, e.g., an electron, in an external magnetic field.⁷⁰

2.3. Solve the previous problem using the Gibbs distribution. Also, calculate the probabilities of the energy level occupation, and give physical interpretations of your results, in both temperature limits.

2.4. Calculate low-field magnetic susceptibility χ of a quantum spin- $\frac{1}{2}$ particle with a gyromagnetic ratio γ , in thermal equilibrium with an environment at temperature T , neglecting its orbital motion. Compare the result with that for a classical spontaneous magnetic dipole \mathbf{m} of a fixed magnitude m_0 , free to change its direction in space.

Hint: The low-field magnetic susceptibility of a single particle is defined⁷¹ as

$$\chi = \left. \frac{\partial \langle m_z \rangle}{\partial \mathcal{H}} \right|_{\mathcal{H} \rightarrow 0},$$

where the z -axis is aligned with the direction of the external magnetic field \mathcal{H} .

2.5. Calculate the low-field magnetic susceptibility of a particle with an arbitrary (either integer or semi-integer) spin s , neglecting its orbital motion. Compare the result with the solution of the previous problem.

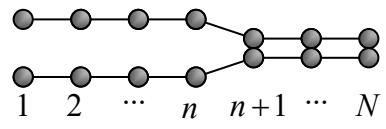

Hint: Quantum mechanics⁷² tells us that the Cartesian component m_z of the magnetic moment of such a particle, in the direction of the applied field, has $(2s + 1)$ stationary values:

$$m_z = \gamma \hbar m_s, \quad \text{with } m_s = -s, -s+1, \dots, s-1, s,$$

where γ is the gyromagnetic ratio of the particle, and \hbar is Planck's constant.

2.6.* Analyze the possibility of using a system of non-interacting spin- $\frac{1}{2}$ particles, placed into a strong, controllable external magnetic field, for refrigeration.

2.7. The rudimentary “zipper” model of DNA replication is a chain of N links that may be either open or closed – see the figure on the right. Opening a link increases the system's energy by $\Delta > 0$; a link may change its state (either open or closed) only if all links to the left of it are

⁷⁰ See, e.g., QM Secs. 4.6 and 5.1, for example, Eq. (4.167).

⁷¹ This “atomic” (or “molecular”) susceptibility should be distinguished from the “volumic” susceptibility $\chi_m \equiv \partial M_z / \partial \mathcal{H}$, where M_z is the magnetization, i.e. the magnetic moment of a unit volume of a system – see, e.g., EM Eq. (5.111). For a uniform medium with $n \equiv N/V$ non-interacting dipoles per unit volume, $\chi_m = n\chi$.

⁷² See, e.g., QM Sec. 5.7, in particular Eq. (5.169).

open, while those on the right of it, are closed. Calculate the average number of open links at thermal equilibrium, and analyze its temperature dependence, especially for the case $N \gg 1$.

2.8. Use the microcanonical distribution to calculate the average entropy, energy, and pressure of a classical particle of mass m , with no internal degrees of freedom, free to move in volume V , at temperature T .

Hint: Try to make a more accurate calculation than has been done in Sec. 2.2 for the system of N harmonic oscillators. For that, you will need to know the volume V_d of a d -dimensional hypersphere of the unit radius. To avoid being too cruel, I am giving it to you:

$$V_d = \pi^{d/2} / \Gamma\left(\frac{d}{2} + 1\right),$$

where $\Gamma(\xi)$ is the gamma function.⁷³

2.9. Solve the previous problem starting from the Gibbs distribution.

2.10. Calculate the average energy, entropy, free energy, and the equation of state of a classical 2D particle (without internal degrees of freedom), free to move within area A , at temperature T , starting from:

- (i) the microcanonical distribution, and
- (ii) the Gibbs distribution.

Hint: For the equation of state, make the appropriate modification of the notion of pressure.

2.11. A quantum particle of mass m is confined to free motion along a 1D segment of length a . Using any approach you like, calculate the average force the particle exerts on the “walls” (ends) of such “1D potential well” in thermal equilibrium, and analyze its temperature dependence, focusing on the low-temperature and high-temperature limits.

Hint: You may consider the series $\Theta(\xi) \equiv \sum_{n=1}^{\infty} \exp\{-\xi n^2\}$ a known function of ξ .⁷⁴

2.12.* Rotational properties of diatomic molecules (such as N_2 , CO , etc.) may be reasonably well described by the so-called *dumbbell model*: two point particles, of masses m_1 and m_2 , with a fixed distance d between them. Ignoring the translational motion of the molecule as the whole, use this model to calculate its heat capacity, and spell out the result in the limits of low and high temperatures. Discuss whether your solution is valid for the so-called *homonuclear* molecules, consisting of two similar atoms, such as H_2 , O_2 , N_2 , etc.

2.13. Calculate the heat capacity of a heteronuclear diatomic molecule, using the simple model described in the previous problem, but now assuming that the rotation is confined to one plane.⁷⁵

⁷³ For its definition and main properties, see, e.g., MA Eqs. (6.6)-(6.9).

⁷⁴ It may be reduced to the so-called elliptic theta-function $\theta_3(z, \tau)$ for a particular case $z = 0$ – see, e.g., Sec. 16.27 in the Abramowitz-Stegun handbook cited in MA Sec. 16(ii). However, you do not need that (or any other) handbook to solve this problem.

⁷⁵ This is a reasonable model of the constraints imposed on small atomic groups (e.g., ligands) by their atomic environment inside some large molecules.

2.14. A classical, rigid, strongly elongated body (such as a thin needle), is free to rotate about its center of mass, and is in thermal equilibrium with its environment. Are the angular velocity vector ω and the angular momentum vector \mathbf{L} , on average, directed along the elongation axis of the body, or normal to it?

2.15. Two similar classical electric dipoles, of a fixed magnitude d , are separated by a fixed distance r . Assuming that each dipole moment \mathbf{d} may take any spatial direction and that the system is in thermal equilibrium, write the general expressions for its statistical sum Z , average interaction energy E , heat capacity C , and entropy S , and calculate them explicitly in the high-temperature limit.

2.16. A classical 1D particle of mass m , residing in the potential well

$$U(x) = \alpha|x|^\gamma, \quad \text{with } \gamma > 0,$$

is in thermal equilibrium with its environment, at temperature T . Calculate the average values of its potential energy U and the full energy E , using two approaches:

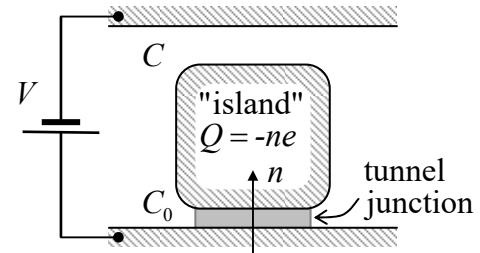

- (i) directly from the Gibbs distribution, and
- (ii) using the virial theorem of classical mechanics.⁷⁶

2.17. For a thermally-equilibrium ensemble of slightly anharmonic classical 1D oscillators, with mass m and potential energy

$$U(q) = \frac{\kappa}{2}x^2 + \alpha x^3,$$

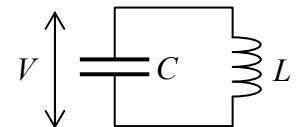

with a small coefficient α , calculate $\langle x \rangle$ in the first approximation in low temperature T .

2.18.^{*} A small conductor (in this context, usually called the *single-electron island*) is placed between two conducting electrodes, with voltage V applied between them. The gap between one of the electrodes and the island is so narrow that electrons may tunnel quantum-mechanically through this gap (the “weak tunnel junction”) – see the figure on the right. Calculate the average charge of the island as a function of V at temperature T .

Hint: The quantum-mechanical tunneling of an electron through a weak junction⁷⁷ between two macroscopic conductors and their subsequent energy relaxation, may be considered as a single inelastic (energy-dissipating) event, so that the only energy relevant for the thermal equilibrium of the system is its electrostatic potential energy.

2.19. An LC circuit (see the figure on the right) is in thermodynamic equilibrium with its environment. Calculate the r.m.s. fluctuation $\delta V \equiv \langle V^2 \rangle^{1/2}$

⁷⁶ See, e.g., CM Problem 1.12.

⁷⁷ In this particular context, the adjective “weak” denotes a junction with the tunneling transparency so low that the tunneling electron’s wavefunction loses its quantum-mechanical coherence before the electron has a chance to tunnel back. In a typical junction of a macroscopic area this condition is fulfilled if its effective resistance is much higher than the quantum unit of resistance (see, e.g., QM Sec. 3.2), $R_Q \equiv \pi\hbar/2e^2 \approx 6.5 \text{ k}\Omega$.

of the voltage across it, for an arbitrary ratio $T/\hbar\omega$, where $\omega = (LC)^{-1/2}$ is the resonance frequency of this “tank circuit”.

2.20. Derive Eq. (92) from simplistic arguments, representing the blackbody radiation as an ideal gas of photons treated as classical ultra-relativistic particles. What do similar arguments give for an ideal gas of classical but non-relativistic particles?

2.21. Calculate the enthalpy, the entropy, and the Gibbs energy of blackbody electromagnetic radiation with temperature T inside volume V , and then use these results to find the law of temperature and pressure drop at an adiabatic expansion.

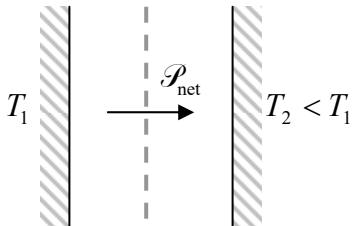

2.22. As was mentioned in Sec. 6(i), the relation between the temperatures T_{\oplus} of the visible Sun’s surface and that (T_0) of the Earth’s surface follows from the balance of the thermal radiation they emit. Prove that the experimentally observed relation indeed follows, with good precision, from a simple model in which the surfaces radiate as perfect black bodies with constant temperatures.

Hint: You may pick up the experimental values you need from any (reliable :-) source.

2.23. If a surface is not perfectly radiation-absorbing (“black”), the electromagnetic power of its thermal radiation differs from the Planck radiation law by a frequency-dependent factor $\varepsilon < 1$, called the *emissivity*. Prove that such surface reflects the $(1 - \varepsilon)$ fraction of the incident radiation.

2.24. If two black surfaces, facing each other, have different temperatures (see the figure on the right), then according to the Stefan radiation law (89), there is a net flow of thermal radiation, from a warmer surface to the colder one:

$$\frac{\mathcal{P}_{\text{net}}}{A} = \sigma(T_1^4 - T_2^4).$$

For many applications, notably including most low-temperature experiments, this flow is detrimental. One way to suppress it is to reduce the emissivity ε (for its definition, see the previous problem) of both surfaces – say by covering them with shiny metallic films. An alternative way toward the same goal is to place, between the surfaces, a thin layer (usually called the *thermal shield*), with a low emissivity of both surfaces – see the dashed line in Fig. above. Assuming that the emissivity is the same in both cases, find out which way is more efficient.

2.25. Two parallel, well-conducting plates of area A are separated by a free-space gap of a constant thickness $t \ll A^{1/2}$. Calculate the energy of the thermally-induced electromagnetic field inside the gap at thermal equilibrium with temperature T in the range

$$\frac{\hbar c}{A^{1/2}} \ll T \ll \frac{\hbar c}{t}.$$

Does the field push the plates apart?

2.26. Use the Debye theory to estimate the specific heat of aluminum at room temperature (say, 300 K), and express the result in the following popular units:

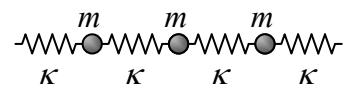

- (i) eV/K per atom,
- (ii) J/K per mole, and
- (iii) J/K per gram.

Compare the last number with the experimental value (from a reliable book or online source).

2.27. Low-temperature specific heat of some solids has a considerable contribution from thermal excitation of spin waves, whose dispersion law scales as $\omega \propto k^2$ at $\omega \rightarrow 0$.⁷⁸ Neglecting anisotropy, calculate the temperature dependence of this contribution to C_V at low temperatures, and discuss conditions of its experimental observation.

Hint: Just as the photons and phonons discussed in section 2.6, the quantum excitations of spin waves (called *magnons*) may be considered as non-interacting bosonic quasiparticles with zero chemical potential, whose statistics obeys Eq. (2.72).

2.28. Derive a general expression for the specific heat of a very long, straight chain of similar particles of mass m , confined to move only in the direction of the chain, and elastically interacting with effective spring constants κ – see the figure on the right. Spell out the result in the limits of very low and very high temperatures.

Hint: You may like to use the following integral:⁷⁹

$$\int_0^{+\infty} \frac{\xi^2 d\xi}{\sinh^2 \xi} = \frac{\pi^2}{6}.$$

2.29. Calculate the r.m.s. thermal fluctuation of the middle point of a uniform guitar string of length l , stretched by force \mathcal{T} , at temperature T . Evaluate your result for $l = 0.7$ m, $\mathcal{T} = 10^3$ N, and room temperature.

Hint: You may like to use the following series:

$$1 + \frac{1}{3^2} + \frac{1}{5^2} + \dots \equiv \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} = \frac{\pi^2}{8}.$$

2.30. Use the general Eq. (123) to re-derive the Fermi-Dirac distribution (115) for a system in equilibrium.

2.31. Each of two identical particles, not interacting directly, may be in any of two quantum states, with single-particle energies ε equal to 0 and Δ . Write down the statistical sum Z of the system, and use it to calculate its average total energy E at temperature T , for the cases when the particles are:

- (i) distinguishable (say, by their positions);
- (ii) indistinguishable fermions;
- (iii) indistinguishable bosons.

Analyze and interpret the temperature dependence of E for each case, assuming that $\Delta > 0$.

2.32. Calculate the chemical potential of a system of $N \gg 1$ independent fermions, kept at a fixed temperature T , if each particle has two non-degenerate energy levels separated by gap Δ .

⁷⁸ Note that the same dispersion law is typical for bending waves in thin elastic rods – see, e.g., CM Sec. 7.8.

⁷⁹ It may be reduced, via integration by parts, to the table integral MA Eq. (6.8d) with $n = 1$.

Chapter 3. Ideal and Not-So-Ideal Gases

In this chapter, the general principles of thermodynamics and statistics, discussed in the previous two chapters, are applied to examine the basic physical properties of gases, i.e. collections of identical particles (for example, atoms or molecules) that are free to move inside a certain volume, either not interacting or weakly interacting with each other. We will see that due to the quantum statistics, properties of even the simplest, so-called ideal gases, with negligible direct interactions between particles, may be highly nontrivial.

3.1. Ideal classical gas

Direct interactions of typical atoms and molecules are well localized, i.e. rapidly decreasing with distance r between them and becoming negligible at a certain distance r_0 . In a gas of N particles inside volume V , the average distance r_{ave} between the particles is $(V/N)^{1/3}$. As a result, if the gas density $n \equiv N/V = (r_{\text{ave}})^{-3}$ is much lower than r_0^{-3} , i.e. if $nr_0^{-3} \ll 1$, the chance for its particles to approach each other and interact is rather small. The model in which such direct interactions are completely ignored is called the *ideal gas*.

Let us start with a *classical* ideal gas, which may be defined as the ideal gas in whose behavior the quantum effects are also negligible. As was discussed in Sec. 2.8, the condition of that is to have the average occupancy of each quantum state low:

$$\langle N_k \rangle \ll 1. \quad (3.1)$$

It may seem that we have already found all properties of such a system, in particular the equilibrium occupancy of its states – see Eq. (2.111):

$$\langle N_k \rangle = \text{const} \times \exp\left\{-\frac{\varepsilon_k}{T}\right\}. \quad (3.2)$$

In some sense this is true, but we still need, first, to see what exactly Eq. (2) means for the gas, a system with an essentially continuous energy spectrum, and, second, to show that, rather surprisingly, the particles' indistinguishability affects some properties of even classical gases.

The first of these tasks is evidently easiest for gas out of any external fields, and with no internal degrees of freedom.¹ In this case, ε_k is just the kinetic energy of the particle, which is an isotropic and parabolic function of p :

$$\varepsilon_k = \frac{p^2}{2m} = \frac{p_x^2 + p_y^2 + p_z^2}{2m}. \quad (3.3)$$

Now we have to use two facts from other fields of physics, hopefully well known to the reader. First, in quantum mechanics, the linear momentum \mathbf{p} is associated with the wavevector \mathbf{k} of the de Broglie wave,

¹ In more realistic cases when particles do have internal degrees of freedom, but they are all in a certain (say, ground) quantum state, Eq. (3) is valid as well, with ε_k referred to the internal ground-state energy. The effect of thermal excitation of the internal degrees of freedom will be briefly discussed at the end of this section.

$\mathbf{p} = \hbar\mathbf{k}$. Second, the eigenvalues of \mathbf{k} for *any* waves (including the de Broglie waves) in free space are uniformly distributed in the momentum space, with a constant density of states, given by Eq. (2.82):

$$\frac{dN_{\text{states}}}{d^3 k} = \frac{gV}{(2\pi)^3}, \quad \text{i.e. } \frac{dN_{\text{states}}}{d^3 p} = \frac{gV}{(2\pi\hbar)^3}, \quad (3.4)$$

where g is the degeneracy of particle's internal states (for example, for all spin- $\frac{1}{2}$ particles, the spin degeneracy $g = 2s + 1 = 2$). Even regardless of the exact proportionality coefficient between dN_{states} and $d^3 p$, the very fact that this coefficient does not depend on \mathbf{p} means that the probability dW to find the particle in a small region $d^3 p = dp_1 dp_2 dp_3$ of the momentum space is proportional to the right-hand side of Eq. (2), with ε_k given by Eq. (3):

$$dW = C \exp\left\{-\frac{p^2}{2mT}\right\} d^3 p = C \exp\left\{-\frac{p_1^2 + p_2^2 + p_3^2}{2mT}\right\} dp_1 dp_2 dp_3. \quad (3.5)$$

Maxwell distribution

This is the famous *Maxwell distribution*.² The normalization constant C may be readily found from the last form of Eq. (5), by requiring the integral of dW over all the momentum space to equal 1. Indeed, the integral is evidently a product of three similar 1D integrals over each Cartesian component p_j of the momentum ($j = 1, 2, 3$), which may be readily reduced to the well-known dimensionless Gaussian integral,³ so that we get

$$C = \left[\int_{-\infty}^{+\infty} \exp\left\{-\frac{p_j^2}{2mT}\right\} dp_j \right]^{-3} \equiv \left[(2mT)^{1/2} \int_{-\infty}^{+\infty} e^{-\xi^2} d\xi \right]^{-3} = (2\pi mT)^{-3/2}. \quad (3.6)$$

As a sanity check, let us use the Maxwell distribution to calculate the average energy corresponding to each half-degree of freedom:

$$\begin{aligned} \left\langle \frac{p_j^2}{2m} \right\rangle &= \int \frac{p_j^2}{2m} dW = \left[C^{1/3} \int_{-\infty}^{+\infty} \frac{p_j^2}{2m} \exp\left\{-\frac{p_j^2}{2mT}\right\} dp_j \right] \times \left[C^{1/3} \int_{-\infty}^{+\infty} \exp\left\{-\frac{p_{j'}^2}{2mT}\right\} dp_{j'} \right]^2 \\ &= \frac{T}{\pi^{1/2}} \int_{-\infty}^{+\infty} \xi^2 e^{-\xi^2} d\xi. \end{aligned} \quad (3.7)$$

The last, dimensionless integral equals $\sqrt{\pi}/2$,⁴ so that, finally,

$$\left\langle \frac{p_j^2}{2m} \right\rangle \equiv \left\langle \frac{mv_j^2}{2} \right\rangle = \frac{T}{2}. \quad (3.8)$$

² This formula had been suggested by J. C. Maxwell as early as 1860, i.e. well before the Boltzmann and Gibbs distributions were developed. Note also that the term “Maxwell distribution” is often associated with the distribution of the particle momentum (or velocity) *magnitude*,

$$dW = 4\pi C p^2 \exp\left\{-\frac{p^2}{2mT}\right\} dp = 4\pi C m^3 v^2 \exp\left\{-\frac{mv^2}{2T}\right\} dv, \quad \text{with } 0 \leq p, v < \infty,$$

which immediately follows from the first form of Eq. (5), combined with the expression $d^3 p = 4\pi p^2 dp$ due to the spherical symmetry of the distribution in the momentum/velocity space.

³ See, e.g., MA Eq. (6.9b).

⁴ See, e.g., MA Eq. (6.9c).

This result is (fortunately :-) in agreement with the equipartition theorem (2.48). It also means that the r.m.s. velocity of each particle is

$$\delta v \equiv \langle v^2 \rangle^{1/2} = \left\langle \sum_{j=1}^3 v_j^2 \right\rangle^{1/2} = \langle 3v_j^2 \rangle^{1/2} = \left(3 \frac{T}{m} \right)^{1/2}. \quad (3.9)$$

For a typical gas (say, for N₂, the air's main component), with $m \approx 28m_p \approx 4.7 \times 10^{-26}$ kg, this velocity, at room temperature ($T = k_B T_K \approx k_B \times 300$ K $\approx 4.1 \times 10^{-21}$ J) is about 500 m/s, comparable with the sound velocity in the same gas – and with the muzzle velocity of a typical handgun bullet. Still, it is measurable using even the simple table-top equipment (say, a set of two concentric, rapidly rotating cylinders with a thin slit collimating an atomic beam emitted at the axis) that was available in the end of the 19th century. Experiments using such equipment gave convincing early confirmations of the Maxwell distribution.

This is all very simple (isn't it?), but actually the thermodynamic properties of a classical gas, especially its entropy, are more intricate. To show that, let us apply the Gibbs distribution to a gas portion consisting of N particles, rather than just one of them. If the particles are exactly similar, the eigenenergy spectrum $\{\varepsilon_k\}$ of each of them is also exactly the same, and each value E_m of the total energy is just the sum of particular energies $\varepsilon_{k(l)}$ of the particles, where $k(l)$, with $l = 1, 2, \dots, N$, is the number of the energy level on which the l^{th} particle resides. Moreover, since the gas is classical, $\langle N_k \rangle \ll 1$, the probability of having two or more particles in any state may be ignored. As a result, we can use Eq. (2.59) to write

$$Z \equiv \sum_m \exp \left\{ -\frac{E_m}{T} \right\} = \sum_{k(1)} \exp \left\{ -\frac{1}{T} \sum_l \varepsilon_{k(l)} \right\} = \sum_{k(1)} \sum_{k(2)} \dots \sum_{k(N)} \prod_l \exp \left\{ -\frac{\varepsilon_{k(l)}}{T} \right\}, \quad (3.10)$$

where the summation has to be carried over all possible states of each particle. Since the summation over each set $\{k(l)\}$ concerns only one of the operands of the product of exponents under the sum, it is tempting to complete the calculation as follows:

$$Z \rightarrow Z_{\text{dist}} = \sum_{k(1)} \exp \left\{ -\frac{\varepsilon_{k(1)}}{T} \right\} \cdot \sum_{k(2)} \exp \left\{ -\frac{\varepsilon_{k(2)}}{T} \right\} \dots \sum_{k(N)} \exp \left\{ -\frac{\varepsilon_{k(N)}}{T} \right\} = \left(\sum_k \exp \left\{ -\frac{\varepsilon_k}{T} \right\} \right)^N, \quad (3.11)$$

where the final summation is over all states of one particle. This formula is indeed valid for distinguishable particles.⁵ However, if the particles are indistinguishable (again, meaning that they are internally identical *and* free to move within the same spatial region), Eq. (11) has to be modified by what is called the *correct Boltzmann counting*:

$$Z = \frac{1}{N!} \left(\sum_k \exp \left\{ -\frac{\varepsilon_k}{T} \right\} \right)^N, \quad (3.12)$$

Correct
Boltzmann
counting

that considers all quantum states different only by particle permutations, as the same state.

⁵ Since, by our initial assumption, each particle belongs to the same portion of gas, i.e. cannot be distinguished from others by its spatial position, this requires some internal “pencil mark” for each particle – for example, a specific structure or a specific quantum state of its internal degrees of freedom.

This expression is valid for any set $\{\varepsilon_k\}$ of eigenenergies. Now let us use it for the translational 3D motion of free particles, taking into account that the fundamental relation (4) implies the following rule for the replacement of a sum over quantum states of such motion with an integral:⁶

$$\sum_k (\dots) \rightarrow \int (\dots) dN_{\text{states}} = \frac{gV}{(2\pi)^3} \int (\dots) d^3k = \frac{gV}{(2\pi\hbar)^3} \int (\dots) d^3p. \quad (3.13)$$

In application to Eq. (12), this rule yields

$$Z = \frac{1}{N!} \left(\frac{gV}{(2\pi\hbar)^3} \left[\int_{-\infty}^{+\infty} \exp \left\{ -\frac{p_j^2}{2mT} \right\} dp_j \right]^3 \right)^N. \quad (3.14)$$

The integral in the square brackets is the same one as in Eq. (6), i.e. is equal to $(2\pi mT)^{1/2}$, so that finally

$$Z = \frac{1}{N!} \left(\frac{gV}{(2\pi\hbar)^3} (2\pi mT)^{3/2} \right)^N \equiv \frac{1}{N!} \left[gV \left(\frac{mT}{2\pi\hbar^2} \right)^{3/2} \right]^N. \quad (3.15)$$

Now, assuming that $N \gg 1$,⁷ and applying the Stirling formula, we can calculate the gas' free energy:

$$F = T \ln \frac{1}{Z} = -NT \ln \frac{V}{N} + Nf(T), \quad (3.16a)$$

with

$$f(T) \equiv -T \left\{ \ln \left[g \left(\frac{mT}{2\pi\hbar^2} \right)^{3/2} \right] + 1 \right\}. \quad (3.16b)$$

The first of these relations exactly coincides with Eq. (1.45), which was derived in Sec. 1.4 from the equation of state $PV = NT$, using thermodynamic identities. At that stage, this equation of state was just postulated, but now we can *derive* it by calculating the pressure from the second of Eqs. (1.35), and Eq. (16a):

$$P = - \left(\frac{\partial F}{\partial V} \right)_T = \frac{NT}{V}. \quad (3.17)$$

So, the equation of state of the ideal classical gas, with density $n \equiv N/V$, is indeed given by Eq. (1.44):

$$P = \frac{NT}{V} \equiv nT. \quad (3.18)$$

Hence we may use Eqs. (1.46)-(1.51), derived from this equation of state, to calculate all other thermodynamic variables of the gas. For example, using Eq. (1.47) with $f(T)$ given by Eq. (16b), for the internal energy and the specific heat of the gas we immediately get

⁶ As a reminder, we have already used this rule (twice) in Sec. 2.6, with particular values of g .

⁷ For the opposite limit when $N = g = 1$, Eq. (15) yields the results obtained, by two alternative methods, in the solutions of Problems 2.8 and 2.9. Indeed, for $N = 1$, the “correct Boltzmann counting” factor $N!$ equals 1, so that the particle distinguishability effects vanish – naturally.

$$E = N \left[f(T) - T \frac{df(T)}{dT} \right] = \frac{3}{2} NT, \quad c_v \equiv \frac{C_v}{N} = \frac{1}{N} \left(\frac{\partial E}{\partial T} \right)_v = \frac{3}{2}, \quad (3.19)$$

in full agreement with Eq. (8) and hence with the equipartition theorem.

Much less trivial is the result for entropy, which may be obtained by combining Eqs. (1.46) and (16a):

$$S = - \left(\frac{\partial F}{\partial T} \right)_V = N \left[\ln \frac{V}{N} - \frac{df(T)}{dT} \right]. \quad (3.20)$$

This formula,⁸ in particular, provides the means to resolve the following *gas mixing paradox* (sometimes called the “Gibbs paradox”). Consider two volumes, V_1 and V_2 , separated by a partition, each filled with the same gas, with the same density n , at the same temperature T , and hence with the same pressure P . Now let us remove the partition and let the gas portions mix; would the total entropy change? According to Eq. (20), it would not, because the ratio $V/N = n$, and hence the expression in the square brackets is the same in the initial and the final state, so that the entropy is additive, as any extensive variable should be. This makes full sense if the gas particles in both parts of the volume are truly identical, i.e. the partition’s removal does not change our information about the system. However, let us assume that all particles are distinguishable; then the entropy should clearly increase because the mixing would decrease our information about the system, i.e. increase its disorder. A quantitative description of this effect may be obtained using Eq. (11). Repeating for Z_{dist} the calculations made above for Z , we readily get a different formula for entropy:

$$S_{\text{dist}} = N \left[\ln V - \frac{df_{\text{dist}}(T)}{dT} \right], \quad f_{\text{dist}}(T) \equiv -T \ln \left[g \left(\frac{mT}{2\pi\hbar^2} \right)^{3/2} \right]. \quad (3.21)$$

Please notice that in contrast to the S given by Eq. (20), this entropy includes the term $\ln V$ instead of $\ln(V/N)$, so that S_{dist} is *not* proportional to N (at fixed temperature T and density N/V). While for distinguishable particles this fact does not present any conceptual problem, for indistinguishable particles it would mean that entropy was not an extensive variable, i.e. would contradict the basic assumptions of thermodynamics. This fact emphasizes again the necessity of the correct Boltzmann counting in the latter case.

Using Eq. (21), we can calculate the change of entropy due to mixing two gas portions, with N_1 and N_2 distinguishable particles, at a fixed temperature T (and hence at unchanged function f_{dist}):

$$\Delta S_{\text{dist}} = (N_1 + N_2) \ln(V_1 + V_2) - (N_1 \ln V_1 + N_2 \ln V_2) = N_1 \ln \frac{V_1 + V_2}{V_1} + N_2 \ln \frac{V_1 + V_2}{V_2} > 0. \quad (3.22)$$

Note that for a particular case, $V_1 = V_2 = V/2$, Eq. (22) reduces to the simple result, $\Delta S_{\text{dist}} = (N_1 + N_2) \ln 2$, which may be readily understood in terms of the information theory. Indeed, allowing each particle of the total number $N = N_1 + N_2$ to spread to a twice larger volume, we lose one bit of information per particle, i.e. $\Delta I = (N_1 + N_2)$ bits for the whole system. Let me leave it for the reader to show that Eq. (22) is also valid if particles in each sub-volume are indistinguishable from each other, but different from

⁸ The result represented by Eq. (20), with the function f given by Eq. (16b), was obtained independently by O. Sackur and H. Tetrode as early as in 1911, i.e. well before the final formulation of quantum mechanics in the late 1920s.

those in another sub-volume, i.e. for mixing of two different gases.⁹ However, it is certainly *not* applicable to the system where *all* particles are identical, stressing again that the correct Boltzmann counting (12) does indeed affect the gas entropy, even though it may be not as consequential as the Maxwell distribution (5), the equation of state (18), and the average energy (19).

In this context, one may wonder whether the change (22) (called the *mixing entropy*) is experimentally observable. The answer is yes. For example, after free mixing of two different gases, and hence boosting their total entropy by ΔS_{dist} , one can use a thin movable membrane that is *semipermeable*, i.e. whose pores are penetrable for particles of one type only, to separate them again, thus reducing the entropy back to the initial value, and measure either the necessary mechanical work $\Delta \mathcal{W} = T\Delta S_{\text{dist}}$ or the corresponding heat discharge into the heat bath. Practically, measurements of this type are easier in *weak solutions*¹⁰ – systems with a small concentration $c \ll 1$ of particles of one sort (*solute*) within much more abundant particles of another sort (*solvent*). The mixing entropy also affects the thermodynamics of chemical reactions in gases and liquids.¹¹ Note that besides purely thermal-mechanical measurements, the mixing entropy in some conducting solutions (*electrolytes*) is also measurable by a purely electrical method, called *cyclic voltammetry*, in which a low-frequency ac voltage, applied between two solid-state electrodes embedded in the solution, is used to periodically separate different ions, and then mix them again.¹²

Now let us briefly discuss two generalizations of our results for ideal classical gases. First, let us consider such gas in an external field of potential forces. It may be described by replacing Eq. (3) with

$$\varepsilon_k = \frac{p_k^2}{2m} + U(\mathbf{r}_k), \quad (3.23)$$

where \mathbf{r}_k is the position of the k^{th} particular particle, and $U(\mathbf{r})$ is the potential energy of the particle. If the potential $U(\mathbf{r})$ is changing in space sufficiently slowly,¹³ Eq. (4) is still applicable, but only to small volumes, $V \rightarrow dV = d^3r$ whose linear size is much smaller than the spatial scale of substantial variations of the function $U(\mathbf{r})$. Hence, instead of Eq. (5), we may only write the probability dW of finding the particle in a small volume d^3rd^3p of the 6-dimensional phase space:

⁹ By the way, if an ideal classical gas consists of particles of several different sorts, its full pressure is a sum of independent *partial pressures* exerted by each component – the so-called *Dalton law*. While this fact was an important experimental discovery in the early 1800s, for statistical physics this is just a straightforward corollary of Eq. (18), because in an ideal gas, the component particles do not interact.

¹⁰ Interestingly, the statistical mechanics of weak solutions is very similar to that of ideal gases, with Eq. (18) recast into the following formula (derived in 1885 by J. van 't Hoff), $PV = cNT$, for the partial pressure of the solute. One of its corollaries is that the net force (called the *osmotic pressure*) exerted on a semipermeable membrane is proportional to the difference of the solute concentrations it is supporting.

¹¹ Unfortunately, I do not have time for even a brief introduction into this important field, and have to refer the interested reader to specialized textbooks – for example, P. A. Rock, *Chemical Thermodynamics*, University Science Books, 1983; or P. Atkins, *Physical Chemistry*, 5th ed., Freeman, 1994; or G. M. Barrow, *Physical Chemistry*, 6th ed., McGraw-Hill, 1996.

¹² See, e.g., either Chapter 6 in A. Bard and L. Falkner, *Electrochemical Methods*, 2nd ed., Wiley, 2000 (which is a good introduction to electrochemistry as the whole); or Sec. II.8.3.1 in F. Scholz (ed.), *Electroanalytical Methods*, 2nd ed., Springer, 2010.

¹³ Quantitatively, the effective distance of substantial variations of the potential, $T/|\nabla U(\mathbf{r})|$, has to be much larger than the *mean free path* l of the gas particles, i.e. the average distance a particle passes its successive collisions with its counterparts. (For more on this notion, see Chapter 6 below.)

$$dW = w(\mathbf{r}, \mathbf{p}) d^3 r d^3 p, \quad w(\mathbf{r}, \mathbf{p}) = \text{const} \times \exp \left\{ -\frac{p^2}{2mT} - \frac{U(\mathbf{r})}{T} \right\}. \quad (3.24)$$

Hence, the Maxwell distribution of particle velocities is still valid at each point \mathbf{r} , so that the equation of state (18) is also valid locally. A new issue here is the spatial distribution of the total density,

$$n(\mathbf{r}) \equiv N \int w(\mathbf{r}, \mathbf{p}) d^3 p, \quad (3.25)$$

of all gas particles, regardless of their momentum/velocity. For this variable, Eq. (24) yields¹⁴

$$n(\mathbf{r}) = n(0) \exp \left\{ -\frac{U(\mathbf{r})}{T} \right\}, \quad (3.26)$$

where the potential energy at the origin ($\mathbf{r} = 0$) is used as the reference of U , and the local gas pressure may be still calculated from the local form of Eq. (18):

$$P(\mathbf{r}) = n(\mathbf{r})T = P(0) \exp \left\{ -\frac{U(\mathbf{r})}{T} \right\}. \quad (3.27)$$

A simple example of numerous applications of Eq. (27) is an approximate description of the Earth's atmosphere. At all heights $h \ll R_E \sim 6 \times 10^6$ m above the Earth's surface (say, above the sea level), we may describe the Earth gravity effect by the potential $U = mgh$, and Eq. (27) yields the so-called *barometric formula*

$$P(h) = P(0) \exp \left\{ -\frac{h}{h_0} \right\}, \quad \text{with } h_0 \equiv \frac{T}{mg} = \frac{k_B T_K}{mg}. \quad (3.28)$$

For the same N_2 , the main component of the atmosphere, at $T_K = 300$ K, $h_0 \approx 7$ km. This gives the correct order of magnitude of the atmosphere's thickness, though the exact law of the pressure change differs somewhat from Eq. (28), because the flow of radiation from Sun and Earth cause a relatively small deviation of the atmospheric air from the thermal equilibrium: a drop of its temperature T with height, with the so-called *lapse rate* of about 2% (~ 6.5 K) per km.

The second generalization I need to discuss is to particles with internal degrees of freedom. Now ignoring the potential energy $U(\mathbf{r})$, we may describe them by replacing Eq. (3) with

$$\varepsilon_k = \frac{p^2}{2m} + \varepsilon'_k, \quad (3.29)$$

where ε'_k describes the internal energy spectrum of the k^{th} particle. If the particles are similar, we may repeat all the above calculations, and see that all their results (including the Maxwell distribution, and the equation of state) are still valid, with the only exception of Eq. (16), which now becomes

$$f(T) = -T \left\{ \ln \left[g \left(\frac{mT}{2\pi\hbar^2} \right)^{3/2} \right] + 1 + \ln \left[\sum_{\varepsilon'_k} \exp \left\{ -\frac{\varepsilon'_k}{T} \right\} \right] \right\}. \quad (3.30)$$

¹⁴ In some textbooks, Eq. (26) is also called the *Boltzmann distribution*, though it certainly should be distinguished from Eq. (2.111).

As we already know from Eqs. (1.50)-(1.51), this change may affect both specific heats of the ideal gas – though not their difference, $c_V - c_P = 1$. They may be readily calculated for usual atoms and molecules, at not very high temperatures (say the room temperature of ~ 25 meV), because in these conditions, $\varepsilon_k' \gg T$ for most their internal degrees of freedom, including the electronic and vibrational ones. (The typical energy of the lowest electronic excitations is of the order of a few eV, and that of the lowest vibrational excitations is only an order of magnitude lower.) As a result, these degrees of freedom are “frozen out”: they are in their ground states, so that their contributions $\exp\{-\varepsilon_k'/T\}$ to the sum in Eq. (30), and hence to the heat capacity, are negligible. In monoatomic gases, this is true for all degrees of freedom besides those of the translational motion, already taken into account by the first term in Eq. (30), i.e. by Eq. (16b), so that their specific heat is typically well described by Eq. (19).

The most important exception is the rotational degrees of freedom of diatomic and polyatomic molecules. As quantum mechanics shows,¹⁵ the excitation energy of these degrees of freedom scales as $\hbar^2/2I$, where I is the molecule’s relevant moment of inertia. In the most important molecules, this energy is rather low (e.g. for N₂, it is close to 0.25 meV, i.e. $\sim 1\%$ of the room temperature), so that at usual conditions they are well excited and, moreover, behave virtually as classical degrees of freedom, each giving a quadratic contribution to the molecule’s energy, and hence obeying the equipartition theorem, i.e. giving an extra contribution of $T/2$ to the energy, i.e. $1/2$ to the specific heat.¹⁶ In polyatomic molecules, there are three such classical degrees of freedom (corresponding to their rotations about three principal axes¹⁷), but in diatomic molecules, only two.¹⁸ Hence, these contributions may be described by the following generalization of Eq. (19):

$$c_V = \begin{cases} 3/2, & \text{for monoatomic gases,} \\ 5/2, & \text{for gases of diatomic molecules,} \\ 3, & \text{for gases of polyatomic molecules.} \end{cases} \quad (3.31)$$

Please keep in mind, however, that as the above discussion shows, this simple result is invalid at very low and very high temperatures; its most notable violation is that the thermal activation of vibrational degrees of freedom for many important molecules at temperatures of a few thousand K.

3.2. Calculating μ

Now let us discuss properties of ideal gases of free, indistinguishable particles in more detail, paying special attention to the chemical potential μ – which, for some readers, may still be a somewhat mysterious aspect of the Fermi and Bose distributions. Note again that particle indistinguishability *requires* the absence of thermal excitations of their internal degrees of freedom, so that in the balance of this chapter such excitations will be ignored, and the particle’s energy ε_k will be associated with its “external” energy alone: for a free particle in an ideal gas, with its kinetic energy (3).

¹⁵ See, e.g., either the model solution of Problem 2.12 (and references therein), or QM Secs. 3.6 and 5.6.

¹⁶ This result may be readily obtained again from the last term of Eq. (30) by treating it exactly like the first one was and then applying the general Eq. (1.50).

¹⁷ See, e.g., CM Sec. 4.1.

¹⁸ This conclusion of the quantum theory may be interpreted as the indistinguishability of the rotations about the molecule’s symmetry axis.

Let us start from the classical gas, and recall the conclusion of thermodynamics that μ is just the Gibbs potential per unit particle – see Eq. (1.56). Hence we can calculate $\mu = G/N$ from Eqs. (1.49) and (16b). The result,

$$\mu = -T \ln \frac{V}{N} + f(T) + T = T \ln \left[\frac{N}{gV} \left(\frac{2\pi\hbar^2}{mT} \right)^{3/2} \right], \quad (3.32a)$$

which may be rewritten as

$$\exp \left\{ \frac{\mu}{T} \right\} = \frac{N}{gV} \left(\frac{2\pi\hbar^2}{mT} \right)^{3/2}, \quad (3.32b)$$

gives us some information about μ not only for a classical gas but for quantum (Fermi and Bose) gases as well. Indeed, we already know that for indistinguishable particles, the Boltzmann distribution (2.111) is valid only if $\langle N_k \rangle \ll 1$. Comparing this condition with the quantum statistics (2.115) and (2.118), we see again that the condition of the gas behaving classically may be expressed as

$$\exp \left\{ \frac{\mu - \varepsilon_k}{T} \right\} \ll 1 \quad (3.33)$$

for all ε_k . Since the lowest value of ε_k given by Eq. (3) is zero, Eq. (33) may be satisfied only if $\exp\{\mu/T\} \ll 1$. This means that the chemical potential of a classical gas has to be not just negative, but also “strongly negative” in the sense

$$-\mu \gg T. \quad (3.34a)$$

According to Eq. (32), this important condition may be represented as

$$T \gg T_0, \quad (3.34b)$$

with T_0 defined as

$$T_0 \equiv \frac{\hbar^2}{m} \left(\frac{N}{gV} \right)^{2/3} \equiv \frac{\hbar^2}{m} \left(\frac{n}{g} \right)^{2/3} \equiv \frac{\hbar^2}{g^{2/3} m r_{\text{ave}}^2}, \quad (3.35)$$

where r_{ave} is the average distance between the gas particles:

$$r_{\text{ave}} \equiv \frac{1}{n^{1/3}} = \left(\frac{V}{N} \right)^{1/3}. \quad (3.36)$$

In this form, the condition (34) is very transparent physically: disregarding the factor $g^{2/3}$ (which is typically of the order of 1), it means that the average thermal energy of a particle, which is always of the order of T , has to be much larger than the energy of quantization of particle's motion at the length r_{ave} . An alternative form of the same condition is¹⁹

$$r_{\text{ave}} \gg g^{-1/3} r_c, \quad \text{where } r_c \equiv \frac{\hbar}{(mT)^{1/2}}. \quad (3.37)$$

For a typical gas (say, N₂, with $m \approx 14m_p \approx 2.3 \times 10^{-26}$ kg) at the standard room temperature ($T = k_B \times 300\text{K} \approx 4.1 \times 10^{-21}$ J), the correlation length r_c is close to 10^{-11} m, i.e. is significantly smaller than the

¹⁹ In quantum mechanics, the parameter r_c so defined is frequently called the *correlation length* – see, e.g., QM Sec. 7.2 and in particular Eq. (7.37).

physical size $a \sim 3 \times 10^{-10}$ m of the molecule. This estimate shows that at room temperature, as soon as any practical gas is rare enough to be ideal ($r_{\text{ave}} \gg a$), it is classical, i.e. the only way to observe quantum effects in the translational motion of molecules is very deep refrigeration. According to Eq. (37), for the same nitrogen molecule, taking $r_{\text{ave}} \sim 10^2 a \sim 10^{-8}$ m (to ensure that direct interaction effects are negligible), the temperature should be well below 1 mK.

In order to analyze quantitatively what happens with gases when T is reduced to such low values, we need to calculate μ for an arbitrary ideal gas of indistinguishable particles. Let us use the lucky fact that the Fermi-Dirac and the Bose-Einstein statistics may be represented with one formula:

$$\langle N(\varepsilon) \rangle = \frac{1}{e^{(\varepsilon-\mu)/T} \pm 1}, \quad (3.38)$$

where (and everywhere in the balance of this section) the top sign stands for fermions and the lower one for bosons, to discuss fermionic and bosonic ideal gases in one shot.

If we deal with a member of the *grand canonical* ensemble (Fig. 2.13), in which not only T but also μ is externally fixed, we may use Eq. (38) to calculate the *average* number N of particles in volume V . If the volume is so large that $N \gg 1$, we may use the general state counting rule (13) to get

$$N = \frac{gV}{(2\pi)^3} \int \langle N(\varepsilon) \rangle d^3k = \frac{gV}{(2\pi\hbar)^3} \int \frac{d^3p}{e^{[\varepsilon(p)-\mu]/T} \pm 1} = \frac{gV}{(2\pi\hbar)^3} \int_0^\infty \frac{4\pi p^2 dp}{e^{[\varepsilon(p)-\mu]/T} \pm 1}. \quad (3.39)$$

In most practical cases, however, the number N of gas particles is fixed by particle confinement (i.e. the gas portion under study is a member of a *canonical* ensemble – see Fig. 2.6), and hence μ rather than N should be calculated. Let us use the trick already mentioned in Sec. 2.8: if N is very large, the relative fluctuation of the particle number, at fixed μ , is negligibly small ($\delta N/N \sim 1/\sqrt{N} \ll 1$), and the relation between the *average* values of N and μ should not depend on which of these variables is exactly fixed. Hence, Eq. (39), with μ having the sense of the *average* chemical potential, should be valid even if N is *exactly* fixed, so that the small fluctuations of N are replaced with (equally small) fluctuations of μ . Physically, in this case the role of the μ -fixing environment for any sub-portion of the gas is played by the rest of it, and Eq. (39) expresses the condition of self-consistency of such chemical equilibrium.

So, at $N \gg 1$, Eq. (39) may be used for calculating the average μ as a function of two independent parameters: N (i.e. the gas density $n = N/V$) and temperature T . For carrying out this calculation, it is convenient to convert the right-hand side of Eq. (39) to an integral over the particle's energy $\varepsilon(p) = p^2/2m$, so that $p = (2m\varepsilon)^{1/2}$, and $dp = (m/2\varepsilon)^{1/2} d\varepsilon$, getting

$$N = \frac{gVm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\varepsilon^{1/2} d\varepsilon}{e^{(\varepsilon-\mu)/T} \pm 1}. \quad (3.40)$$

Basic equation for μ

This key result may be represented in two other, more convenient forms. First, Eq. (40), derived for our current (3D, isotropic and parabolic-dispersion) approximation (3), is just a particular case of the following self-evident state-counting relation

$$N = \int_0^\infty g(\varepsilon) \langle N(\varepsilon) \rangle d\varepsilon, \quad (3.41)$$

where

$$g(\varepsilon) \equiv dN_{\text{states}}/d\varepsilon \quad (3.42)$$

is the temperature-independent density of all quantum states of a particle – regardless of whether they are occupied or not. Indeed, according to the general Eq. (4), for our simple model (3),

$$g(\varepsilon) = g_3(\varepsilon) \equiv \frac{dN_{\text{states}}}{d\varepsilon} = \frac{d}{d\varepsilon} \left(\frac{gV}{(2\pi\hbar)^3} \frac{4\pi}{3} p^3 \right) = \frac{gVm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \varepsilon^{1/2}, \quad (3.43)$$

so that we return to Eq. (39).

On the other hand, for some calculations, it is convenient to introduce the following dimensionless energy variable: $\xi \equiv \varepsilon/T$, to express Eq. (40) via a dimensionless integral:

$$N = \frac{gV(mT)^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^{\xi - \mu/T} \pm 1}. \quad (3.44)$$

As a sanity check, in the classical limit (34), the exponent in the denominator of the fraction under the integral is much larger than 1, and Eq. (44) reduces to

$$N = \frac{gV(mT)^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^{\xi - \mu/T}} \approx \frac{gV(mT)^{3/2}}{\sqrt{2\pi^2\hbar^3}} \exp\left\{\frac{\mu}{T}\right\} \int_0^\infty \xi^{1/2} e^{-\xi} d\xi, \quad \text{at } -\mu \gg T. \quad (3.45)$$

By the definition of the gamma function $\Gamma(\xi)$,²⁰ the last integral is just $\Gamma(3/2) = \pi^{1/2}/2$, and we get

$$\exp\left\{\frac{\mu}{T}\right\} = N \frac{\sqrt{2\pi^2\hbar^3}}{gV(mT)^{3/2}} \frac{2}{\sqrt{\pi}} = \left(2\pi \frac{T_0}{T}\right)^{3/2}, \quad (3.46)$$

which is exactly the same result as given by Eq. (32), obtained earlier in a rather different way – from the Boltzmann distribution and thermodynamic identities.

Unfortunately, in the general case of arbitrary μ , the integral in Eq. (44) cannot be worked out analytically.²¹ The best we can do is to use T_0 , defined by Eq. (35), to rewrite Eq. (44) in the following convenient, fully dimensionless form:

$$\frac{T}{T_0} = \left[\frac{1}{\sqrt{2\pi^2}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^{\xi - \mu/T} \pm 1} \right]^{-2/3}, \quad (3.47)$$

and then use this relation to calculate the ratios T/T_0 and $\mu/T_0 \equiv (\mu/T) \times (T/T_0)$, as functions of μ/T numerically. After that, we may plot the results versus each other, now considering the first ratio as the argument. Figure 1 below shows the resulting plots, for both particle types. They show that at high temperatures, $T \gg T_0$, the chemical potential is negative and approaches the classical behavior given by Eq. (46) for both fermions and bosons – just as we could expect. However, at temperatures $T \sim T_0$ the type of statistics becomes crucial. For fermions, the reduction of temperature leads to μ changing its

²⁰ See, e.g., MA Eq. (6.7a).

²¹ For the reader's reference only: for the upper sign, the integral in Eq. (40) is a particular form (for $s = 1/2$) of a special function called the *complete Fermi-Dirac integral* F_s , while for the lower sign, it is a particular case (for $s = 3/2$) of another special function called the *polylogarithm* Li_s . (In what follows, I will not use these notations.)

sign from negative to positive, and then approaching a constant positive value called the *Fermi energy*, $\varepsilon_F \approx 7.595 T_0$ at $T \rightarrow 0$. On the contrary, the chemical potential of a bosonic gas stays negative, and then turns into zero at a certain *critical temperature* $T_c \approx 3.313 T_0$. Both these limits, which are very important for applications, may (and will be :-) explored analytically, separately for each statistics.

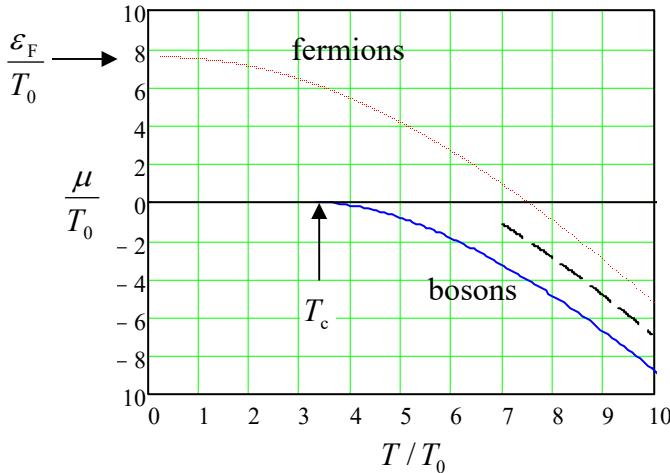

Fig. 3.1. The chemical potential of an ideal gas of $N \gg 1$ indistinguishable quantum particles, as a function of temperature at a fixed gas density $n \equiv N/V$ (i.e. fixed $T_0 \propto n^{2/3}$), for two different particle types. The dashed line shows the classical approximation (46), valid only at $T \gg T_0$.

Before carrying out such studies (in the next two sections), let me show that, rather surprisingly, for any non-relativistic, ideal quantum gas, the relation between the product PV and the energy,

$$PV = \frac{2}{3} E, \quad (3.48)$$
Ideal gas:
 PV vs. E

is exactly the same as follows from Eqs. (18) and (19) for the classical gas, and hence does *not* depend on the particle statistics. To prove this, it is sufficient to use Eqs. (2.114) and (2.117) for the grand thermodynamic potential of each quantum state, which may be conveniently represented by a single formula,

$$\Omega_k = \mp T \ln \left(1 \pm e^{(\mu - \varepsilon_k)/T} \right), \quad (3.49)$$

and sum them over all states k , using the general summation formula (13). The result for the total grand potential of a 3D gas with the dispersion law (3) is

$$\Omega = \mp T \frac{gV}{(2\pi\hbar)^3} \int_0^\infty \ln \left(1 \pm e^{(\mu - p^2/2m)/T} \right) 4\pi p^2 dp = \mp T \frac{gVm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \ln \left(1 \pm e^{(\mu - \varepsilon)/T} \right) \varepsilon^{1/2} d\varepsilon. \quad (3.50)$$

Working out this integral by parts, exactly as we did it with the one in Eq. (2.90), we get

$$\Omega = -\frac{2}{3} \frac{gVm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\varepsilon^{3/2} d\varepsilon}{e^{(\varepsilon - \mu)/T} \pm 1} = -\frac{2}{3} \int_0^\infty \varepsilon g_3(\varepsilon) \langle N(\varepsilon) \rangle d\varepsilon. \quad (3.51)$$

But the last integral is just the total energy E of the gas:

$$E = \frac{gV}{(2\pi\hbar)^3} \int_0^\infty \frac{p^2}{2m} \frac{4\pi p^2 dp}{e^{[\varepsilon(p) - \mu]/T} \pm 1} = \frac{gVm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\varepsilon^{3/2} d\varepsilon}{e^{(\varepsilon - \mu)/T} \pm 1} = \int_0^\infty \varepsilon g_3(\varepsilon) \langle N(\varepsilon) \rangle d\varepsilon, \quad (3.52)$$
Ideal
gas:
energy

so that for any temperature and any particle type, $\Omega = -(2/3)E$. But since, from thermodynamics, $\Omega = -PV$, we have Eq. (48) proved. This universal relation²² will be repeatedly used below.

3.3. Degenerate Fermi gas

Analysis of low-temperature properties of a *Fermi gas* is very simple in the limit $T = 0$. Indeed, in this limit, the Fermi-Dirac distribution (2.115) is just the step function:

$$\langle N(\varepsilon) \rangle = \begin{cases} 1, & \text{for } \varepsilon < \mu, \\ 0, & \text{for } \mu < \varepsilon, \end{cases} \quad (3.53)$$

- see by the bold line in Fig. 2a. Since $\varepsilon = p^2/2m$ is isotropic in the momentum space, in that space the particles, at $T = 0$, fully occupy all possible quantum states inside a sphere (frequently called either the *Fermi sphere* or the *Fermi sea*) with some radius p_F (Fig. 2b), while all states above the sea surface are empty. Such *degenerate Fermi gas* is a striking manifestation of the Pauli principle: though in thermodynamic equilibrium at $T = 0$ all particles try to lower their energies as much as possible, only g of them may occupy each translational (“orbital”) quantum state. As a result, the sphere’s volume is proportional to the particle number N , or rather to their density $n = N/V$.

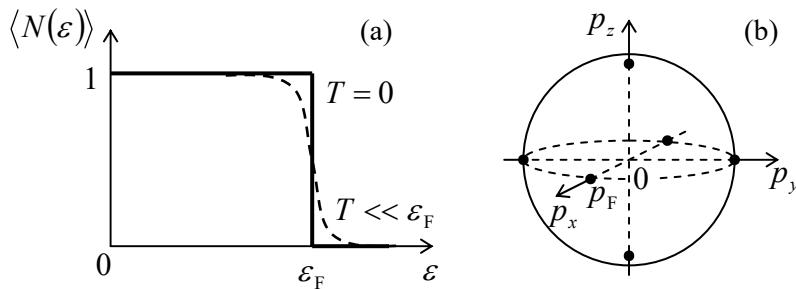

Fig. 3.2. Representations of the Fermi sea: (a) on the Fermi distribution plot, and (b) in the momentum space.

Indeed, the radius p_F may be readily related to the number of particles N using Eq. (39), with the upper sign, whose integral in this limit is just the Fermi sphere’s volume:

$$N = \frac{gV}{(2\pi\hbar)^3} \int_0^{p_F} 4\pi p^2 dp = \frac{gV}{(2\pi\hbar)^3} \frac{4\pi}{3} p_F^3. \quad (3.54)$$

Now we can use Eq. (3) to express via N the chemical potential μ (which, in the limit $T = 0$, it bears the special name of the *Fermi energy* ε_F)²³:

Fermi energy

$$\varepsilon_F \equiv \mu|_{T=0} = \frac{p_F^2}{2m} = \frac{\hbar^2}{2m} \left(6\pi^2 \frac{N}{gV} \right)^{2/3} \equiv \left(\frac{9\pi^4}{2} \right)^{1/3} T_0 \approx 7.595 T_0, \quad (3.55a)$$

where T_0 is the quantum temperature scale defined by Eq. (35). This formula quantifies the low-temperature trend of the function $\mu(T)$, clearly visible in Fig. 1, and in particular, explains the ratio ε_F/T_0 mentioned in Sec. 2. Note also a simple and very useful relation,

²² For gases of diatomic and polyatomic molecules at relatively high temperatures, when some of their internal degrees of freedom are thermally excited, Eq. (48) is valid only for the translational-motion energy.

²³ Note that in the electronic engineering literature, μ is usually called the *Fermi level*, for any temperature.

$$\varepsilon_F = \frac{3}{2} \frac{N}{g_3(\varepsilon_F)}, \quad \text{i.e. } g_3(\varepsilon_F) = \frac{3}{2} \frac{N}{\varepsilon_F}, \quad (3.55b)$$

that may be obtained immediately from the comparison of Eqs. (43) and (54).

The total energy of the degenerate Fermi gas may be (equally easily) calculated from Eq. (52):

$$E = \frac{gV}{(2\pi\hbar)^3} \int_0^{p_F} \frac{p^2}{2m} 4\pi p^2 dp = \frac{gV}{(2\pi\hbar)^3} \frac{4\pi}{2m} \frac{p_F^5}{5} = \frac{3}{5} \varepsilon_F N, \quad (3.56)$$

showing that the average energy, $\langle \varepsilon \rangle \equiv E/N$, of a particle inside the Fermi sea is equal to 3/5 of that (ε_F) of the particles in the most energetic occupied states, on the Fermi surface. Since, according to the formulas of Chapter 1, at zero temperature $H = G = N\mu$, and $F = E$, the only thermodynamic variable still to be calculated is the gas pressure P . For it, we could use any of the thermodynamic relations $P = (H - E)/V$ or $P = -(\partial F/\partial V)_T$, but it is even easier to use our recent result (48). Together with Eq. (56), it yields

$$P = \frac{2}{3} \frac{E}{V} = \frac{2}{5} \varepsilon_F \frac{N}{V} = \left(\frac{36\pi^4}{125} \right)^{1/3} P_0 \approx 3.035 P_0, \quad \text{where } P_0 \equiv nT_0 = \frac{\hbar^2 n^{5/3}}{mg^{2/3}}. \quad (3.57)$$

From here, it is straightforward to calculate the *bulk modulus* (reciprocal compressibility),²⁴

$$K \equiv -V \left(\frac{\partial P}{\partial V} \right)_T = \frac{2}{3} \varepsilon_F \frac{N}{V}, \quad (3.58)$$

which may be simpler to measure experimentally than P .

Perhaps the most important example²⁵ of the degenerate Fermi gas is the *conduction electrons* in metals – the electrons that belong to outer shells of the isolated atoms but become shared in solid metals, and as a result, can move through the crystal lattice almost freely. Though the electrons (which are fermions with spin $s = 1/2$ and hence with the spin degeneracy $g = 2s + 1 = 2$) are negatively charged, the Coulomb interaction of the conduction electrons with each other is substantially compensated by the positively charged ions of the atomic lattice, so that they follow the simple model discussed above, in which the interaction is disregarded, reasonably well. This is especially true for alkali metals (forming Group 1 of the periodic table of elements), whose experimentally measured Fermi surfaces are spherical within 1% – even within 0.1% for Na.

Table 1 lists, in particular, the experimental values of the bulk modulus for such metals, together with the values given by Eq. (58) using the ε_F calculated from Eq. (55) with the experimental density of the conduction electrons. The agreement is pretty impressive, taking into account that the simple theory

²⁴ For a general discussion of this notion, see, e.g., CM Eqs. (7.32) and (7.36).

²⁵ Recently, nearly degenerate gases (with $\varepsilon_F \sim 5T$) have been formed of weakly interacting Fermi atoms as well – see, e.g., K. Aikawa *et al.*, *Phys. Rev. Lett.* **112**, 010404 (2014), and references therein. Another interesting example of the system that may be approximately treated as a degenerate Fermi gas is the set of $Z \gg 1$ electrons in a heavy atom. However, in this system the account of electron interaction via the electrostatic field they create is important. Since for this *Thomas-Fermi model* of atoms, the thermal effects are unimportant, it was discussed already in the quantum-mechanical part of this series (see QM Chapter 8). However, its analysis may be streamlined using the notion of the chemical potential, introduced only in this course – the problem left for the reader's exercise.

described above completely ignores the Coulomb and exchange interactions of the electrons. This agreement implies that, surprisingly, the experimentally observed rigidity of solids (or at least metals) is predominantly due to the kinetic energy (3) of the conduction electrons, rather than any electrostatic interactions – though, to be fair, these interactions are the crucial factor defining the equilibrium value of n . Numerical calculations using more accurate approximations (e.g., the Density Functional Theory²⁶), which agree with experiment with a few-percent accuracy, confirm this conclusion.²⁷

Table 3.1. Experimental and theoretical parameters of electrons' Fermi sea in some alkali metals²⁸

Metal	ε_F (eV) Eq. (55)	K (GPa) Eq. (58)	K (GPa) experiment	γ (mcal/mole-K ²) Eq. (69)	γ (mcal/mole-K ²) experiment
Na	3.24	923	642	0.26	0.35
K	2.12	319	281	0.40	0.47
Rb	1.85	230	192	0.46	0.58
Cs	1.59	154	143	0.53	0.77

Looking at the values of ε_F listed in this table, note that room temperatures ($T_K \sim 300$ K) correspond to $T \sim 25$ meV. As a result, virtually all experiments with metals, at least in their solid or liquid form, are performed in the limit $T \ll \varepsilon_F$. According to Eq. (39), at such temperatures, the occupancy step described by the Fermi-Dirac distribution has a non-zero but relatively small width of the order of T – see the dashed line in Fig. 2a. Calculations for this case are much facilitated by the so-called *Sommerfeld expansion formula*²⁹ for the integrals like those in Eqs. (41) and (52):

$$I(T) \equiv \int_0^\infty \varphi(\varepsilon) \langle N(\varepsilon) \rangle d\varepsilon \approx \int_0^\mu \varphi(\varepsilon) d\varepsilon + \frac{\pi^2}{6} T^2 \frac{d\varphi(\mu)}{d\mu}, \quad \text{for } T \ll \mu, \quad (3.59)$$

Sommerfeld expansion

where $\varphi(\varepsilon)$ is an arbitrary function that is sufficiently smooth at $\varepsilon = \mu$ and integrable at $\varepsilon = 0$. To prove this formula, let us introduce another function,

$$f(\varepsilon) \equiv \int_0^\varepsilon \varphi(\varepsilon') d\varepsilon', \quad \text{so that } \varphi(\varepsilon) = \frac{df(\varepsilon)}{d\varepsilon}, \quad (3.60)$$

and work out the integral $I(T)$ by parts:

$$I(T) \equiv \int_0^\infty \frac{df(\varepsilon)}{d\varepsilon} \langle N(\varepsilon) \rangle d\varepsilon = \int_{\varepsilon=0}^{\varepsilon=\infty} \langle N(\varepsilon) \rangle df$$

²⁶ See, e.g., QM Sec. 8.4.

²⁷ Note also a huge difference between the very high bulk modulus of metals ($K \sim 10^{11}$ Pa) and its very low values in usual, atomic gases (for them, at ambient conditions, $K \sim 10^5$ Pa). About four orders of magnitude of this difference is due to that in the particle density N/V , but the balance is due to the electron gas' degeneracy. Indeed, in an ideal classical gas, $K = P = T(N/V)$, so that the factor $(2/3)\varepsilon_F$ in Eq. (58), of the order of a few eV in metals, should be compared with the factor $T \approx 25$ meV in the classical gas at room temperature.

²⁸ Data from N. Ashcroft and N. D. Mermin, *Solid State Physics*, W. B. Saunders, 1976.

²⁹ Named after Arnold Sommerfeld, who was the first (in 1927) to apply quantum mechanics to degenerate Fermi gases, in particular to electrons in metals, and may be credited for most of the results discussed in this section.

$$= \left[\langle N(\varepsilon) \rangle f(\varepsilon) \right]_{\varepsilon=0}^{\varepsilon=\infty} - \int_{\varepsilon=0}^{\varepsilon=\infty} f(\varepsilon) d\langle N(\varepsilon) \rangle = \int_0^{\infty} f(\varepsilon) \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon. \quad (3.61)$$

As evident from Eq. (2.115) and/or Fig. 2a, at $T \ll \mu$ the function $-\partial \langle N(\varepsilon) \rangle / \partial \varepsilon$ is close to zero for all energies, besides a narrow peak of the unit area, at $\varepsilon \approx \mu$. Hence, if we expand the function $f(\varepsilon)$ in the Taylor series near this point, just a few leading terms of the expansion should give us a good approximation:

$$\begin{aligned} I(T) &\approx \int_0^{\infty} \left[f(\mu) + \frac{df}{d\varepsilon} \Big|_{\varepsilon=\mu} (\varepsilon - \mu) + \frac{1}{2} \frac{d^2 f}{d\varepsilon^2} \Big|_{\varepsilon=\mu} (\varepsilon - \mu)^2 \right] \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon \\ &= \int_0^{\mu} \varphi(\varepsilon') d\varepsilon' \int_0^{\infty} \left(-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right) d\varepsilon + \varphi(\mu) \int_0^{\infty} (\varepsilon - \mu) \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon \\ &\quad + \frac{1}{2} \frac{d\varphi(\mu)}{d\mu} \int_0^{\infty} (\varepsilon - \mu)^2 \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon. \end{aligned} \quad (3.62)$$

In the last form of this relation, the first integral over ε equals $\langle N(\varepsilon=0) \rangle - \langle N(\varepsilon=\infty) \rangle = 1$, the second one vanishes (because the function under it is antisymmetric with respect to the point $\varepsilon = \mu$), and only the last one needs to be dealt with explicitly, by working it out by parts and then using a table integral:³⁰

$$\int_0^{\infty} (\varepsilon - \mu)^2 \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon \approx T^2 \int_{-\infty}^{+\infty} \xi^2 \frac{d}{d\xi} \left(-\frac{1}{e^\xi + 1} \right) d\xi = 4T^2 \int_0^{+\infty} \frac{\xi d\xi}{e^\xi + 1} = 4T^2 \frac{\pi^2}{12}. \quad (3.63)$$

Being plugged into Eq. (62), this result proves the Sommerfeld formula (59).

The last preparatory step we need to make is to account for a possible small difference (as we will see below, also proportional to T^2) between the temperature-dependent chemical potential $\mu(T)$ and the Fermi energy defined as $\varepsilon_F \equiv \mu(0)$, in the largest (first) term on the right-hand side of Eq. (59), to write

$$I(T) \approx \int_0^{\varepsilon_F} \varphi(\varepsilon) d\varepsilon + (\mu - \varepsilon_F) \varphi(\mu) + \frac{\pi^2}{6} T^2 \frac{d\varphi(\mu)}{d\mu} \equiv I(0) + (\mu - \varepsilon_F) \varphi(\mu) + \frac{\pi^2}{6} T^2 \frac{d\varphi(\mu)}{d\mu}. \quad (3.64)$$

Now, applying this formula to Eq. (41) and the last form of Eq. (52), we get the following results (which are valid for any dispersion law $\varepsilon(\mathbf{p})$ and even any dimensionality of the gas):

$$N(T) = N(0) + (\mu - \varepsilon_F) g(\mu) + \frac{\pi^2}{6} T^2 \frac{dg(\mu)}{d\mu}, \quad (3.65)$$

$$E(T) = E(0) + (\mu - \varepsilon_F) \mu g(\mu) + \frac{\pi^2}{6} T^2 \frac{d}{d\mu} [\mu g(\mu)]. \quad (3.66)$$

If the number of particles does not change with temperature, $N(T) = N(0)$, as in most experiments, Eq. (65) gives the following formula for finding the temperature-induced change of μ :

³⁰ See, e.g., MA Eqs. (6.8c) and (2.12b), with $n = 1$.

$$\mu - \varepsilon_F = -\frac{\pi^2}{6} T^2 \frac{1}{g(\mu)} \frac{dg(\mu)}{d\mu}. \quad (3.67)$$

Note that the change is quadratic in T and negative, in agreement with the numerical results shown with the red line in Fig. 1. Plugging this expression (which is only valid when the magnitude of the change is much smaller than ε_F) into Eq. (66), we get the following temperature correction to the energy:

$$E(T) - E(0) = \frac{\pi^2}{6} g(\mu) T^2, \quad (3.68)$$

where within the accuracy of our approximation, μ may be replaced with ε_F . (Due to the universal relation (48), this result also gives the temperature correction to the Fermi gas' pressure.) Now we may use Eq. (68) to calculate the heat capacity of the degenerate Fermi gas:

Low-T
heat
capacity

$$C_V \equiv \left(\frac{\partial E}{\partial T} \right)_V = \gamma T, \quad \text{with } \gamma = \frac{\pi^2}{3} g(\varepsilon_F). \quad (3.69)$$

According to Eq. (55b), in the particular case of a 3D gas with the isotropic and parabolic dispersion law (3), Eq. (69) reduces to

$$\gamma = \frac{\pi^2}{2} \frac{N}{\varepsilon_F}, \quad \text{i.e. } c_V \equiv \frac{C_V}{N} = \frac{\pi^2}{2} \frac{T}{\varepsilon_F} \ll 1. \quad (3.70)$$

This important result deserves a discussion. First, note that within the range of validity of the Sommerfeld approximation ($T \ll \varepsilon_F$), the specific heat of the degenerate gas is much smaller than that of the classical gas, even without internal degrees of freedom: $c_V = 3/2$ – see Eq. (19). The physical reason for such a low heat capacity is that the particles deep inside the Fermi sea cannot pick up thermal excitations with available energies of the order of $T \ll \varepsilon_F$, because the states immediately above them are already occupied. The only particles (or rather quantum states, due to the particle indistinguishability) that may be excited with such small energies are those at the Fermi surface, more exactly within a surface layer of thickness $\Delta\varepsilon \sim T \ll \varepsilon_F$, and Eq. (70) presents a very vivid manifestation of this fact.

The second important feature of Eqs. (69)-(70) is the linear dependence of the heat capacity on temperature, which decreases with a reduction of T much slower than that of crystal vibrations – see Eq. (2.99). This means that in metals the specific heat at temperatures $T \ll T_D$ is dominated by the conduction electrons. Indeed, experiments confirm not only the linear dependence (70) of the specific heat,³¹ but also the values of the proportionality coefficient $\gamma \equiv C_V/T$ for cases when ε_F can be calculated independently, for example for alkali metals – see the two rightmost columns of Table 1 above. More typically, Eq. (69) is used for the experimental measurement of the density of states on the Fermi surface, $g(\varepsilon_F)$ – the factor which participates in many theoretical results, in particular in transport properties of degenerate Fermi gases (see Chapter 6 below).

³¹ Solids, with their low thermal expansion coefficients, provide a virtually-fixed-volume confinement for the electron gas, so that the specific heat measured at ambient conditions may be legitimately compared with the calculated c_V .

3.4. Bose-Einstein condensation

Now let us explore what happens at the cooling of an ideal gas of bosons. Figure 3a shows the same plot as Fig. 1b, i.e. the result of a numerical solution of Eq. (47) with the appropriate (lower) sign in the denominator, on a more appropriate, log-log scale. One can see that the chemical potential μ indeed tends to zero at some finite “critical temperature” T_c . This temperature may be found by taking $\mu = 0$ in Eq. (47), reducing it to a table integral:³²

$$T_c = T_0 \left[\frac{1}{\sqrt{2\pi^2}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^\xi - 1} \right]^{-2/3} = T_0 \left[\frac{1}{\sqrt{2\pi^2}} \Gamma\left(\frac{3}{2}\right) \zeta\left(\frac{3}{2}\right) \right]^{-2/3} \approx 3.313 T_0, \quad (3.71)$$

BEC:
critical
temperature

the result explaining the T_c/T_0 ratio mentioned in Sec. 2 and indicated in Fig. 1.

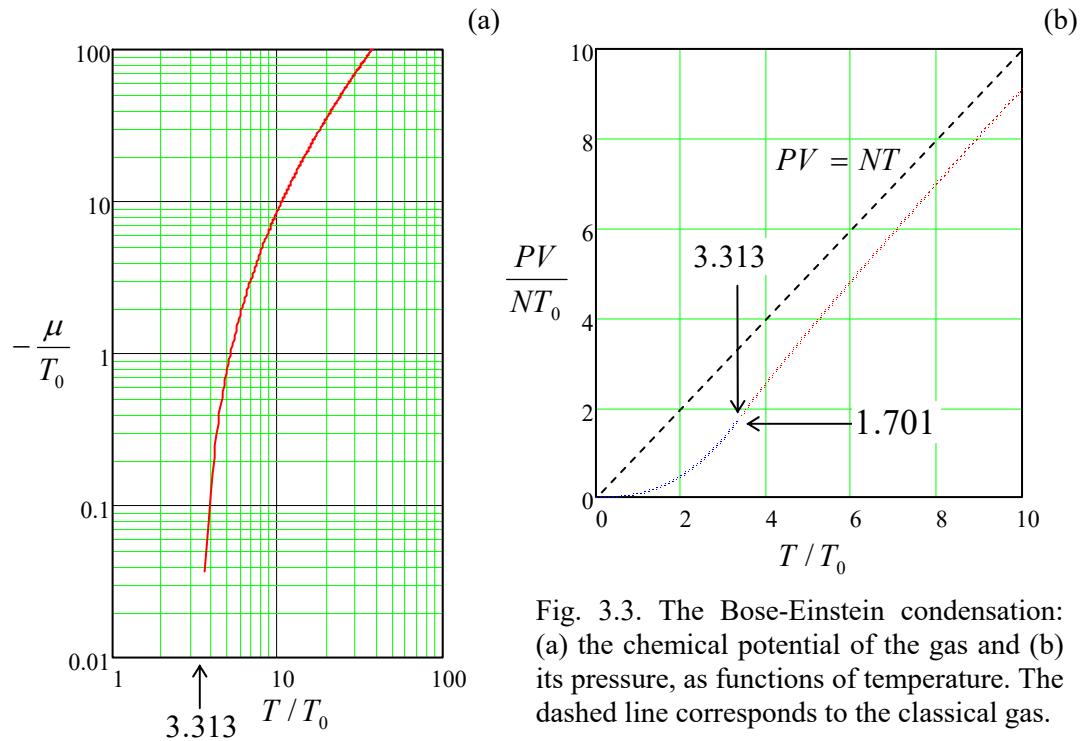

Fig. 3.3. The Bose-Einstein condensation: (a) the chemical potential of the gas and (b) its pressure, as functions of temperature. The dashed line corresponds to the classical gas.

Let us have a good look at the temperature interval $0 < T < T_c$, which cannot be directly described by Eq. (40) (with the appropriate negative sign in the denominator), and hence may look rather mysterious. Indeed, within this range, the chemical potential μ , cannot either be negative or equal zero, because according to Eq. (71), in this case, Eq. (40) would give a value of N smaller than the number of particles we actually have. On the other hand, μ cannot be positive either, because the integral (40) would diverge at $\varepsilon \rightarrow \mu$ due to the divergence of $\langle N(\varepsilon) \rangle$ – see, e.g., Fig. 2.15. The only possible resolution of the paradox, suggested by A. Einstein in 1925, is as follows: at $T < T_c$, the chemical potential of each particle of the system still equals exactly zero, but a certain number (N_0 of N) of them are in the ground state (with $\varepsilon \equiv p^2/2m = 0$), forming the so-called *Bose-Einstein condensate*, usually referred to as the BEC. Since the condensate particles do not contribute to Eq. (40) (because of

³² See, e.g., MA Eq. (6.8b) with $s = 3/2$, and then Eqs. (2.7b) and (6.7e).

the factor $\varepsilon^{1/2} = 0$), their number N_0 may be calculated by using that formula (or, equivalently, Eq. (44)), with $\mu = 0$, to find the number $(N - N_0)$ of particles still remaining in the gas, i.e. having energy $\varepsilon > 0$:

$$N - N_0 = \frac{gV(mT)^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^\xi - 1}. \quad (3.72)$$

This result is even simpler than it may look. Indeed, let us write it for the case $T = T_c$, when $N_0 = 0$:³³

$$N = \frac{gV(mT_c)^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\xi^{1/2} d\xi}{e^\xi - 1}. \quad (3.73)$$

Dividing both sides of Eqs. (72) and (73), we get an extremely simple and elegant result:

$$\frac{N - N_0}{N} = \left(\frac{T}{T_c} \right)^{3/2}, \quad \text{so that } N_0 = N \left[1 - \left(\frac{T}{T_c} \right)^{3/2} \right], \quad \text{for } T \leq T_c. \quad (3.74a)$$

Please note that this result is only valid for the particles whose motion, within the volume V , is free – in other words, for a system of free particles confined within a rigid-wall box of volume V . In most experiments with the Bose-Einstein condensation of dilute gases of neutral (and hence very weakly interacting) atoms, they are held not in such a box, but at the bottom of a “soft” potential well, which may be well approximated by a 3D quadratic parabola: $U(\mathbf{r}) = m\omega^2 r^2/2$. It is straightforward (and hence left for the reader’s exercise) to show that in this case, the dependence of $N_0(T)$ is somewhat different:

$$N_0 = N \left[1 - \left(\frac{T}{T_c^*} \right)^3 \right], \quad \text{for } T \leq T_c^*, \quad (3.74b)$$

where T_c^* is a different critical temperature, which now depends on $\hbar\omega$, i.e. on the confining potential’s “steepness”. (In this case, V is not exactly fixed; however, the effective volume occupied by the particles at $T = T_c^*$ is related to this temperature by a formula close to Eq. (71), so that all estimates given above are still valid.) Figure 4 shows one of the first sets of experimental data for the Bose-Einstein condensation of a dilute gas of neutral atoms. Taking into account the finite number of particles in the experiment, the agreement with the simple theory is surprisingly good.

Returning to the spatially-uniform Bose system, let us explore what happens below the critical temperature with its other parameters. Formula (52) with the appropriate (lower) sign shows that approaching T_c from higher temperatures, the gas energy and hence its pressure do not vanish – see the red line in Fig. 3b. Indeed, at $T = T_c$ (where $\mu = 0$), that formula yields³⁴

$$E(T_c) = gV \frac{m^{3/2} T_c^{5/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \frac{\xi^{3/2} d\xi}{e^\xi - 1} = gV \frac{m^{3/2} T_c^{5/2}}{\sqrt{2\pi^2\hbar^3}} \Gamma\left(\frac{5}{2}\right) \zeta\left(\frac{5}{2}\right) \approx 0.7701 NT_c, \quad (3.75)$$

so that using the universal relation (48), we get the pressure value,

$$P(T_c) = \frac{2}{3} \frac{E(T_c)}{V} = \frac{\zeta(5/2)}{\zeta(3/2)} \frac{N}{V} T_c \approx 0.5134 \frac{N}{V} T_c \approx 1.701 P_0, \quad (3.76)$$

³³ This is, of course, just another form of Eq. (71).

³⁴ For the involved dimensionless integral see, e.g., MA Eqs. (6.8b) with $s = 5/2$, and then (2.7b) and (6.7c).

which is somewhat lower than, but comparable to $P(0)$ for the fermions – cf. Eq. (57).

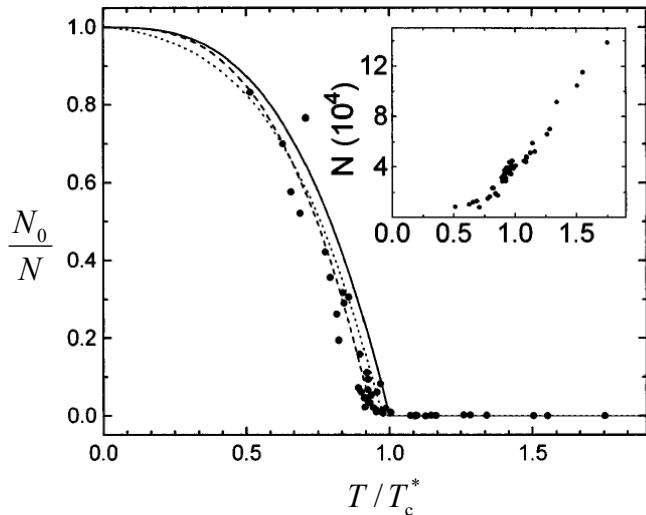

Fig. 3.4. The total number N of trapped ^{87}Rb atoms (inset) and their ground-state fraction N_0/N , as functions of the ratio T/T_c , as measured in one of the pioneering experiments – see J. Ensher *et al.*, *Phys. Rev. Lett.* **77**, 4984 (1996). In this experiment, T_c^* was as low as 0.28×10^{-6} K. The solid line shows the simple theoretical dependence $N(T)$ given by Eq. (74b), while other lines correspond to more detailed theories taking into account the finite number N of trapped atoms. © 1996 APS, reproduced with permission.

Now we can use the same Eq. (52), also with $\mu = 0$, to calculate the energy of the gas at $T < T_c$,

$$E(T) = gV \frac{m^{3/2} T^{5/2}}{\sqrt{2\pi^2 \hbar^3}} \int_0^\infty \frac{\xi^{3/2} d\xi}{e^\xi - 1}. \quad (3.77)$$

Comparing this relation with the first form of Eq. (75), which features the same integral, we immediately get one more simple temperature dependence:

$$E(T) = E(T_c) \left(\frac{T}{T_c} \right)^{5/2}, \quad \text{for } T \leq T_c. \quad (3.78)$$

BEC:
energy

From the universal relation (48), we immediately see that the gas pressure follows the same dependence:

$$P(T) = P(T_c) \left(\frac{T}{T_c} \right)^{5/2}, \quad \text{for } T \leq T_c. \quad (3.79)$$

BEC:
pressure

This temperature dependence of pressure is shown with the blue line in Fig. 3b. The plot shows that for all temperatures (both below and above T_c) the pressure is lower than that of the classical gas of the same density. Now note also that since, according to Eqs. (57) and (76), $P(T_c) \propto P_0 \propto V^{5/3}$, while according to Eqs. (35) and (71), $T_c \propto T_0 \propto V^{2/3}$, the pressure (79) is proportional to $V^{5/3}/(V^{2/3})^{5/2} = V^0$, i.e. does not depend on the volume at all! The physics of this result (which is valid at $T < T_c$ only) is that as we decrease the volume at a fixed total number N of particles, more and more of them go to the condensate, decreasing the number $(N - N_0)$ of particles in the gas phase, but not changing its spatial density pressure. Such behavior is very typical for the coexistence of two different phases of the same matter – see, in particular, the next chapter.

The last thermodynamic variable of major interest is heat capacity, because it may be most readily measured. For temperatures $T \leq T_c$, it may be easily calculated from Eq. (78):

$$C_V(T) \equiv \left(\frac{\partial E}{\partial T} \right)_{N,V} = E(T_c) \frac{5}{2} \frac{T^{3/2}}{T_c^{5/2}}, \quad (3.80)$$

so that below T_c , the capacity *increases* with temperature, at the critical temperature reaching the value

$$C_V(T_c) = \frac{5}{2} \frac{E(T_c)}{T_c} \approx 1.925 N, \quad (3.81)$$

which is approximately 28% above that ($3N/2$) of the classical gas. (As a reminder, in both cases we ignore possible contributions from the internal degrees of freedom.) The analysis for $T \geq T_c$ is a little bit more cumbersome because differentiating E over temperature – say, using Eq. (52) – one should also take into account the temperature dependence of μ that follows from Eq. (40) – see also Fig. 1. However, the most important feature of the result may be predicted without the calculation (which is being left for the reader's exercise). Namely, since at $T \gg T_c$ the heat capacity has to approach the classical value $1.5N$, starting from the value (81), it must *decrease* with temperature at $T > T_c$, thus forming a sharp maximum (a “cusp”) at the critical point $T = T_c$ – see Fig. 5.

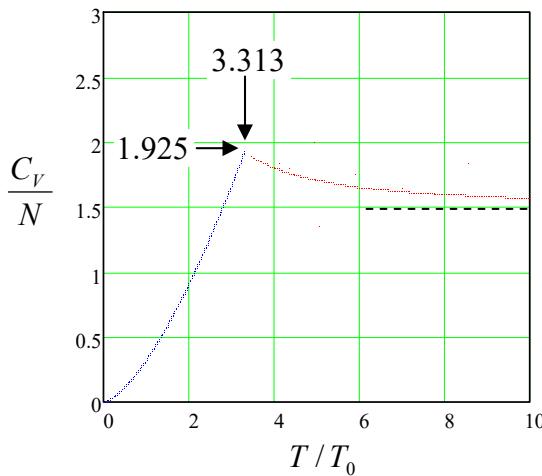

Fig. 3.5. Temperature dependences of the heat capacity of an ideal Bose-Einstein gas, numerically calculated from Eqs. (52) and (40) for $T \geq T_c$, and given by Eq. (80) for $T \leq T_c$.

Such a cusp is a good indication of the Bose-Einstein condensation in virtually any experimental system, especially because inter-particle interactions (unaccounted for in our simple discussion) typically make this feature even more substantial, frequently turning it into a weak (logarithmic) singularity. Historically, such a singularity was the first noticed, though not immediately understood sign of the Bose-Einstein condensation, observed in 1931 by W. Keesom and K. Clusius in liquid ^4He at its λ -point (called so exactly because of the characteristic shape of the $C_V(T)$ dependence) $T = T_c \approx 2.17$ K. Other milestones of the Bose-Einstein condensation studies include:

- the experimental discovery of superconductivity (which was later explained as the result of the Bose-Einstein condensation of electron pairs) by H. Kamerlingh-Onnes in 1911;
- the development of the Bose-Einstein statistics, and predicting the condensation, by S. Bose and A. Einstein, in 1924-1925;
- the discovery of superfluidity in liquid ^4He by P. Kapitza and (independently) by J. Allen and D. Misener in 1937, and its explanation as a result of the Bose-Einstein condensation by F. and H. Londons and L. Titza, with further significant elaborations by L. Landau – all in 1938;
- the explanation of superconductivity as a result of electron binding into *Cooper pairs*, with a simultaneous Bose-Einstein condensation of the resulting bosons, by J. Bardeen, L. Cooper, and J. Schrieffer in 1957;

- the discovery of superfluidity of two different phases of ^3He , due to the similar Bose-Einstein condensation of pairs of its fermion atoms, by D. Lee, D. Osheroff, and R. Richardson in 1972;

- the first observation of the Bose-Einstein condensation in dilute gases (^{87}Ru by E. Cornell, C. Wieman, *et al.*, and ^{23}Na by W. Ketterle *et al.*) in 1995.

The importance of the last achievement stems from the fact that in contrast to other Bose-Einstein condensates, in dilute gases (with the typical density n as low as $\sim 10^{14} \text{ cm}^{-3}$) the particles interact very weakly, and hence many experimental results are very close to the simple theory described above and its straightforward elaborations – see, e.g., Fig. 4.³⁵ On the other hand, the importance of other Bose-Einstein condensates, which involve more complex and challenging physics, should not be underestimated – as it sometimes is.

Perhaps the most important feature of any Bose-Einstein condensate is that all N_0 condensed particles are in the same quantum state, and hence are described by exactly the same wavefunction. This wavefunction is substantially less “feeble” than that of a single particle – in the following sense. In the second quantization language,³⁶ the well-known Heisenberg’s uncertainty relation may be rewritten for the creation/annihilation operators; in particular, for bosons,

$$|\delta\hat{a}\delta\hat{a}^\dagger| \geq 1. \quad (3.82)$$

Since \hat{a} and \hat{a}^\dagger are the quantum-mechanical operators of the complex amplitude $a = A\exp\{i\varphi\}$ and its complex conjugate $a^* = A\exp\{-i\varphi\}$, where A and φ are real amplitude and phase of the wavefunction, Eq. (82) yields the following approximate uncertainty relation (strict in the limit $\delta\varphi \ll 1$) between the number of particles $N = AA^*$ and the phase φ :

$$\delta N \delta\varphi \geq \frac{1}{2}. \quad (3.83)$$

This means that a condensate of $N \gg 1$ bosons may be in a state with both phase and amplitude of the wavefunction behaving virtually as *c*-numbers, with very small relative uncertainties: $\delta N \ll N$, $\delta\varphi \ll 1$. Moreover, such states are much less susceptible to perturbations by experimental instruments. For example, the electric current carried along a superconducting wire by a coherent Bose-Einstein condensate of Cooper pairs may be as high as hundreds of amperes. As a result, the “strange” behaviors predicted by the quantum mechanics are not averaged out as in the usual particle ensembles (see, e.g., the discussion of the density matrix in Sec. 2.1), but may be directly revealed in macroscopic, measurable dynamics of the condensate.

For example, the density \mathbf{j} of the electric “supercurrent” of the Cooper pairs may be described by the same formula as the well-known usual probability current density of a single quantum particle,³⁷ just multiplied by the electric charge $q = -2e$ of a single pair, and the pair density n :

³⁵ Such controllability of theoretical description has motivated the use of dilute-gas BECs for modeling of renowned problems of many-body physics – see, e.g. the review by I. Bloch *et al.*, *Rev. Mod. Phys.* **80**, 885 (2008). These efforts are assisted by the development of better techniques for reaching the necessary sub- μK temperatures – see, e.g., the recent work by J. Hu *et al.*, *Science* **358**, 1078 (2017). For a more general, detailed discussion see, e.g., C. Pethick and H. Smith, *Bose-Einstein Condensation in Dilute Gases*, 2nd ed., Cambridge U. Press, 2008.

³⁶ See, e.g., QM Sec. 8.3.

³⁷ See, e.g., QM Eq. (3.28).

$$\mathbf{j} = qn \frac{\hbar}{m} \left(\nabla \varphi - \frac{q}{\hbar} \mathbf{A} \right), \quad (3.84)$$

where \mathbf{A} is the vector potential of the (electro)magnetic field. If a superconducting wire is not extremely thin, the supercurrent does not penetrate into its interior.³⁸ As a result, the integral of Eq. (84), taken along a closed superconducting loop, inside its interior (where $\mathbf{j} = 0$), yields

$$\frac{q}{\hbar} \oint_C \mathbf{A} \cdot d\mathbf{r} = \Delta\varphi = 2\pi M, \quad (3.85)$$

where M is an integer. But, according to the basic electrodynamics, the integral on the left-hand side of this relation is nothing more than the flux Φ of the magnetic field \mathcal{B} piercing the wire loop area A . Thus we immediately arrive at the famous *magnetic flux quantization* effect:

$$\Phi \equiv \int_A \mathcal{B}_n d^2 r = M\Phi_0, \quad \text{where } \Phi_0 \equiv \frac{2\pi\hbar}{|q|} \approx 2.07 \times 10^{-15} \text{ Wb}, \quad (3.86)$$

which was theoretically predicted in 1950 and experimentally observed in 1961. Amazingly, this effect holds even “over miles of dirty lead wire”, citing H. Casimir’s famous expression, sustained by the coherence of the Bose-Einstein condensate of Cooper pairs.

Other prominent examples of such *macroscopic quantum effects* in Bose-Einstein condensates include not only the superfluidity and superconductivity as such, but also the Josephson effect, quantized Abrikosov vortices, etc. Some of these effects are briefly discussed in other parts of this series.³⁹

3.5. Gases of weakly interacting particles

Now let us discuss the effects of weak particle interaction effects on properties of their gas. (Unfortunately, I will have time to do that only very briefly, and only for classical gases.⁴⁰) In most cases of interest, particle interaction may be well described by a certain potential energy U , so that in the simplest model, the total energy is

$$E = \sum_{k=1}^N \frac{p_k^2}{2m} + U(\mathbf{r}_1, \dots, \mathbf{r}_j, \dots, \mathbf{r}_N), \quad (3.87)$$

where \mathbf{r}_k is the radius-vector of the k^{th} particle’s center.⁴¹ First, let us see how far would the statistical physics allow us to proceed for an arbitrary potential U . For $N \gg 1$, at the calculation of the Gibbs statistical sum (2.59), we may perform the usual transfer from the summation over all quantum states of the system to the integration over the $6N$ -dimensional space, with the correct Boltzmann counting:

³⁸ This is the *Meissner-Ochsenfeld* (or just “Meissner”) effect which may be also readily explained using Eq. (84) combined with the Maxwell equations – see, e.g., EM Sec. 6.4.

³⁹ See EM Secs. 6.4-6.5, and QM Secs. 1.6 and 3.1.

⁴⁰ A concise discussion of the effects of weak interactions on the properties of *quantum* gases may be found, for example, in Chapter 10 of the textbook by K. Huang, *Statistical Mechanics*, 2nd ed., Wiley, 2003.

⁴¹ One of the most significant effects *neglected* by Eq. (87) is the influence of atomic/molecular angular orientations on their interactions.

$$\begin{aligned}
Z = \sum_m e^{-E_m/T} &\rightarrow \frac{1}{N!} \frac{g^N}{(2\pi\hbar)^{3N}} \int \exp \left\{ -\sum_{k=1}^N \frac{p_j^2}{2mT} \right\} d^3 p_1 \dots d^3 p_N \int \exp \left\{ -\frac{U(\mathbf{r}_1, \dots, \mathbf{r}_N)}{T} \right\} d^3 r_1 \dots d^3 r_N \\
&\equiv \left(\frac{1}{N!} \frac{g^N V^N}{(2\pi\hbar)^{3N}} \int \exp \left\{ -\sum_{k=1}^N \frac{p_j^2}{2mT} \right\} d^3 p_1 \dots d^3 p_N \right) \times \left(\frac{1}{V^N} \int \exp \left\{ -\frac{U(\mathbf{r}_1, \dots, \mathbf{r}_N)}{T} \right\} d^3 r_1 \dots d^3 r_N \right).
\end{aligned} \tag{3.88}$$

But according to Eq. (14), the first operand in the last product is just the statistical sum of an ideal gas (with the same g , N , V , and T), so that we may use Eq. (2.63) to write

$$F = F_{\text{ideal}} - T \ln \left[\frac{1}{V^N} \int d^3 r_1 \dots d^3 r_N e^{-U/T} \right] \equiv F_{\text{ideal}} - T \ln \left[1 + \frac{1}{V^N} \int d^3 r_1 \dots d^3 r_N (e^{-U/T} - 1) \right], \tag{3.89}$$

where F_{ideal} is the free energy of the ideal gas (i.e. the same gas but with $U=0$), given by Eq. (16).

I believe that Eq. (89) is a very convincing demonstration of the enormous power of statistical physics methods. Instead of trying to solve an impossibly complex problem of classical dynamics of $N \gg 1$ (think of $N \sim 10^{23}$) interacting particles, and only then calculating appropriate ensemble averages, the Gibbs approach reduces finding the free energy (and then, from thermodynamic relations, all other thermodynamic variables) to the calculation of just one integral on its right-hand side of Eq. (89). Still, this integral is $3N$ -dimensional and may be worked out analytically only if the particle interactions are weak in some sense. Indeed, the last form of Eq. (89) makes it especially evident that if $U \rightarrow 0$ everywhere, the term in the parentheses under the integral vanishes, and so does the integral itself, and hence the addition to F_{ideal} .

Now let us see what would this integral yield for the simplest, *short-range* interactions, in which the potential U is substantial only when the mutual distance $\mathbf{r}_{kk'} \equiv \mathbf{r}_k - \mathbf{r}_{k'}$ between the centers of two particles is smaller than certain value $2r_0$, where r_0 may be interpreted as the particle's radius. If the gas is sufficiently dilute, so that the radius r_0 is much smaller than the average distance r_{ave} between the particles, the integral in the last form of Eq. (89) is of the order of $(2r_0)^{3N}$, i.e. much smaller than $(r_{\text{ave}})^{3N} = V^N$. Then we may expand the logarithm in that expression into the Taylor series with respect to the small second term in the square brackets, and keep only its first non-zero term:

$$F \approx F_{\text{ideal}} - \frac{T}{V^N} \int d^3 r_1 \dots d^3 r_N (e^{-U/T} - 1). \tag{3.90}$$

Moreover, if the gas density is so low, the chances for three or more particles to come close to each other and interact (collide) simultaneously are typically very small, so that *pair collisions* are the most important. In this case, we may recast the integral in Eq. (90) as a sum of $N(N-1)/2 \approx N^2/2$ similar terms describing such pair interactions, each of the type

$$V^{N-2} \int (e^{-U(\mathbf{r}_{kk'})/T} - 1) d^3 r_k d^3 r_{k'}. \tag{3.91}$$

It is convenient to think about the $\mathbf{r}_{kk'} \equiv \mathbf{r}_k - \mathbf{r}_{k'}$ as the radius-vector of the particle number k in the reference frame with the origin placed at the center of the particle number k' – see Fig. 6a.

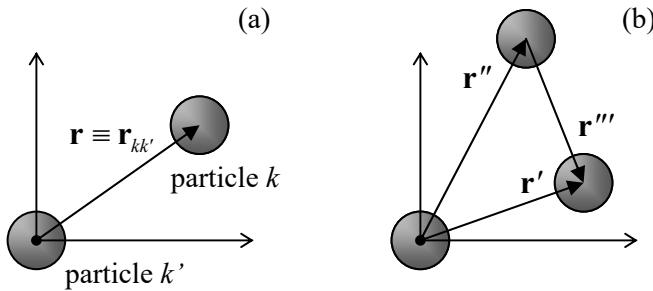

Fig. 3.6. The definition of the interparticle distance vectors at their (a) pair and (b) triple interactions.

Then in Eq. (91), we may first calculate the integral over \mathbf{r}_k , while keeping the distance vector $\mathbf{r}_{kk'}$, and hence $U(\mathbf{r}_{kk'})$, constant, getting one more factor V . Moreover, since all particle pairs are similar, in the remaining integral over $\mathbf{r}_{kk'}$ we may drop the radius-vector's index, so that Eq. (90) becomes

$$F = F_{\text{ideal}} - \frac{T}{V^N} \frac{N^2}{2} V^{N-1} \int (e^{-U(\mathbf{r})/T} - 1) d^3 r \equiv F_{\text{ideal}} + \frac{T}{V} N^2 B(T), \quad (3.92)$$

where the function $B(T)$, called the *second virial coefficient*,⁴² has an especially simple form for spherically-symmetric interactions:

Second
virial
coefficient

$$B(T) \equiv \frac{1}{2} \int (1 - e^{-U(\mathbf{r})/T}) d^3 r \rightarrow \frac{1}{2} \int_0^\infty 4\pi r^2 dr (1 - e^{-U(r)/T}). \quad (3.93)$$

From Eq. (92), and the second of the thermodynamic relations (1.35), we already know something particular about the equation of state $P(V, T)$:

$$P = -\left(\frac{\partial F}{\partial V}\right)_{T,N} = P_{\text{ideal}} + \frac{N^2 T}{V^2} B(T) = T \left[\frac{N}{V} + B(T) \frac{N^2}{V^2} \right]. \quad (3.94)$$

We see that at a fixed gas density $n = N/V$, the pair interaction creates additional pressure, proportional to $(N/V)^2 = n^2$ and a function of temperature, $B(T)T$.

Let us calculate $B(T)$ for a few simple models of particle interactions. The solid curve in Fig. 7 shows (schematically) a typical form of the interaction potential between electrically neutral atoms/molecules. At large distances the interaction of particles that do not have their own permanent electrical dipole moment \mathbf{p} , is dominated by the attraction (the so-called *London dispersion force*) between the correlated components of the spontaneously induced dipole moments, giving $U(r) \rightarrow r^{-6}$ at $r \rightarrow \infty$.⁴³ At closer distances the potential is repulsive, growing very fast at $r \rightarrow 0$, but its quantitative

⁴² The term “virial”, from Latin *viris* (meaning “force”), was introduced to molecular physics by R. Clausius. The motivation for the adjective “second” for $B(T)$ is evident from the last form of Eq. (94), with the “first virial coefficient”, standing before the N/V ratio and sometimes denoted $A(T)$, equal to 1 – see also Eq. (100) below.

⁴³ Indeed, independent fluctuation-induced components $\mathbf{p}(t)$ and $\mathbf{p}'(t)$ of dipole moments of two particles have random mutual orientation, so that the time average of their interaction energy, proportional to $\mathbf{p}(t) \cdot \mathbf{p}'(t)/r^3$, vanishes. However, the electric field \mathcal{E} of each dipole \mathbf{p} , proportional to r^{-3} , induces a correlated component of \mathbf{p}' , also proportional to r^{-3} , giving interaction energy proportional to $\mathbf{p}' \cdot \mathcal{E} \propto r^{-6}$, with a non-zero statistical average. Quantitative discussions of this effect, within several models, may be found, for example, in QM Chapters 3, 5, and 6.

form is specific for particular atoms/molecules.⁴⁴ The crudest description of such repulsion is given by the so-called *hardball model*:

$$U(r) = \begin{cases} +\infty, & \text{for } 0 < r < 2r_0, \\ 0, & \text{for } 2r_0 < r < \infty, \end{cases} \quad (3.95)$$

– see the dashed line and the inset in Fig. 7.

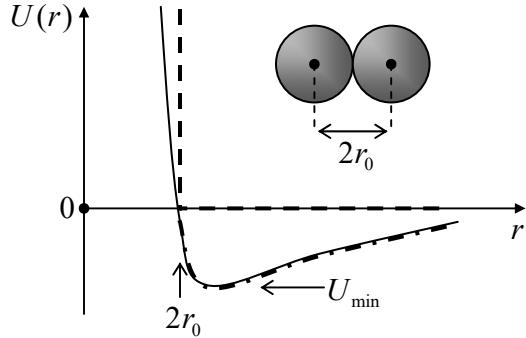

Fig. 3.7. Pair interactions of particles. Solid line: a typical interaction potential; dashed line: its hardball model (95); dash-dotted line: the improved model (97) – all schematically. The inset illustrates the hardball model’s physics.

As Eq. (93) shows, in this model the second virial coefficient is temperature-independent:

$$B(T) = b \equiv \frac{1}{2} \int_0^{2r_0} 4\pi r^2 dr = \frac{2\pi}{3} (2r_0)^3 \equiv 4V_0, \quad \text{where } V_0 \equiv \frac{4\pi}{3} r_0^3, \quad (3.96)$$

so that the equation of state (94) still gives a linear dependence of pressure on temperature.

A correction to this result may be obtained by the following approximate account of the long-range attraction (see the dash-dotted line in Fig. 7):⁴⁵

$$U(r) = \begin{cases} +\infty, & \text{for } 0 < r < 2r_0, \\ U(r), & \text{with } |U| \ll T, \quad \text{for } 2r_0 < r < \infty. \end{cases} \quad (3.97)$$

For this improved model, Eq. (93) yields:

$$B(T) = b + \frac{1}{2} \int_{2r_0}^{\infty} 4\pi r^2 dr \frac{U(r)}{T} \equiv b - \frac{a}{T}, \quad \text{with } a \equiv 2\pi \int_{2r_0}^{\infty} r^2 dr |U(r)|. \quad (3.98)$$

In this model, the equation of state (94) acquires a temperature-independent term:

⁴⁴ Note that the particular form of the first term in the approximation $U(r) = a/r^{12} - b/r^6$ (called either the *Lennard-Jones potential* or the “12-6 potential”), that had been suggested in 1924, lacks physical justification, and in professional physics was soon replaced with other approximations, including the so-called *exp-6 model*, which fits most experimental data much better. However, the Lennard-Jones potential still keeps creeping from one undergraduate textbook to another one, apparently for a not better reason than enabling a simple analytical calculation of the equilibrium distance between the particles at $T \rightarrow 0$.

⁴⁵ The strong inequality $|U| \ll T$ in this model is necessary not only to make the calculations simpler. A deeper reason is that if $(-U_{\min})$ becomes comparable with T , particles may become trapped in this potential well, forming a different phase – a liquid or a solid. In such phases, the probability of finding more than two particles interacting simultaneously is high, so that Eq. (92), on which Eqs. (93)-(94) and Eqs. (98)-(99) are based, becomes invalid.

$$P = T \left[\frac{N}{V} + \left(\frac{N}{V} \right)^2 \left(b - \frac{a}{T} \right) \right] \equiv T \left[\frac{N}{V} + b \left(\frac{N}{V} \right)^2 \right] - a \left(\frac{N}{V} \right)^2. \quad (3.99)$$

Still, the correction to the ideal-gas pressure is proportional to $(N/V)^2$ and has to be relatively small for this result to be valid.

Generally, the right-hand side of Eq. (99) may be considered as the sum of two leading terms in the general expansion of P into the Taylor series in the density $n = N/V$ of the gas:

Pressure:
virial
expansion

$$P = T \left[\frac{N}{V} + B(T) \left(\frac{N}{V} \right)^2 + C(T) \left(\frac{N}{V} \right)^3 + \dots \right], \quad (3.100)$$

where $C(T)$ is called the *third virial coefficient*. It is natural to ask how can we calculate $C(T)$ and the higher virial coefficients. This may be done, first of all, just by a careful direct analysis of Eq. (90),⁴⁶ but I would like to use this occasion to demonstrate a different, very interesting and counter-intuitive approach, called the *cluster expansion method*,⁴⁷ which allows streamlining such calculations.

Let us apply to our system, with the energy given by Eq. (87), the grand canonical distribution. (Just as in Sec. 2, we may argue that if the average number $\langle N \rangle$ of particles in a member of a grand canonical ensemble, with fixed μ and T , is much larger than 1, the relative fluctuations of N are small, so that all its thermodynamic properties should be similar to those when N is exactly fixed.) For our current case, Eq. (2.109) takes the form

$$\Omega = -T \ln \sum_{N=0}^{\infty} Z_N, \quad \text{with } Z_N \equiv e^{\mu N/T} \sum_m e^{-E_{m,N}/T}, \quad E_{m,N} = \sum_{k=1}^N \frac{p_k^2}{2m} + U(r_1, \dots, r_N). \quad (3.101)$$

(Notice that here, as at all discussions of the grand canonical distribution, N means a particular rather than the average number of particles.) Now let us try to forget for a minute that in real systems of interest the number of particles is extremely large, and start to calculate, one by one, the first terms Z_N .

In the term with $N = 0$, both contributions to $E_{m,N}$ vanish, and so does the factor $\mu N/T$, so that $Z_0 = 1$. In the next term, with $N = 1$, the interaction term vanishes, so that $E_{m,1}$ is reduced to the kinetic energy of one particle, giving

$$Z_1 = e^{\mu/T} \sum_k \exp \left\{ -\frac{p_k^2}{2mT} \right\}. \quad (3.102)$$

Making the usual transition from the summation to integration, we may write

$$Z_1 = Z I_1, \quad \text{where } Z \equiv e^{\mu/T} \frac{gV}{(2\pi\hbar)^3} \int \exp \left\{ -\frac{p^2}{2mT} \right\} d^3 p, \quad \text{and } I_1 \equiv 1. \quad (3.103)$$

This is the same simple (Gaussian) integral as in Eq. (6), giving

⁴⁶ L. Boltzmann has used that way to calculate the 3rd and 4th virial coefficients for the hardball model – as much as can be done analytically.

⁴⁷ This method was developed in 1937-38 by J. Mayer and collaborators for the classical gas, and generalized to quantum systems in 1938 by B. Kahn and G. Uhlenbeck.

$$Z = e^{\mu/T} \frac{gV}{(2\pi\hbar)^3} (2\pi mT)^{3/2} = e^{\mu/T} gV \left(\frac{mT}{2\pi\hbar^2} \right)^{3/2}. \quad (3.104)$$

Now let us explore the next term, with $N=2$, which describes, in particular, pair interactions $U=U(\mathbf{r})$, with $\mathbf{r} = \mathbf{r} - \mathbf{r}'$. Due to the assumed particle indistinguishability, this term needs the “correct Boltzmann counting” factor $1/2!$ – cf. Eqs. (12) and (88):

$$Z_2 = e^{2\mu/T} \frac{1}{2!} \sum_{k,k'} \left[\exp \left\{ -\frac{p_k^2}{2mT} - \frac{p_{k'}^2}{2mT} \right\} e^{-U(\mathbf{r})/T} \right]. \quad (3.105)$$

Since U is coordinate-dependent, here the transfer from the summation to integration should be done more carefully than in the first term – cf. Eqs. (24) and (88):

$$Z_2 = e^{2\mu/T} \frac{1}{2!} \frac{(gV)^2}{(2\pi\hbar)^6} \int \exp \left\{ -\frac{p^2}{2mT} \right\} d^3 p \times \int \exp \left\{ -\frac{p'^2}{2mT} \right\} d^3 p' \times \frac{1}{V} \int e^{-U(\mathbf{r})/T} d^3 r. \quad (3.106)$$

Comparing this expression with the Eq. (104) for the parameter Z , we get

$$Z_2 = \frac{Z^2}{2!} I_2, \quad \text{where } I_2 \equiv \frac{1}{V} \int e^{-U(\mathbf{r})/T} d^3 r. \quad (3.107)$$

Acting absolutely similarly, for the third term of the grand canonical sum we may get

$$Z_3 = \frac{Z^3}{3!} I_3, \quad \text{where } I_3 \equiv \frac{1}{V^2} \int e^{-U(\mathbf{r}', \mathbf{r}'')/T} d^3 r' d^3 r'', \quad (3.108)$$

where \mathbf{r}' and \mathbf{r}'' are the vectors characterizing the mutual positions of 3 particles – see Fig. 6b.

These results may be extended by induction to an arbitrary N . Plugging the expression for Z_N into the first of Eqs. (101) and recalling that $\Omega = -PV$, we get the equation of state of the gas in the form

$$P = \frac{T}{V} \ln \left(1 + ZI_1 + \frac{Z^2}{2!} I_2 + \frac{Z^3}{3!} I_3 + \dots \right). \quad (3.109)$$

As a sanity check: at $U=0$, all integrals I_N are equal to 1, and the expression under the logarithm is just the Taylor expansion of the function e^Z , giving $P = TZ/V$, and $\Omega = -PV = -TZ$. In this case, according to the last of Eqs. (1.62), the *average* number of particles of particles in the system is $\langle N \rangle = -(\partial\Omega/\partial\mu)_{T,V} = Z$, because since $Z \propto \exp\{\mu/T\}$, $\partial Z/\partial\mu = Z/T$.⁴⁸ Thus, in this limit, we have happily recovered the equation of state of the ideal gas.

Returning to the general case of non-zero interactions, let us assume that the logarithm in Eq. (109) may be also represented as a direct Taylor expansion in Z :

$$P = \frac{T}{V} \sum_{l=1}^{\infty} \frac{J_l}{l!} Z^l. \quad (3.110)$$

Cluster expansion: pressure

⁴⁸ Actually, the fact that in that case $Z = \langle N \rangle$ could have been noted earlier – just by comparing Eq. (104) with Eq. (32).

(The lower limit of the sum reflects the fact that according to Eq. (109), at $Z = 0$, $P = (T/V) \ln 1 = 0$, so that the coefficient J_0 in a more complete version of Eq. (110) would equal 0 anyway.) According to Eq. (1.60), this expansion corresponds to the grand potential

$$\Omega = -PV = -T \sum_{l=1}^{\infty} \frac{J_l}{l!} Z^l. \quad (3.111)$$

Again using the last of Eqs. (1.62), and the definition (104) of the parameter Z , we get

Cluster
expansion:
 $\langle N \rangle$

$$\langle N \rangle = \sum_{l=1}^{\infty} \frac{J_l}{(l-1)!} Z^l. \quad (3.112)$$

This equation may be used for finding Z for the given $\langle N \rangle$, and hence for the calculation of the equation of state from Eq. (110). The only remaining conceptual action item is to express the coefficients J_l via the integrals I_N participating in the expansion (109). This may be done using the well-known Taylor expansion of the logarithm function,⁴⁹

$$\ln(1 + \xi) = \sum_{l=1}^{\infty} (-1)^{l+1} \frac{\xi^l}{l}. \quad (3.113)$$

Using it together with Eq. (109), we get a Taylor series in Z , starting as

$$P = \frac{T}{V} \left[Z + \frac{Z^2}{2!} (I_2 - 1) + \frac{Z^3}{3!} [(I_3 - 1) - 3(I_2 - 1)] + \dots \right]. \quad (3.114)$$

Comparing this expression with Eq. (110), we see that

$$\begin{aligned} J_1 &= 1, \\ J_2 &= I_2 - 1 = \frac{1}{V} \int (e^{-U(\mathbf{r})/T} - 1) d^3 r, \\ J_3 &= (I_3 - 1) - 3(I_2 - 1) \\ &= \frac{1}{V^2} \int (e^{-U(\mathbf{r}', \mathbf{r}'')/T} - e^{-U(\mathbf{r}')/T} - e^{-U(\mathbf{r}'')/T} - e^{-U(\mathbf{r}'')/T} + 2) d^3 r' d^3 r'', \dots \end{aligned} \quad (3.115)$$

where $\mathbf{r}''' \equiv \mathbf{r}' - \mathbf{r}''$ - see Fig. 6b. The expression of J_2 , describing the pair interactions of particles, is (besides a different numerical factor) equal to the second virial coefficient $B(T)$ - see Eq. (93). As a reminder, the subtraction of 1 from the integral I_2 in the second of Eqs. (115) makes the contribution of each elementary 3D volume $d^3 r$ into the integral J_2 different from zero only if at this \mathbf{r} two particles interact ($U \neq 0$). Very similarly, in the last of Eqs. (115), the subtraction of three pair-interaction terms from $(I_3 - 1)$ makes the contribution from an elementary 6D volume $d^3 r' d^3 r''$ into the integral J_3 different from zero only if at that mutual location of particles, all *three* of them interact simultaneously, etc.

⁴⁹ Looking at Eq. (109), one may think that since $\xi = Z + Z^2 I_2 / 2 + \dots$ is of the order of at least $Z \sim \langle N \rangle \gg 1$, the expansion (113), which converges only if $|\xi| < 1$, is illegitimate. However, the expansion is justified by its result (114), in which the n^{th} term is of the order of $\langle N \rangle^n (V_0/V)^{n-1} / n!$, so that the series does converge if the gas density is sufficiently low: $\langle N \rangle / V \ll 1 / V_0$, i.e. $r_{\text{ave}} \gg r_0$. This is the very beauty of the cluster expansion, whose few first terms, rather unexpectedly, give good approximation even for a gas with $\langle N \rangle \gg 1$ particles.

In order to illustrate the cluster expansion method at work, let us eliminate the factor Z from the system of equations (110) and (112), with accuracy to terms $O(Z^2)$. For that, let us spell out these equations up to the terms $O(Z^3)$:

$$\frac{PV}{T} = J_1 Z + \frac{J_2}{2} Z^2 + \frac{J_3}{6} Z^3 + \dots, \quad (3.116)$$

$$\langle N \rangle = J_1 Z + J_2 Z^2 + \frac{J_3}{2} Z^3 + \dots, \quad (3.117)$$

and then divide these two expressions. We get the following result:

$$\frac{PV}{\langle N \rangle T} = \frac{1 + (J_2 / 2J_1)Z + (J_3 / 6J_1)Z^2 + \dots}{1 + (J_2 / J_1)Z + (J_3 / 2J_1)Z^2 + \dots} \approx 1 - \frac{J_2}{2J_1}Z + \left(\frac{J_2^2}{2J_1^2} - \frac{J_3}{3J_1} \right) Z^2, \quad (3.118)$$

whose final form is accurate to terms $O(Z^2)$. In this approximation, we may again use Eq. (117), now solved for Z with the same accuracy:

$$Z \approx \langle N \rangle - \frac{J_2}{J_1} \langle N \rangle^2. \quad (3.119)$$

Plugging this expression into Eq. (118), we get the virial expansion (100) with

$$B(T) = -\frac{J_2}{2J_1}V, \quad C(T) = \left(\frac{J_2^2}{2J_1^2} - \frac{J_3}{3J_1} \right) V^2. \quad (3.120)$$

2nd and 3rd virial coefficients

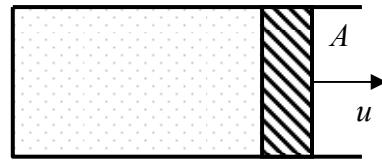

The first of these relations, combined with the first two of Eqs. (115), yields for the 2nd virial coefficient the same Eq. (96), $B(T) = 4V_0$, that was obtained from the Gibbs distribution. The second of these relations enables the calculation of the 3rd virial coefficient $C(T)$. (Let me leave the calculation of J_3 and $C(T)$, for the hardball model, for the reader's exercise.) Evidently, a more complete solution of Eqs. (114), (116), and (117) may be used to calculate an arbitrary virial coefficient, though starting from the 5th coefficient, such calculations may be completed only numerically even in the simplest hardball model.

3.6. Exercise problems

3.1. Use the Maxwell distribution for an alternative (statistical) calculation of the mechanical work performed by the Szilard engine discussed in Sec. 2.3.

Hint: You may assume the simplest geometry of the engine – see Fig. 2.4.

3.2. Use the Maxwell distribution to calculate the *drag coefficient* $\eta \equiv -\partial \langle \mathcal{F} \rangle / \partial u$, where \mathcal{F} is the force exerted by an ideal classical gas on a piston moving with a low velocity u , in the simplest geometry shown in the figure on the right, assuming that collisions of gas particles with the piston are elastic.

3.3. Derive the equation of state of the ideal classical gas from the grand canonical distribution.

3.4. Prove that Eq. (22),

$$\Delta S = N_1 \ln \frac{V_1 + V_2}{V_1} + N_2 \ln \frac{V_1 + V_2}{V_2},$$

derived for the change of entropy at mixing of two ideal classical gases of completely distinguishable particles (that initially had equal densities N/V and temperatures T), is also valid if particles in each of the initial volumes are indistinguishable from each other but different from those in the counterpart volume. For simplicity, you may assume that masses and internal degeneracy factors of all particles are equal.

3.5. A round cylinder of radius R and length L , containing an ideal classical gas of $N \gg 1$ particles of mass m each, is rotated about its symmetry axis with angular velocity ω . Assuming that the gas as the whole rotates with the cylinder, and is in thermal equilibrium at temperature T ,

- (i) calculate the gas pressure distribution along its radius, and analyze its temperature dependence, and
- (ii) neglecting the internal degrees of freedom of the particles, calculate the total energy of the gas and its heat capacity in the high- and low-temperature limits.

3.6. $N \gg 1$ classical, non-interacting, indistinguishable particles of mass m are confined in a parabolic, spherically-symmetric 3D potential well $U(\mathbf{r}) = \kappa r^2/2$. Use two different approaches to calculate all major thermodynamic characteristics of the system, in thermal equilibrium at temperature T , including its heat capacity. Which of the results should be changed if the particles are distinguishable, and how?

Hint: Suggest a replacement of the notions of volume and pressure, appropriate for this system.

3.7. In the simplest model of thermodynamic equilibrium between the liquid and gas phases of the same molecules, temperature and pressure do not affect the molecule's condensation energy Δ . Calculate the concentration and pressure of such *saturated vapor*, assuming that it behaves as an ideal gas of classical particles.

3.8. An ideal classical gas of $N \gg 1$ particles is confined in a container of volume V and wall surface area A . The particles may condense on container walls, releasing energy Δ per particle, and forming an ideal 2D gas. Calculate the equilibrium number of condensed particles and the gas pressure, and discuss their temperature dependences.

3.9. The inner surfaces of the walls of a closed container of volume V , filled with $N \gg 1$ particles, have $N_S \gg 1$ similar traps (small potential wells). Each trap can hold only one particle, at potential energy $-\Delta < 0$. Assuming that the gas of the particles in the volume is ideal and classical, derive an equation for the chemical potential μ of the system in equilibrium, and use it to calculate the potential and the gas pressure in the limits of small and large values of the N/N_S ratio.

3.10. Calculate the magnetic response (the *Pauli paramagnetism*) of a degenerate ideal gas of spin- $1/2$ particles to a weak external magnetic field, due to a partial spin alignment with the field.

3.11. Calculate the magnetic response (the *Landau diamagnetism*) of a degenerate ideal gas of electrically charged fermions to a weak external magnetic field, due to their orbital motion.

3.12.* Explore the *Thomas-Fermi model* of a heavy atom, with nuclear charge $Q = Ze \gg e$, in which the electrons are treated as a degenerate Fermi gas, interacting with each other only via their contribution to the common electrostatic potential $\phi(\mathbf{r})$. In particular, derive the ordinary differential equation obeyed by the radial distribution of the potential, and use it to estimate the effective radius of the atom.⁵⁰

3.13.* Use the Thomas-Fermi model, explored in the previous problem, to calculate the total binding energy of a heavy atom. Compare the result with that for a simpler model, in that the Coulomb electron-electron interaction of electrons is completely ignored.

3.14. Calculate the characteristic *Thomas-Fermi length* λ_{TF} of weak electric field's screening by conduction electrons in a metal, modeling their ensemble as an ideal, degenerate, isotropic Fermi gas.

Hint: Assume that λ_{TF} is much larger than the Bohr radius r_B .

3.15. For a degenerate ideal 3D Fermi gas of N particles, confined in a rigid-wall box of volume V , calculate the temperature dependencies of its pressure P and the heat capacity difference $(C_P - C_V)$, in the leading approximation in $T \ll \varepsilon_F$. Compare the results with those for the ideal classical gas.

Hint: You may like to use the solution of Problem 1.9.

3.16. How would the Fermi statistics of an ideal gas affect the barometric formula (28)?

3.17. Derive general expressions for the energy E and the chemical potential μ of a uniform Fermi gas of $N \gg 1$ non-interacting, indistinguishable, ultra-relativistic particles.⁵¹ Calculate E , and also the gas pressure P explicitly in the degenerate gas limit $T \rightarrow 0$. In particular, is Eq. (48) valid in this case?

3.18. Use Eq. (49) to calculate the pressure of an ideal gas of ultra-relativistic, indistinguishable quantum particles, for an arbitrary temperature, as a function of the total energy E of the gas, and its volume V . Compare the result with the corresponding relations for the electromagnetic blackbody radiation and for an ideal gas of non-relativistic particles.

3.19.* Calculate the speed of sound in an ideal gas of ultra-relativistic fermions of density n at negligible temperature.

⁵⁰ Since this problem, and the next one, are important for atomic physics, and at their solution, thermal effects may be ignored, they were given in Chapter 8 of the QM part of the series as well, for the benefit of readers who would not take this SM part. Note, however, that the argumentation in their solutions may be streamlined by using the notion of the chemical potential μ , which was introduced only in this course.

⁵¹ This is, for example, an approximate but reasonable model for electrons in white dwarf stars, whose Coulomb interaction is mostly compensated by the charge of nuclei of fully ionized helium atoms.

3.20. Calculate basic thermodynamic characteristics, including all relevant thermodynamic potentials, specific heat, and the surface tension of a uniform, non-relativistic 2D electron gas with given areal density $n \equiv N/A$:

- (i) at $T = 0$, and
- (ii) at low temperatures (in the lowest order in $T/\varepsilon_F \ll 1$, giving a nonzero result),

neglecting the Coulomb interaction effects.⁵²

3.21. Calculate the effective latent heat $\Lambda_{\text{ef}} \equiv -N(\partial Q/\partial N_0)_{N,V}$ of evaporation of the spatially-uniform Bose-Einstein condensate as a function of temperature T . Here Q is the heat absorbed by the (condensate + gas) system of $N \gg 1$ particles as a whole, while N_0 is the number of particles in the condensate alone.

3.22.* For an ideal, spatially-uniform Bose gas, calculate the law of the chemical potential's disappearance at $T \rightarrow T_c$, and use the result to prove that the heat capacity C_V is a continuous function of temperature at the critical point $T = T_c$.

3.23. In Chapter 1 of these notes, several thermodynamic relations involving entropy have been discussed, including the first of Eqs. (1.39):

$$S = -(\partial G / \partial T)_P.$$

If we combine this expression with Eq. (1.56), $G = \mu N$, it looks like that for the Bose-Einstein condensate, whose chemical potential μ equals zero at temperatures below the critical point T_c , the entropy should vanish as well. On the other hand, dividing both parts of Eq. (1.19) by dT , and assuming that at this temperature change the volume is kept constant, we get

$$C_V = T(\partial S / \partial T)_V.$$

(This equality was also mentioned in Chapter 1.) If the C_V is known as a function of temperature, the last relation may be integrated over T to calculate S :

$$S = \int_{V=\text{const}} \frac{C_V(T)}{T} dT + \text{const.}$$

According to Eq. (80), the specific heat for the Bose-Einstein condensate is proportional to $T^{3/2}$, so that the integration gives a non-zero entropy $S \propto T^{3/2}$. Resolve this apparent contradiction, and calculate the genuine entropy at $T = T_c$.

3.24. The standard analysis of the Bose-Einstein condensation, outlined in Sec. 4, may seem to ignore the energy quantization of the particles confined in volume V . Use the particular case of a cubic confining volume $V = a \times a \times a$ with rigid walls to analyze whether the main conclusions of the standard theory, in particular Eq. (71) for the critical temperature of the system of $N \gg 1$ particles, are affected by such quantization.

⁵² This condition may be approached reasonably well, for example, in 2D electron gases formed in semiconductor heterostructures (see, e.g., the discussion in QM Sec. 1.6, and the solution of Problem 3.2 of that course), due to the electron field's compensation by background ionized atoms, and its screening by highly doped semiconductor bulk.

3.25.* $N \gg 1$ non-interacting bosons are confined in a soft, spherically-symmetric potential well $U(\mathbf{r}) = m\omega^2 r^2/2$. Develop the theory of the Bose-Einstein condensation in this system; in particular, prove Eq. (74b), and calculate the critical temperature T_c^* . Looking at the solution, what is the most straightforward way to detect the condensation in experiment?

3.26. Calculate the chemical potential of an ideal, uniform 2D gas of spin-0 Bose particles as a function of its areal density n (the number of particles per unit area), and find out whether such gas can condense at low temperatures. Review your result for the case of a large ($N \gg 1$) but finite number of particles.

3.27. Can the Bose-Einstein condensation be achieved in a 2D system of $N \gg 1$ non-interacting bosons placed into a soft, axially-symmetric potential well, whose potential may be approximated as $U(\mathbf{r}) = m\omega^2 \rho^2/2$, where $\rho^2 \equiv x^2 + y^2$, and $\{x, y\}$ are the Cartesian coordinates in the particle confinement plane? If yes, calculate the critical temperature of the condensation.

3.28. Use Eqs. (115) and (120) to calculate the third virial coefficient $C(T)$ for the hardball model of particle interactions.

3.29. Assuming the hardball model, with volume V_0 per molecule, for the liquid phase, describe how the results of Problem 3.7 change if the liquid forms spherical drops of radius $R \gg V_0^{1/3}$. Briefly discuss the implications of the result for water cloud formation.

Hint: Surface effects in macroscopic volumes of liquids may be well described by attributing an additional energy γ (equal to the surface tension) to the unit surface area.⁵³

⁵³ See, e.g., CM Sec. 8.2.

Chapter 4. Phase Transitions

This chapter gives a rather brief discussion of coexistence between different states (“phases”) of collections of many similar particles, and transitions between these phases. Due to the complexity of these phenomena, which involve particle interactions, quantitative analytical results in this field have been obtained only for a few very simple models, typically giving only a very approximate description of real systems.

4.1. First-order phase transitions

From our everyday experience, say with water ice, liquid water, and water vapor, we know that one chemical substance (i.e. a set of many similar particles) may exist in different stable states – *phases*. A typical substance may have:

- (i) a dense *solid phase*, in which interatomic forces keep all atoms/molecules in virtually fixed relative positions, with just small thermal fluctuations about them;
- (ii) a *liquid phase*, of comparable density, in which the relative distances between atoms or molecules are almost constant, but the particles are virtually free to move around each other, and
- (iii) a *gas phase*, typically of a much lower density, in which the molecules are virtually free to move all around the containing volume.¹

Experience also tells us that at certain conditions, two different phases may be in thermal and chemical equilibrium – say, ice floating on water with the freezing-point temperature. Actually, in Sec. 3.4 we already discussed a qualitative theory of one such equilibrium: the Bose-Einstein condensate’s coexistence with the uncondensed “vapor” of similar particles. However, this is a rather exceptional case when the phase coexistence is due to the quantum nature of the particles (bosons) that may not interact directly. Much more frequently, the formation of different phases, and transitions between them, are due to particle repulsive and attractive interactions, briefly discussed in Sec. 3.5.

Phase transitions are sometimes classified by their *order*.² I will start their discussion with the so-called *first-order phase transitions* that feature non-zero *latent heat* Λ – the amount of heat that is necessary to turn one phase into another phase completely, even if temperature and pressure are kept constant.³ Unfortunately, even the simplest “microscopic” models of particle interaction, such as those discussed in Sec. 3.5, give rather complex equations of state. (As a reminder, even the simplest hardball model leads to the series (3.100), whose higher virial coefficients defy analytical calculation.) This is

¹ The plasma phase, in which atoms are partly or completely ionized, is frequently mentioned on one more phase, on equal footing with the three phases listed above, but one has to remember that in contrast to them, a typical electroneutral plasma consists of particles of two very different sorts – positive ions and electrons.

² Such classification schemes, started by Paul Ehrenfest in the early 1930s, have been repeatedly modified to accommodate new results for particular systems, and by now only the “first-order phase transition” is still a generally accepted term, but with a definition different from the original one.

³ For example, for water the latent heat of vaporization at the ambient pressure is as high as $\sim 2.2 \times 10^6$ J/kg, i.e. ~ 0.4 eV per molecule, making this ubiquitous liquid indispensable for effective fire fighting. (The latent heat of water ice’s melting is an order of magnitude lower.)

why I will follow the tradition to discuss the first-order phase transitions using a simple phenomenological model suggested in 1873 by Johannes Diderik van der Waals.

For its introduction, it is useful to recall that in Sec. 3.5 we have derived Eq. (3.99) – the equation of state for a classical gas of weakly interacting particles, which takes into account (albeit approximately) both interaction components necessary for a realistic description of gas condensation/liquefaction: the long-range attraction of the particles and their short-range repulsion. Let us rewrite that result as follows:

$$P + a \frac{N^2}{V^2} = \frac{NT}{V} \left(1 + \frac{Nb}{V}\right). \quad (4.1)$$

As we saw at the derivation of this formula, the physical meaning of the constant b is the effective volume of space taken by a particle pair collision – see Eq. (3.96). The relation (1) is quantitatively valid only if the second term in the parentheses is small, $Nb \ll V$, i.e. if the total volume excluded from particles' free motion because of their collisions is much smaller than the whole volume V . In order to describe the condensed phase (which I will call “liquid”⁴), we need to generalize this relation to the case $Nb \sim V$. Since the effective volume left for particles' motion is $V - Nb$, it is very natural to make the following replacement: $V \rightarrow V - Nb$, in the equation of state of the ideal gas. If we also keep on the left-hand side the term aN^2/V^2 , which describes the long-range attraction of particles, we get the *van der Waals equation of state*:

$$P + a \frac{N^2}{V^2} = \frac{NT}{V - Nb}. \quad (4.2)$$

Van der
Waals
equation

One advantage of this simple model is that in the rare gas limit, $Nb \ll V$, it reduces back to the microscopically-justified Eq. (1). (To verify this, it is sufficient to Taylor-expand the right-hand side of Eq. (2) in small $Nb/V \ll 1$, and retain only two leading terms.) Let us explore the basic properties of this model.

It is frequently convenient to discuss any equation of state in terms of its isotherms, i.e. the $P(V)$ curves plotted at constant T . As Eq. (2) shows, in the van der Waals model such a plot depends on four parameters: a , b , N , and T , complicating general analysis of the model. To simplify the task, it is convenient to introduce dimensionless variables: pressure $p \equiv P/P_c$, volume $v \equiv V/V_c$, and temperature $t \equiv T/T_c$, normalized to their so-called *critical values*,

$$P_c \equiv \frac{1}{27} \frac{a}{b^2}, \quad V_c \equiv 3Nb, \quad T_c \equiv \frac{8}{27} \frac{a}{b}, \quad (4.3)$$

whose meaning will be clear in a minute. In this notation, Eq. (2) acquires the following form,

$$p + \frac{3}{v^2} = \frac{8t}{3v - 1}, \quad (4.4)$$

so that the normalized isotherms $p(v)$ depend on only one parameter, the normalized temperature t – see Fig. 1.

⁴ Due to the phenomenological character of the van der Waals model, one cannot say for sure whether the condensed phase it predicts corresponds to a liquid or a solid. However, in most real substances at ambient conditions, gas coexists with liquid, hence the name.

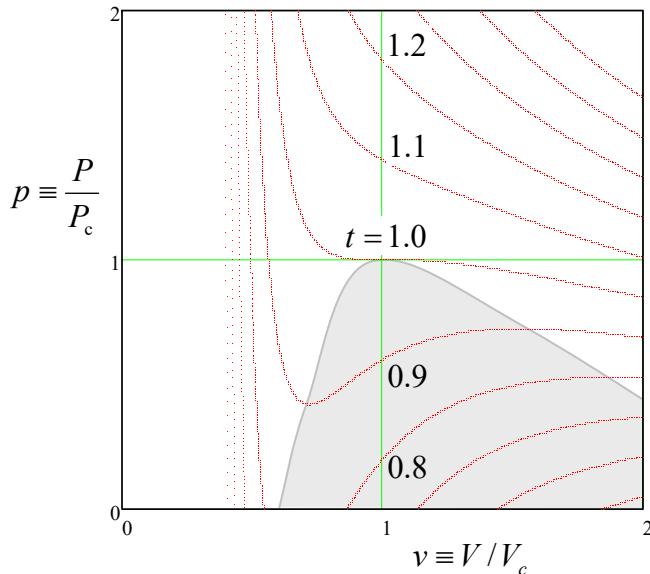

Fig. 4.1. The van der Waals equation of state, plotted on the $[p, v]$ plane for several values of the reduced temperature $t \equiv T/T_c$. Shading shows the single-phase instability range in that $(\partial P / \partial V)_T > 0$.

The most important property of these plots is that the isotherms have qualitatively different shapes in two temperature regions. At $t > 1$, i.e. $T > T_c$, pressure increases monotonically at gas compression (qualitatively, as in an ideal classical gas, with $P = NT/V$, to which the van der Waals system tends at $T \gg T_c$), i.e. with $(\partial P / \partial V)_T < 0$ at all points of the isotherm.⁵ However, below the critical temperature T_c , any isotherm features a segment with $(\partial P / \partial V)_T > 0$. It is easy to understand that, as least in a constant-pressure experiment (see, for example, Fig. 1.5),⁶ these segments describe a mechanically unstable equilibrium. Indeed, if due to a random fluctuation, the volume deviated upward from the equilibrium value, the pressure would also increase, forcing the environment (say, the heavy piston in Fig. 1.5) to allow further expansion of the system, leading to even higher pressure, etc. A similar deviation of volume downward would lead to a similar avalanche-like decrease of the volume. Such avalanche instability would develop further and further until the system has reached one of the stable branches with a negative slope $(\partial P / \partial V)_T$. In the range where the single-phase equilibrium state is unstable, the system as a whole may be stable only if it consists of the two phases (one with a smaller, and another with a higher density $n = N/V$) that are described by the two stable branches – see Fig. 2.

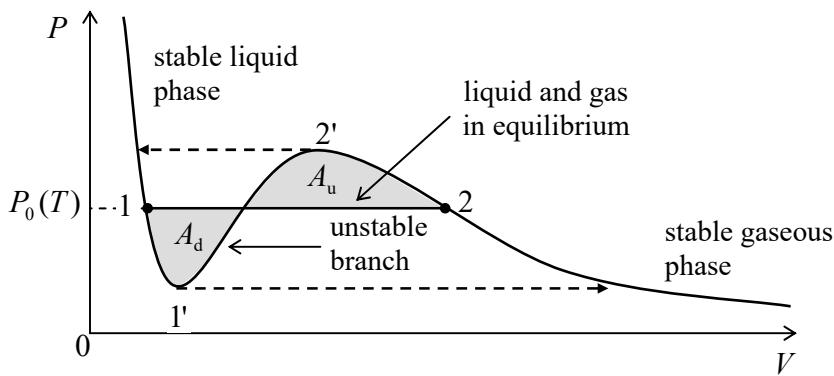

Fig. 4.2. Phase equilibrium at $T < T_c$ (schematically).

⁵ The special choice of numerical coefficients in Eq. (3) makes the border between these two regions to take place exactly at $t = 1$, i.e. at the temperature equal to T_c , with the critical point's coordinates equal to P_c and V_c .

⁶ Actually, this assumption is not crucial for our analysis of mechanical stability, because if a fluctuation takes place in a small part of the total volume V , its other parts play the role of pressure-fixing environment.

In order to understand the basic properties of this two-phase system, let us recall the general conditions of the thermodynamic equilibrium of two systems, which have been discussed in Chapter 1:

$$T_1 = T_2 \text{ (thermal equilibrium),} \quad (4.5)$$

$$\mu_1 = \mu_2 \text{ (“chemical” equilibrium),} \quad (4.6)$$

the latter condition meaning that the average energy of a single (“probe”) particle in both systems has to be the same. To those, we should add the evident condition of mechanical equilibrium,

$$P_1 = P_2 \text{ (mechanical equilibrium),} \quad (4.7)$$

which immediately follows from the balance of normal forces exerted on an inter-phase boundary.

If we discuss isotherms, Eq. (5) is fulfilled automatically, while Eq. (7) means that the effective isotherm $P(V)$ describing a two-phase system should be a horizontal line – see Fig. 2:

$$P = P_0(T). \quad (4.8)$$

Along this line,⁷ internal properties of each phase do not change; only the particle distribution is: it evolves gradually from all particles being in the liquid phase at point 1 to all particles being in the gas phase at point 2.⁸ In particular, according to Eq. (6), the chemical potentials μ of the phases should be equal at each point of the horizontal line (8). This fact enables us to find the line’s position: it has to connect points 1 and 2 in that the chemical potentials of the two phases are equal to each other. Let us recast this condition as

$$\int_1^2 d\mu = 0, \quad \text{i.e.} \quad \int_1^2 dG = 0, \quad (4.9)$$

where the integral may be taken along the single-phase isotherm. (For this mathematical calculation, the mechanical instability of states on some part of this curve is not important.) By its construction, along that curve, $N = \text{const}$ and $T = \text{const}$, so that according to Eq. (1.53c), $dG = -SdT + VdP + \mu dN$, for a slow (reversible) change, $dG = VdP$. Hence Eq. (9) yields

$$\int_1^2 VdP = 0. \quad (4.10)$$

This equality means that in Fig. 2, the shaded areas A_d and A_u should be equal.⁹

⁷ Frequently, $P_0(T)$ is called the *saturated vapor pressure*.

⁸ A natural question: is the two-phase state with $P = P_0(T)$ the only state existing between points 1 and 2? Indeed, the branches 1-1' and 2-2' of the single-phase isotherm also have negative derivatives $(\partial P/\partial V)_T$ and hence are mechanically stable with respect to small perturbations. However, these branches are actually *metastable*, i.e. have larger Gibbs energy per particle (i.e. μ) than the counterpart phase and are hence unstable to *larger* perturbations – such as foreign microparticles (say, dust), protrusions on the confining walls, etc. In very controlled conditions, these single-phase “superheated” and “supercooled” states can survive almost all the way to the zero-derivative points 1' and 2', leading to sudden jumps of the system into the counterpart phase. (At fixed pressure, such jumps go as shown by dashed lines in Fig. 2.) In particular, at the atmospheric pressure, purified water may be supercooled to almost -50°C , and superheated to nearly $+270^\circ\text{C}$. However, at more realistic conditions, perturbations result in the two-phase coexistence formation close to points 1 and 2.

⁹ This *Maxwell equal-area rule* (also called “Maxwell’s construct”) was suggested by J. C. Maxwell in 1875 using more complex reasoning.

As the same Fig. 2 figure shows, the Maxwell rule may be rewritten in a different form,

Maxwell
equal-area
rule

$$\int_1^2 [P - P_0(T)] dV = 0. \quad (4.11)$$

which is more convenient for analytical calculations than Eq. (10) if the equation of state may be explicitly solved for P – as it is in the van der Waals model (2). Such calculation (left for the reader’s exercise) shows that for that model, the temperature dependence of the saturated vapor pressure at low T is exponential,¹⁰

$$P_0(T) \propto P_c \exp\left\{-\frac{\Delta}{T}\right\}, \quad \text{with } \Delta = \frac{a}{b} \equiv \frac{27}{8} T_c, \quad \text{for } T \ll T_c, \quad (4.12)$$

corresponding very well to the physical picture of particle’s thermal activation from a potential well of depth Δ .

The signature parameter of a first-order phase transition, the latent heat of evaporation

Latent
heat:
definition

$$\Lambda \equiv \int_1^2 dQ, \quad (4.13)$$

may also be found by a similar integration along the single-phase isotherm. Indeed, using Eq. (1.19), $dQ = TdS$, we get

$$\Lambda = \int_1^2 TdS = T(S_2 - S_1). \quad (4.14)$$

Let us express the right-hand side of Eq. (14) via the equation of state. For that, let us take the full derivative of both sides of Eq. (6) over temperature, considering the value of $G = N\mu$ for each phase as a function of P and T , and taking into account that according to Eq. (7), $P_1 = P_2 = P_0(T)$:

$$\left(\frac{\partial G_1}{\partial T}\right)_P + \left(\frac{\partial G_1}{\partial P}\right)_T \frac{dP_0}{dT} = \left(\frac{\partial G_2}{\partial T}\right)_P + \left(\frac{\partial G_2}{\partial P}\right)_T \frac{dP_0}{dT}. \quad (4.15)$$

According to the first of Eqs. (1.39), the partial derivative $(\partial G/\partial T)_P$ is just minus the entropy, while according to the second of those equalities, $(\partial G/\partial P)_T$ is the volume. Thus Eq. (15) becomes

$$-S_1 + V_1 \frac{dP_0}{dT} = -S_2 + V_2 \frac{dP_0}{dT}. \quad (4.16)$$

Solving this equation for $(S_2 - S_1)$, and plugging the result into Eq. (14), we get the following *Clapeyron-Clausius formula*:

$$\Lambda = T(V_2 - V_1) \frac{dP_0}{dT}. \quad (4.17)$$

For the van der Waals model, this formula may be readily used for the analytical calculation of Λ in two limits: $T \ll T_c$ and $(T_c - T) \ll T_c$ – the exercises left for the reader. In the latter limit, $\Lambda \propto (T_c - T)^{1/2}$, naturally vanishing at the critical temperature.

¹⁰ It is fascinating how well is this Arrhenius exponent hidden in the polynomial van der Waals equation (2)!

Finally, some important properties of the van der Waals' model may be revealed more easily by looking at the set of its isochores $P = P(T)$ for $V = \text{const}$, rather than at the isotherms. Indeed, as Eq. (2) shows, all single-phase isochores are straight lines. However, if we interrupt these lines at the points when the single phase becomes metastable, and complement them with the (very nonlinear!) dependence $P_0(T)$, we get the pattern (called the *phase diagram*) shown schematically in Fig. 3a.

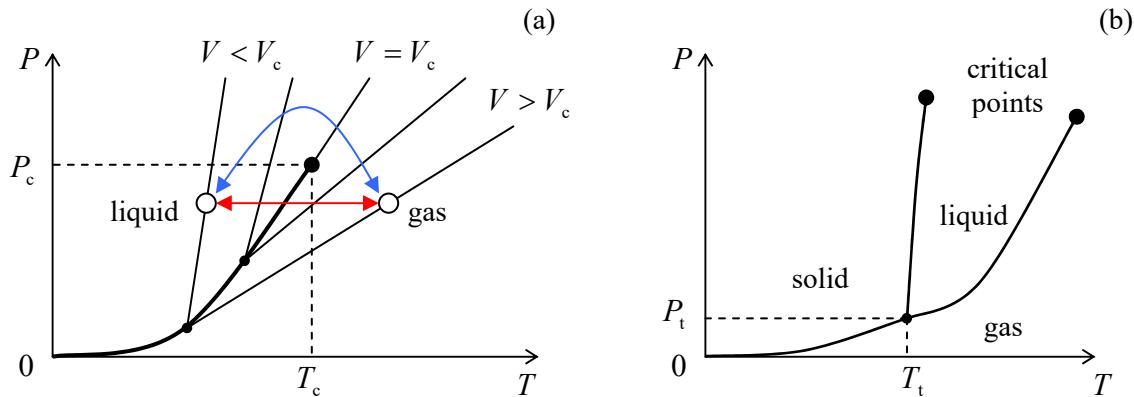

Fig. 4.3. (a) Van der Waals model's isochores, the saturated gas pressure diagram, and the critical point, and (b) the phase diagram of a typical three-phase system (all schematically).

At this plot, one more meaning of the critical point $\{P_c, T_c\}$ becomes very vivid. At fixed pressure $P < P_c$, the liquid and gaseous phases are clearly separated by the saturated pressure line $P_0(T)$, so if we achieve the transition between the phases just by changing temperature (see the red horizontal line in Fig. 3a), we have to pass through the phase equilibrium point, being delayed there to either give to the system the latent heat or take it out. However, if we perform the transition between the same initial and final points by changing both the pressure and temperature, going around the critical point (see the blue line in Fig. 3a), no definite point of transition may be observed: the substance stays in a single phase, and it is a subjective judgment of the observer in which region that phase should be called the liquid, and in which region – the gas. For water, the critical point corresponds to the temperature of 647 K (374°C), and $P_c \approx 22.1$ MPa (i.e. ~200 bars), so that a lecture demonstration of its critical behavior would require substantial safety precautions. This is why such demonstrations are typically carried out with other substances such as either diethyl ether,¹¹ with its much lower T_c (194°C) and P_c (3.6 MPa), or the now-infamous carbon dioxide CO₂, with even lower T_c (31.1°C), though higher P_c (7.4 MPa). Though these substances are colorless and clear in both gas and liquid phases, their separation (by gravity) is still visible, due to small differences in the optical refraction coefficient, at $P < P_c$, but not above P_c .¹²

Thus, in the van der Waals model, two phases may coexist, though only at certain conditions – in particular, $T < T_c$. Now a natural, more general question is whether the coexistence of more than two

¹¹ (CH₃-CH₂)-O-(CH₂-CH₃), historically the first popular general anesthetic.

¹² It is interesting that very close to the critical point the substance suddenly becomes opaque – in the case of ether, whitish. The qualitative explanation of this effect, called the *critical opalescence*, is simple: at this point, the difference of the Gibbs energies per particle (i.e. the chemical potentials) of the two phases becomes so small that unavoidable thermal fluctuations lead to spontaneous appearance and disappearance of relatively large (a few-μm-scale) single-phase regions in all the volume. A large concentration of boundaries of such randomly-shaped regions leads to strong light scattering.

phases of the same substance is possible. For example, can the water ice, the liquid water, and the water vapor (steam) all be in thermodynamic equilibrium? The answer is essentially given by Eq. (6). From thermodynamics, we know that for a uniform system (i.e. a single phase), pressure and temperature completely define the chemical potential $\mu(P, T)$. Hence, dealing with two phases, we had to satisfy just *one* chemical equilibrium condition (6) for *two* common arguments P and T . Evidently, this leaves us with one extra degree of freedom, so that the two-phase equilibrium is possible within a certain range of P at fixed T (or vice versa) – see again the horizontal line in Fig. 2 and the bold line in Fig. 3a. Now, if we want *three* phases to be in equilibrium, we need to satisfy *two* equations for these variables:

$$\mu_1(P, T) = \mu_2(P, T) = \mu_3(P, T). \quad (4.18)$$

Typically, the functions $\mu(P, T)$ are monotonic, so that the two equations (18) have just one solution, the so-called *triple point* $\{P_t, T_t\}$. Of course, the triple point $\{P_t, T_t\}$ of equilibrium between *three* phases should not be confused with the critical points $\{P_c, T_c\}$ of transitions between each of *two*-phase pairs. Fig. 3b shows, very schematically, their relation for a typical three-phase system solid-liquid-gas. For example, water, ice, and water vapor are at equilibrium at a triple point corresponding to $P_t \approx 0.612$ kPa¹³ and $T_t = 273.16$ K. The practical importance of this particular temperature point is that by an international agreement it has been accepted for the definition of not only the Kelvin temperature scale, but also of the Celsius scale's reference, as 0.01°C , so that the absolute temperature zero corresponds to exactly -273.15°C .¹⁴ More generally, triple points of purified simple substances (such as H₂, N₂, O₂, Ar, Hg, and H₂O) are broadly used for thermometer calibration, defining the so-called *international temperature scales* including the currently accepted scale ITS-90.

This analysis may be readily generalized to multi-component systems consisting of particles of several (say, L) sorts.¹⁵ If such a mixed system is in a single phase, i.e. is macroscopically uniform, its chemical potential may be defined by a natural generalization of Eq. (1.53c):

$$dG = -SdT + VdP + \sum_{l=1}^L \mu^{(l)} dN^{(l)}. \quad (4.19)$$

The last term reflects the fact that usually, each single phase is not a pure chemical substance, but has certain concentrations of all other components, so that $\mu^{(l)}$ may depend not only on P and T but also on the *concentrations* $c^{(l)} \equiv N^{(l)}/N$ of particles of each sort. If the total number N of particles is fixed, the number of independent concentrations is $(L - 1)$. For the chemical equilibrium of R phases, all R values of $\mu_r^{(l)}$ ($r = 1, 2, \dots, R$) have to be equal for particles of each sort: $\mu_1^{(l)} = \mu_2^{(l)} = \dots = \mu_R^{(l)}$, with each $\mu_r^{(l)}$ depending on $(L - 1)$ concentrations $c_r^{(l)}$, and also on P and T . This requirement gives $L(R - 1)$ equations for $(L - 1)R$ concentrations $c_r^{(l)}$, plus two common arguments P and T , i.e. for $[(L - 1)R + 2]$ independent variables. This means that the number of phases has to satisfy the limitation

Gibbs
phase
rule

$$L(R - 1) \leq (L - 1)R + 2, \quad \text{i.e. } R \leq L + 2, \quad (4.20)$$

¹³ Please note that for water, P_t is much lower than the normal atmospheric pressure (101.325 kPa).

¹⁴ Note the recent (2018) re-definition of the “legal” kelvin via joule (see, appendix CA: *Selected Physical Constants*); however, the new definition is compatible, within experimental accuracy, with that mentioned above.

¹⁵ Perhaps the most practically important example is the air/water system. For its detailed discussion, based on Eq. (19), the reader may be referred, e.g., to Sec. 3.9 in F. Schwabl, *Statistical Mechanics*, Springer (2000). Other important applications include liquid solutions, and metallic *alloys* – solid solutions of metal elements.

where the equality sign may be reached in just one point in the whole parameter space. This is the *Gibbs phase rule*. As a sanity check, for a single-component system, $L = 1$, the rule yields $R \leq 3$ – exactly the result we have already discussed.

4.2. Continuous phase transitions

As Fig. 2 illustrates, if we fix pressure P in a system with a first-order phase transition, and start changing its temperature, then the complete crossing of the transition-point line, defined by the equation $P_0(T) = P$, requires the insertion (or extraction) some non-zero latent heat Λ . Eqs. (14) and (17) show that Λ is directly related to non-zero differences between the entropies and volumes of the two phases (at the same pressure). As we know from Chapter 1, both S and V may be represented as the first derivatives of appropriate thermodynamic potentials. This is why P. Ehrenfest called such transitions, involving jumps of potentials' first derivatives, the *first-order* phase transitions.

On the other hand, there are phase transitions that have no first derivative jumps at the transition temperature T_c , so that the temperature point may be clearly marked, for example, by a jump of the second derivative of a thermodynamic potential – for example, the derivative $\partial C/\partial T$ which, according to Eq. (1.24), equals to $\partial^2 E/\partial T^2$. In the initial Ehrenfest classification, this was an example of a *second-order* phase transition. However, most features of such phase transitions are also pertinent to some systems in which the second derivatives of potentials are continuous as well. Due to this reason, I will use a more recent terminology (suggested in 1967 by M. Fisher), in which all phase transitions with $\Lambda = 0$ are called *continuous*.

Most (though not all) continuous phase transitions result from particle interactions. Here are some representative examples:

(i) At temperatures above ~ 490 K, the crystal lattice of barium titanate (BaTiO_3) is cubic, with a Ba ion in the center of each Ti-cornered cube (or vice versa) – see Fig. 4a. However, as the temperature is being lowered below that critical value, the sublattice of Ba ions starts moving along one of six sides of the TiO_3 sublattice, leading to a small deformation of both lattices – which become tetragonal. This is a typical example of a *structural transition*, in this particular case combined with a *ferroelectric transition*, because (due to the positive electric charge of the Ba ions) below the critical temperature the BaTiO_3 crystal acquires a spontaneous electric polarization even in the absence of external electric field.

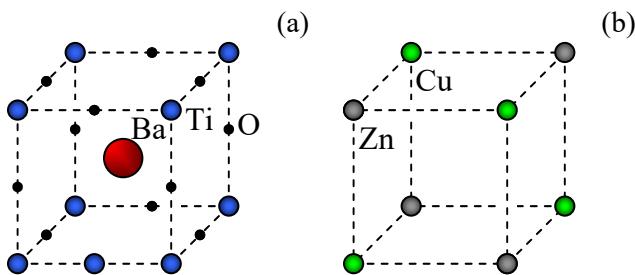

Fig. 4.4. Single cells of crystal lattices of (a) BaTiO_3 and (b) CuZn .

(ii) A different kind of phase transition happens, for example, in $\text{Cu}_x\text{Zn}_{1-x}$ alloys – so-called *brasses*. Their crystal lattice is always cubic, but above certain critical temperature T_c (which depends on x) any of its nodes may be occupied by either a copper or a zinc atom, at random. At $T < T_c$, a trend toward ordered atom alternation arises, and at low temperatures, the atoms are fully ordered, as shown in Fig. 4b for the stoichiometric case $x = 0.5$. This is a good example of an *order-disorder* transition.

(iii) At *ferromagnetic* transitions (such as the one taking place, for example, in Fe at 1,388 K) and *antiferromagnetic* transitions (e.g., in MnO at 116 K), lowering of temperature below the critical value¹⁶ does not change atom positions substantially, but results in a partial ordering of atomic spins, eventually leading to their full ordering (Fig. 5).

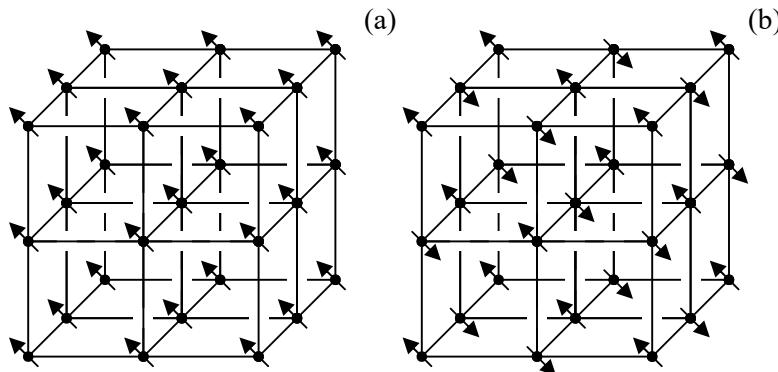

Fig. 4.5. Classical images of fully ordered phases: (a) a ferromagnet, and (b) an antiferromagnet.

Note that, as it follows from Eqs. (1.1)-(1.3), at ferroelectric transitions the role of pressure is played by the external electric field \mathcal{E} , and at the ferromagnetic transitions, by the external magnetic field \mathcal{H} . As we will see very soon, even in systems with continuous phase transitions, a gradual change of such an external field, at a fixed temperature, may induce jumps between metastable states, similar to those in systems with first-order phase transitions (see, e.g., the dashed arrows in Fig. 2), with non-zero decreases of the appropriate free energy.

Besides these standard examples, some other threshold phenomena, such as the formation of a coherent optical field in a laser, and even the self-excitation of oscillators with negative damping (see, e.g., CM Sec. 5.4), may be treated, at certain conditions, as continuous phase transitions.¹⁷

The general feature of all these transitions is the gradual formation, at $T < T_c$, of certain *ordering*, which may be characterized by some *order parameter* $\eta \neq 0$. The simplest example of such an order parameter is the magnetization at the ferromagnetic transitions, and this is why the continuous phase transitions are usually discussed on certain models of ferromagnetism. (I will follow this tradition, while mentioning in passing other important cases that require a substantial modification of the theory.) Most of such models are defined on an infinite 3D cubic lattice (see, e.g., Fig. 5), with evident generalizations to lower dimensions. For example, the *Heisenberg model* of a ferromagnet (suggested in 1928) is defined by the following Hamiltonian:

Heisenberg model

$$\hat{H} = -J \sum_{\{k,k'\}} \hat{\sigma}_k \cdot \hat{\sigma}_{k'} - \sum_k \mathbf{h} \cdot \hat{\sigma}_k , \quad (4.21)$$

where $\hat{\sigma}_k$ is the Pauli vector operator¹⁸ acting on the k^{th} spin, and \mathbf{h} is the normalized external magnetic field:

¹⁶ For ferromagnets, this point is usually referred to at the *Curie temperature*, and for antiferromagnets, as the *Néel temperature*.

¹⁷ Unfortunately, I will have no time/space for these interesting (and practically important) generalizations, and have to refer the interested reader to the famous monograph by R. Stratonovich, *Topics in the Theory of Random Noise*, in 2 vols., Gordon and Breach, 1963 and 1967, and/or the influential review by H. Haken, *Ferstkörperprobleme* **10**, 351 (1970).

$$\mathbf{h} \equiv m_0 \mu_0 \mathcal{H} . \quad (4.22)$$

(Here m_0 is the magnitude of the spin's magnetic moment; for the Heisenberg model to be realistic, it should be of the order of the *Bohr magneton* $\mu_B \equiv e\hbar/2m_e \approx 0.927 \times 10^{-23}$ J/T.) The figure brackets $\{j, j'\}$ in Eq. (21) denote the summation over the pairs of adjacent lattice sites, so that the magnitude of the constant J may be interpreted as the maximum coupling energy per “bond” between two adjacent particles. At $J > 0$, the coupling tries to keep spins aligned, i.e. to install the ferromagnetic ordering.¹⁹ The second term in Eq. (21) describes the effect of the external magnetic field, which tries to orient all spin magnetic moments along its direction.²⁰

However, even the Heisenberg model, while being rather approximate (in particular because its standard form (21) is only valid for spins- $\frac{1}{2}$), is still rather complex for analysis. This is why most theoretical results have been obtained for its classical twin, the *Ising model*:²¹

$$E_m = -J \sum_{\{k, k'\}} s_k s_{k'} - h \sum_k s_k . \quad (4.23)$$
Ising
model

Here E_m are the particular values of the system's energy in each of its 2^N possible states with all possible combinations of the binary classical variables $s_k = \pm 1$, while h is the normalized external magnetic field's magnitude – see Eq. (22). (Despite its classical character, the variable s_k , modeling the field-oriented Cartesian component of the real spin, is usually called “spin” for brevity, and I will follow this tradition.) Somewhat shockingly, even for this toy model, no exact analytical 3D solution that would be valid at arbitrary temperature has been found yet, and the solution of its 2D version by L. Onsager in 1944 (see Sec. 5 below) is still considered one of the top intellectual achievements of statistical physics. Still, Eq. (23) is very useful for the introduction of basic notions of continuous phase transitions, and methods of their analysis, so that for my brief discussion I will mostly use this model.²²

Evidently, if $T = 0$ and $h = 0$, the lowest possible energy,

$$E_{\min} = -JNd , \quad (4.24)$$

where d is the lattice dimensionality, is achieved in the “ferromagnetic” phase in which all spins s_k are equal to either $+1$ or -1 , so that $\langle s_k \rangle = \pm 1$ as well. On the other hand, at $J = 0$, the spins are independent, and if $h = 0$ as well, all s_k are completely random, with the 50% probability to take either of values ± 1 , so that $\langle s_k \rangle = 0$. Hence in the general case (with arbitrary J and h), we may use the average

$$\eta = \langle s_k \rangle \quad (4.25)$$
Ising
model:
order
parameter

¹⁸ See, e.g., QM Sec. 4.4.

¹⁹ At $J < 0$, the first term of Eq. (21) gives a reasonable model of an antiferromagnet, but in this case, the external magnetic field effects are more subtle; I will not have time to discuss them.

²⁰ See, e.g., QM Eq. (4.163).

²¹ Named after Ernst Ising who explored the 1D version of the model in detail in 1925, though a similar model was discussed earlier (in 1920) by Wilhelm Lenz.

²² For more detailed discussions of phase transition theories (including other popular models of the ferromagnetic phase transition, e.g., the *Potts model*), see, e.g., either H. Stanley, *Introduction to Phase Transitions and Critical Phenomena*, Oxford U. Press, 1971; or A. Patashinskii and V. Pokrovskii, *Fluctuation Theory of Phase Transitions*, Pergamon, 1979; or B. McCoy, *Advanced Statistical Mechanics*, Oxford U. Press, 2010. For a very concise text, I can recommend J. Yeomans, *Statistical Mechanics of Phase Transitions*, Clarendon, 1992.

as a good measure of spin ordering, i.e. as the order parameter. Since in a real ferromagnet, each spin carries a magnetic moment, the order parameter η is proportional to the Cartesian component of the system's magnetization, in the direction of the applied magnetic field.

Now that the Ising model gave us a very clear illustration of the order parameter, let me use this notion for quantitative characterization of continuous phase transitions. Due to the difficulty of theoretical analyses of most models of the transitions at arbitrary temperatures, their theoretical discussions are focused mostly on a close vicinity of the critical point T_c . Both experiment and theory show that in the absence of an external field, the function $\eta(T)$ is close to a certain power,

$$\eta \propto \tau^\beta, \quad \text{for } \tau > 0, \text{ i.e. } T < T_c, \quad (4.26)$$

of the small deviation from the critical temperature – which is conveniently normalized as

$$\tau \equiv \frac{T_c - T}{T_c}. \quad (4.27)$$

Remarkably, most other key variables follow a similar temperature behavior, with *critical exponents* being the same for both signs of τ . In particular, the heat capacity at a fixed magnetic field behaves as²³

$$c_h \propto |\tau|^{-\alpha}. \quad (4.28)$$

Similarly, the (normalized) low-field *susceptibility*²⁴

$$\chi \equiv \frac{\partial \eta}{\partial h} \Big|_{h=0} \propto |\tau|^{-\gamma}. \quad (4.29)$$

Two other important critical exponents, ζ and ν , describe the temperature behavior of the *correlation function* $\langle s_k s_{k'} \rangle$, whose dependence on the distance $r_{kk'}$ between two spins may be well fitted by the following law,

$$\langle s_k s_{k'} \rangle \propto \frac{1}{r_{kk'}^{d-2+\zeta}} \exp\left\{-\frac{r_{kk'}}{r_c}\right\}, \quad (4.30)$$

with the *correlation radius*

$$r_c \propto |\tau|^{-\nu}. \quad (4.31)$$

Finally, three more critical exponents, usually denoted ε , δ , and μ , describe the external field dependences of, respectively, c , η , and r_c at $\tau > 0$. For example, δ is defined as

$$\eta \propto h^{1/\delta}. \quad (4.32)$$

(Other field exponents are used less frequently, and for their discussion, the interested reader is referred to the special literature that was cited above.)

The leftmost column of Table 1 shows the ranges of experimental values of the critical exponents for various 3D physical systems featuring continuous phase transitions. One can see that their values vary from system to system, leaving no hope for a universal theory that would describe them all

²³ The forms of this and other functions of τ are selected to make all critical exponents non-negative.

²⁴ In most models of ferromagnetic phase transitions, this variable is proportional to the genuine low-field magnetic susceptibility χ_m of the material – see, e.g., EM Eq. (5.111).

exactly. However, certain combinations of the exponents are much more reproducible – see the four bottom lines of the table.

Table 4.1. Major critical exponents of continuous phase transitions

Exponents and combinations	Experimental range (3D) ^(a)	Landau's theory	2D Ising model	3D Ising model	3D Heisenberg Model ^(d)
α	0 – 0.14	0 ^(b)	(c)	0.12	-0.14
β	0.32 – 0.39	1/2	1/8	0.31	0.3
γ	1.3 – 1.4	1	7/4	1.25	1.4
δ	4-5	3	15	5	?
ν	0.6 – 0.7	1/2	1	0.64	0.7
ζ	0.05	0	1/4	0.05	0.04
$(\alpha + 2\beta + \gamma)/2$	1.00 ± 0.005	1	1	1	1
$\delta - \gamma/\beta$	0.93 ± 0.08	1	1	1	?
$(2 - \zeta)\nu/\gamma$	1.02 ± 0.05	1	1	1	1
$(2 - \alpha)/\nu d$?	4/d	1	1	1

(a) Experimental data are from the monograph by A. Patashinskii and V. Pokrovskii, cited above.

(b) Discontinuity at $\tau = 0$ – see below.

(c) Instead of following Eq. (28), in this case c_h diverges as $\ln|\tau|$.

(d) With the order parameter η defined as $\langle \mathbf{\sigma}_j \cdot \mathbf{B} \rangle / \mathcal{B}$.

Historically the first (and perhaps the most fundamental) of these *universal relations* was derived in 1963 by J. Essam and M. Fisher:

$$\alpha + 2\beta + \gamma = 2. \quad (4.33)$$

It may be proved, for example, by finding the temperature dependence of the magnetic field value, h_τ , that changes the order parameter by the same amount as a finite temperature deviation $\tau > 0$ gives at $h = 0$. Comparing Eqs. (26) and (29), we get

$$h_\tau \propto \tau^{\beta+\gamma}. \quad (4.34)$$

By the physical sense of h_τ , we may expect that such a field has to affect the system's free energy F by an amount comparable to the effect of a bare temperature change τ . Ensemble-averaging the last term of Eq. (23) and using the definition (25) of the order parameter η , we see that the change of F (per particle) due to the field equals $-h_\tau \eta$ and, according to Eq. (26), scales as $h_\tau \tau^\beta \propto \tau^{(2\beta+\gamma)}$ ²⁵

²⁵ As was already discussed in Secs. 1.4 and 2.4, there is some dichotomy of terminology for free energies in literature. In models (21) and (23), the magnetic field effects are accounted for at the microscopic level, by the inclusion of the corresponding term into each particular value E_m . From this point of view, the list of macroscopic variables in these systems does not include either P and V or their magnetic analogs, so that we may take $G \equiv F +$

In order to estimate the thermal effect on F , let me first elaborate a bit more on the useful thermodynamic formula already mentioned in Sec. 1.3:

$$C_X = T \left(\frac{\partial S}{\partial T} \right)_X , \quad (4.35)$$

where X means the variable(s) maintained constant at the temperature variation. In the standard “ P - V ” thermodynamics, we may use Eqs. (1.35) for $X = V$, and Eqs. (1.39) for $X = P$, to write

$$C_V = T \left(\frac{\partial S}{\partial T} \right)_{V,N} = -T \left(\frac{\partial^2 F}{\partial T^2} \right)_{V,N} , \quad C_P = T \left(\frac{\partial S}{\partial T} \right)_{P,N} = -T \left(\frac{\partial^2 G}{\partial T^2} \right)_{P,N} . \quad (4.36)$$

As was just discussed, in the ferromagnetic models of the type (21) or (23), at a constant field h , the role of G is played by F , so that Eq. (35) yields

$$C_h = T \left(\frac{\partial S}{\partial T} \right)_{h,N} = -T \left(\frac{\partial^2 F}{\partial T^2} \right)_{h,N} . \quad (4.37)$$

The last form of this relation means that F may be found by double integration of $(-C_h/T)$ over temperature. With Eq. (28) for $c_h \propto C_h$, this means that near T_c , the free energy scales as the double integral of $c_h \propto \tau^{-\alpha}$ over τ . In the limit $\tau \ll 1$, the factor T may be treated as a constant; as a result, the change of F due to $\tau > 0$ alone scales as $\tau^{2-\alpha}$. Requiring this change to be proportional to the same power of τ as the field-induced part of the energy, we finally get the Essam-Fisher relation (33).

Using similar reasoning, it is straightforward to derive a few other universal relations of critical exponents, including the *Widom relation*,

$$\delta - \frac{\gamma}{\beta} = 1 , \quad (4.38)$$

very similar relations for other high-field exponents ε and μ (which I do not have time to discuss), and the *Fisher relation*

$$\nu(2-\zeta) = \gamma . \quad (4.39)$$

A slightly more complex reasoning, involving the so-called *scaling hypothesis*, yields the following dimensionality-dependent *Josephson relation*

$$\nu d = 2 - \alpha . \quad (4.40)$$

The second column of Table 1 shows that at least three of these relations are in a very reasonable agreement with experiment, so that we may use their set as a testbed for various theoretical approaches to continuous phase transitions.

4.3. Landau’s mean-field theory

The highest-level approach to continuous phase transitions, formally not based on any particular microscopic model (though in fact implying either the Ising model (23) or one of its siblings), is the *mean-field theory* developed in 1937 by L. Landau, on the basis of prior ideas by P. Weiss – to be

$PV = F + \text{const}$, and the equilibrium (at fixed h , T and N) corresponds to the minimum of the *Helmholtz* free energy F .

discussed in the next section. The main idea of this phenomenological approach is to represent the free energy's change ΔF at the phase transition as an explicit function of the order parameter η (25). Since at $T \rightarrow T_c$, the order parameter has to tend to zero, this change,

$$\Delta F \equiv F(T) - F(T_c), \quad (4.41)$$

may be expanded into the Taylor series in η , and only a few, most important first terms of that expansion retained. In order to keep the symmetry between two possible signs of the order parameter (i.e. between two possible spin directions in the Ising model) in the absence of external field, at $h = 0$ this expansion should include only even powers of η :

$$\Delta f|_{h=0} \equiv \frac{\Delta F}{V}|_{h=0} = A(T)\eta^2 + \frac{1}{2}B(T)\eta^4 + \dots, \quad \text{at } T \approx T_c. \quad (4.42)$$

As Fig. 6 shows, at $A(T) < 0$, and $B(T) > 0$, these two terms are sufficient to describe the minimum of the free energy at $\eta^2 > 0$, i.e. to calculate stationary values of the order parameter; this is why Landau's theory ignores higher terms of the Taylor expansion – which are much smaller at $\eta \rightarrow 0$.

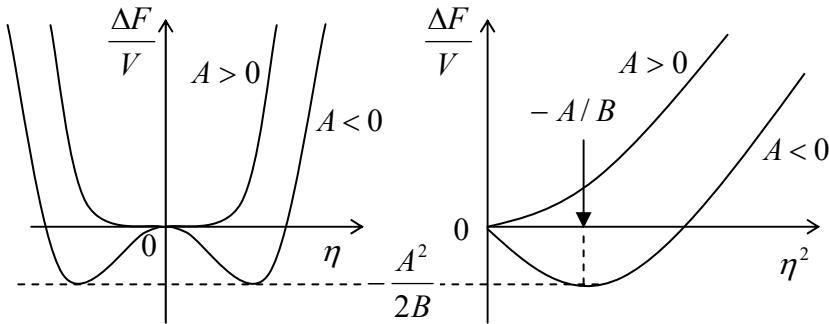

Fig. 4.6. The Landau free energy (42) as a function of (a) η and (b) η^2 , for two signs of the coefficient $A(T)$, both for $B(T) > 0$.

Now let us discuss the temperature dependencies of the coefficients A and B . As Eq. (42) shows, first of all, the coefficient $B(T)$ has to be positive for any sign of $\tau \propto (T_c - T)$, to ensure the equilibrium at a finite value of η^2 . Thus, it is reasonable to ignore the temperature dependence of B near the critical temperature altogether, i.e. use the approximation

$$B(T) = b > 0. \quad (4.43)$$

On the other hand, as Fig. 6 shows, the coefficient $A(T)$ has to change sign at $T = T_c$, to be positive at $T > T_c$ and negative at $T < T_c$, to ensure the transition from $\eta = 0$ at $T > T_c$ to a certain non-zero value of the order parameter at $T < T_c$. Assuming that A is a smooth function of temperature, we may approximate it by the leading term of its Taylor expansion in τ :

$$A(T) = -a\tau, \quad \text{with } a > 0, \quad (4.44)$$

so that Eq. (42) becomes

$$\Delta f|_{h=0} = -a\tau\eta^2 + \frac{1}{2}b\eta^4. \quad (4.45)$$

In this rudimentary form, the Landau theory may look almost trivial, and its main strength is the possibility of its straightforward extension to the effects of the external field and of spatial variations of the order parameter. First, as the field terms in Eqs. (21) or (23) show, the applied field gives such

systems, on average, the energy addition of $-h\eta$ per particle, i.e. $-nh\eta$ per unit volume, where n is the particle density. Second, since according to Eq. (31) (with $\nu > 0$, see Table 1) the correlation radius diverges at $\tau \rightarrow 0$, in this limit the spatial variations of the order parameter should be slow, $|\nabla\eta| \rightarrow 0$. Hence, the effects of the gradient on ΔF may be approximated by the first non-zero term of its expansion into the Taylor series in $(\nabla\eta)^2$.²⁶ As a result, Eq. (45) may be generalized as

Landau theory:
free energy

$$\Delta F = \int \Delta f d^3 r, \quad \text{with } \Delta f = -a\tau\eta^2 + \frac{1}{2}b\eta^4 - nh\eta + c(\nabla\eta)^2, \quad (4.46)$$

where c is a coefficient independent of η . To avoid the unphysical effect of spontaneous formation of spatial variations of the order parameter, that factor has to be positive at all temperatures and hence may be taken for a constant in a small vicinity of T_c – the only region where Eq. (46) may be expected to provide quantitatively correct results.

Let us find out what critical exponents are predicted by this phenomenological approach. First of all, we may find the equilibrium values of the order parameter from the condition of F having a minimum, $\partial F / \partial \eta = 0$. At $h = 0$, it is easier to use the equivalent equation $\partial F / \partial (\eta^2) = 0$, where F is given by Eq. (45) – see Fig. 6b. This immediately yields

$$|\eta| = \begin{cases} (a\tau/b)^{1/2}, & \text{for } \tau > 0, \\ 0, & \text{for } \tau < 0. \end{cases} \quad (4.47)$$

Comparing this result with Eq. (26), we see that in the Landau theory, $\beta = 1/2$. Next, plugging the result (47) back into Eq. (45), for the equilibrium (minimal) value of the free energy, we get

$$\Delta f = \begin{cases} -a^2\tau^2/2b, & \text{for } \tau > 0, \\ 0, & \text{for } \tau < 0. \end{cases} \quad (4.48)$$

From here and Eq. (37), the specific heat,

$$\frac{C_h}{V} = \begin{cases} a^2/bT_c, & \text{for } \tau > 0, \\ 0, & \text{for } \tau < 0, \end{cases} \quad (4.49)$$

has, at the critical point, a discontinuity rather than a singularity, so that we need to prescribe zero value to the critical exponent α .

In the presence of a uniform field, the equilibrium order parameter should be found from the condition $\partial f / \partial \eta = 0$ applied to Eq. (46) with $\nabla\eta = 0$, giving

$$\frac{\partial f}{\partial \eta} \equiv -2a\tau\eta + 2b\eta^3 - nh = 0. \quad (4.50)$$

In the limit of a small order parameter, $\eta \rightarrow 0$, the term with η^3 is negligible, and Eq. (50) gives

$$\eta = -\frac{nh}{2a\tau}, \quad (4.51)$$

²⁶ Historically, the last term belongs to the later (1950) extension of the theory by V. Ginzburg and L. Landau – see below.

so that according to Eq. (29), $\gamma = 1$. On the other hand, at $\tau = 0$ (or at relatively high fields at other temperatures), the cubic term in Eq. (50) is much larger than the linear one, and this equation yields

$$\eta = \left(\frac{nh}{2b} \right)^{1/3}, \quad (4.52)$$

so that comparison with Eq. (32) yields $\delta = 3$. Finally, according to Eq. (30), the last term in Eq. (46) scales as $c\eta^2/r_c^2$. (If $r_c \neq \infty$, the effects of the pre-exponential factor in Eq. (30) are negligible.) As a result, the gradient term's contribution is comparable²⁷ with the two leading terms in Δf (which, according to Eq. (47), are of the same order), if

$$r_c \approx \left(\frac{c}{a|\tau|} \right)^{1/2}, \quad (4.53)$$

so that according to the definition (31) of the critical exponent ν , in the Landau theory it is equal to $\frac{1}{2}$.

The third column in Table 1 summarizes the critical exponents and their combinations in Landau's theory. It shows that these values are somewhat out of the experimental ranges, and while some of their “universal” relations are correct, some are not; for example, the Josephson relation would be only correct at $d = 4$ (not the most realistic spatial dimensionality :-). The main reason for this disappointing result is that describing the spin interaction with the field, the Landau mean-field theory neglects spin randomness, i.e. fluctuations. Though a quantitative theory of fluctuations will be discussed only in the next chapter, we can readily perform their crude estimate. Looking at Eq. (46), we see that its first term is a quadratic function of the effective “half-degree of freedom”, η . Hence per the equipartition theorem (2.28), we may expect that the average square of its thermal fluctuations, within a d -dimensional volume with a linear size of the order of r_c , should be of the order of $T/2$ (close to the critical temperature, $T_c/2$ is a good enough approximation):

$$a|\tau| \langle \tilde{\eta}^2 \rangle r_c^d \sim \frac{T_c}{2}. \quad (4.54)$$

In order to be negligible, the variance has to be small in comparison with the average $\eta^2 \sim a\tau/b$ – see Eq. (47). Plugging in the τ -dependences of the operands of this relation, and values of the critical exponents in the Landau theory, for $\tau > 0$ we get the so-called *Levanyuk-Ginzburg criterion* of its validity:

$$\frac{T_c}{2a\tau} \left(\frac{a\tau}{c} \right)^{d/2} \ll \frac{a\tau}{b}. \quad (4.55)$$

We see that for any realistic dimensionality, $d < 4$, at $\tau \rightarrow 0$ the order parameter's fluctuations grow faster than its average value, and hence the theory becomes invalid.

Thus the Landau mean-field theory is not a perfect approach to finding critical indices at continuous phase transitions in Ising-type systems with their next-neighbor interactions between the particles. Despite that fact, this theory is very much valued because of the following reason. Any long-range interactions between particles increase the correlation radius r_c , and hence suppress the order

²⁷ According to Eq. (30), the correlation radius may be interpreted as the distance at which the order parameter η relaxes to its equilibrium value, if it is deflected from that value at some point. Since the law of such spatial change may be obtained by a variational differentiation of F , for the actual relaxation law, all major terms of (46) have to be comparable.

parameter fluctuations. As one example, at laser self-excitation, the emerging coherent optical field couples essentially *all* photon-emitting particles in the electromagnetic cavity (resonator). As another example, in superconductors the role of the correlation radius is played by the Cooper-pair size ξ_0 , which is typically of the order of 10^{-6} m, i.e. much larger than the average distance between the pairs ($\sim 10^{-8}$ m). As a result, the mean-field theory remains valid at all temperatures besides an extremely small temperature interval near T_c – for bulk superconductors, of the order of 10^{-6} K.

Another strength of Landau's *classical* mean-field theory (46) is that it may be readily generalized for a description of Bose-Einstein condensates, i.e. *quantum* fluids. Of those generalizations, the most famous is the *Ginzburg-Landau theory* of superconductivity. It was developed in 1950, i.e. even before the microscopic-level explanation of this phenomenon by J. Bardeen, L. Cooper, and R. Schrieffer in 1956-57. In this theory, the real order parameter η is replaced with the modulus of a complex function ψ , physically the wavefunction of the coherent Bose-Einstein condensate of Cooper pairs. Since each pair carries the electric charge $q = -2e$ and has zero spin, it interacts with the magnetic field in a way different from that described by the Heisenberg or Ising models. Namely, as was already discussed in Sec. 3.4, in the magnetic field, the del operator ∇ in Eq. (46) has to be complemented with the term $-i(q/\hbar)\mathbf{A}$, where \mathbf{A} is the vector potential of the total magnetic field $\mathcal{B} = \nabla \times \mathbf{A}$, including not only the external magnetic field \mathcal{H} but also the field induced by the supercurrent itself. With the account for the well-known formula for the magnetic field energy, Eq. (46) is now replaced with

GL theory:
free energy

$$\Delta f = -a\tau|\psi|^2 + \frac{1}{2}b|\psi|^4 - \frac{\hbar^2}{2m}\left|\left(\nabla - i\frac{q}{\hbar}\mathbf{A}\right)\psi\right|^2 + \frac{\mathcal{B}^2}{2\mu_0}, \quad (4.56)$$

where m is a phenomenological coefficient rather than the actual particle's mass.

The variational minimization of the resulting Gibbs energy density $\Delta g \equiv \Delta f - \mu_0\mathcal{H}\mathcal{M} \equiv \Delta f - \mathcal{H}\mathcal{B} + \text{const}^{28}$ over the variables ψ and \mathcal{B} (which is suggested for reader's exercise) yields two differential equations:

GL
equations

$$\frac{\nabla \times \mathcal{B}}{\mu_0} = q\frac{i\hbar}{2m}\left[\psi\left(\nabla - i\frac{q}{\hbar}\mathbf{A}\right)\psi^* - \text{c.c.}\right], \quad (4.57a)$$

$$a\tau\psi = b|\psi|^2\psi - \frac{\hbar^2}{2m}\left(\nabla - i\frac{q}{\hbar}\mathbf{A}\right)^2\psi. \quad (4.57b)$$

The first of these *Ginzburg-Landau equations* (57a) should be no big surprise for the reader, because according to the Maxwell equations, in magnetostatics the left-hand side of Eq. (57a) has to be equal to the electric current density, while its right-hand side is the usual quantum-mechanical probability current density multiplied by q , i.e. the density \mathbf{j} of the electric current of the Cooper pair condensate. (Indeed, after plugging $\psi = n^{1/2}\exp\{i\varphi\}$ into that expression, we come back to Eq. (3.84) which, as we already know, explains such macroscopic quantum phenomena as the magnetic flux quantization and the Meissner-Ochsenfeld effect.)

²⁸ As an immediate elementary sanity check of this relation, resulting from the analogy of Eqs. (1.1) and (1.3), the minimization of Δg in the absence of superconductivity ($\psi = 0$) gives the correct result $\mathcal{B} = \mu_0\mathcal{H}$. Note that this account of the difference between Δf and Δg is necessary here because (unlike Eqs. (21) and (23)), the Ginzburg-Landau free energy (56) does not take into account the effect of the field on each particle directly.

However, Eq. (57b) is new for us – at least for this course.²⁹ Since the last term on its right-hand side is the standard wave-mechanical expression for the kinetic energy of a particle in the presence of a magnetic field,³⁰ if this term dominates that side of the equation, Eq. (57b) is reduced to the stationary Schrödinger equation $E\psi = \hat{H}\psi$, for the ground state of free Cooper pairs, with the total energy $E = a\tau$. However, in contrast to the usual (single-particle) Schrödinger equation, in which $|\psi|$ is determined by the normalization condition, the Cooper pair condensate density $n = |\psi|^2$ is determined by the thermodynamic balance of the condensate with the ensemble of “normal” (unpaired) electrons, which plays the role of the uncondensed part of the particles in the usual Bose-Einstein condensate – see Sec. 3.4. In Eq. (57b), such balance is enforced by the first term $b|\psi|^2\psi$ on the right-hand side. As we have already seen, in the absence of magnetic field and spatial gradients, such term yields $|\psi| \propto \tau^{1/2} \propto (T_c - T)^{1/2}$ – see Eq. (47).

As a parenthetic remark, from the mathematical standpoint, the term $b|\psi|^2\psi$, which is nonlinear in ψ , makes Eq. (57b) a member of the family of the so-called *nonlinear Schrödinger equations*. Another member of this family, important for physics, is the *Gross-Pitaevskii equation*,

$$a\tau\psi = b|\psi|^2\psi - \frac{\hbar^2}{2m}\nabla^2\psi + U(\mathbf{r})\psi, \quad (4.58)$$

Gross-Pitaevskii equation

which gives a reasonable (albeit approximate) description of gradient and field effects on Bose-Einstein condensates of electrically neutral atoms at $T \approx T_c$. The differences between Eqs. (58) and (57) reflect, first, the zero electric charge q of the atoms (so that Eq. (57a) becomes trivial) and, second, the fact that the atoms forming the condensates may be readily placed in external potentials $U(\mathbf{r}) \neq \text{const}$ (including the time-averaged potentials of optical traps – see EM Chapter 7), while in superconductors such potential profiles are much harder to create due to the screening of external electric and optical fields by conductors – see, e.g., EM Sec. 2.1.

Returning to the discussion of Eq. (57b), it is easy to see that its last term increases as either the external magnetic field or the density of current passed through a superconductor are increased, increasing the vector potential. In the Ginzburg-Landau equation, this *increase* is matched by a corresponding *decrease* of $|\psi|^2$, i.e. of the condensate density n , until it is completely suppressed. This balance describes the well-documented effect of superconductivity suppression by an external magnetic field and/or the supercurrent passed through the sample. Moreover, together with Eq. (57a), naturally describing the flux quantization (see Sec. 3.4), Eq. (57b) explains the existence of the so-called *Abrikosov vortices* – thin magnetic-field tubes, each carrying one quantum Φ_0 of magnetic flux – see Eq. (3.86). At the core part of the vortex, $|\psi|^2$ is suppressed (down to zero at its central line) by the persistent, dissipation-free current of the superconducting condensate, which circulates around the core and screens the rest of the superconductor from the magnetic field carried by the vortex.³¹ The penetration of such vortices into the so-called type-II superconductors enables them to sustain zero dc resistance up to very high magnetic fields of the order of 20 T, and as a result, to be used in very compact magnets – including those used for beam bending in particle accelerators.

Moreover, generalizing Eqs. (57) to the time-dependent case, just as it is done with the usual Schrödinger equation, one can describe other fascinating quantum macroscopic phenomena such as the

²⁹ It is discussed in EM Sec. 6.5.

³⁰ See, e.g., QM Sec. 3.1.

³¹ See, e.g., EM Sec. 6.5.

Josephson effects, including the generation of oscillations with frequency $\omega_J = (q/\hbar)\mathcal{V}$ by weak links between two superconductors, biased by dc voltage \mathcal{V} . Unfortunately, time/space restrictions do not allow me to discuss these effects in any detail in this course, and I have to refer the reader to special literature.³² Let me only note that in the limit $T \rightarrow T_c$, and for not extremely pure superconductor crystals (in which the so-called non-local transport phenomena may be important), the Ginzburg-Landau equations are exact, and may be derived (and their parameters T_c , a , b , q , and m determined) from the standard “microscopic” theory of superconductivity, based on the initial work by Bardeen, Cooper, and Schrieffer.³³ Most importantly, such derivation proves that $q = -2e$ – the electric charge of a single Cooper pair.

4.4. Ising model: The Weiss molecular-field theory

The Landau mean-field theory is phenomenological in the sense that even within the range of its validity, it tells us nothing about the value of the critical temperature T_c and other parameters (in Eq. (46), the coefficients a , b , and c), so that they have to be found from a particular “microscopic” model of the system under analysis. In this course, we would have time to discuss only the Ising model (23) for various dimensionalities d .

The most simplistic way to map this model on a mean-field theory is to assume that all spins are exactly equal, $s_k = \eta$, with an additional condition $\eta^2 \leq 1$, ignoring for a minute the fact that in the genuine Ising model, s_k may equal only +1 or -1. Plugging this relation into Eq. (23), we get³⁴

$$F = -(NJd)\eta^2 - Nh\eta. \quad (4.59)$$

This energy is plotted in Fig. 7a as a function of η , for several values of h .

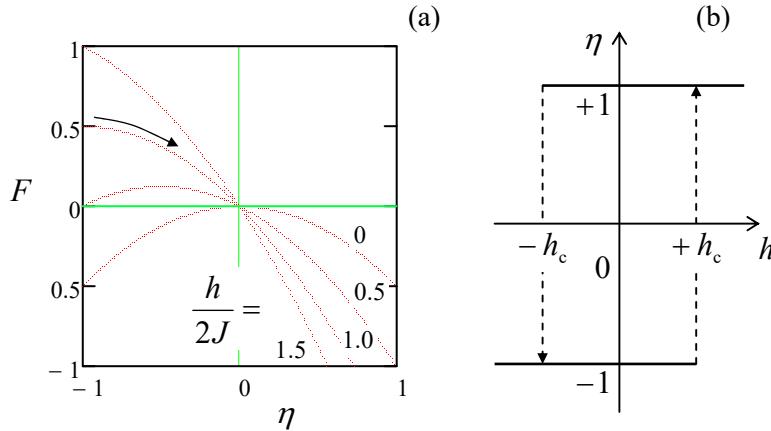

Fig. 4.7. Field dependences of (a) the free energy profile and (b) the order parameter (i.e. magnetization) in the crudest mean-field approach to the Ising model.

The plots show that at $h = 0$, the system may be in either of two stable states, with $\eta = \pm 1$, corresponding to two different spin directions (i.e. two different directions of magnetization), with equal

³² See, e.g., M. Tinkham, *Introduction to Superconductivity*, 2nd ed., McGraw-Hill, 1996. A short discussion of the Josephson effects and Abrikosov vortices may be found in QM Sec. 1.6 and EM Sec. 6.5 of this series.

³³ See, e.g., Sec. 45 in E. Lifshitz and L. Pitaevskii, *Statistical Physics*, Part 2, Pergamon, 1980.

³⁴ Since in this naïve approach we neglect the fluctuations of spin, i.e. their disorder, the assumption of full ordering implies $S = 0$, so that $F \equiv E - TS = E$, and we may use either notation for the system’s energy.

energy.³⁵ (Formally, the state with $\eta = 0$ is also stationary, because at this point $\partial F/\partial\eta = 0$, but it is unstable, because for the ferromagnetic interaction, $J > 0$, the second derivative $\partial^2 F/\partial\eta^2$ is always negative.)

As the external field is increased, it tilts the potential profile, and finally at the critical field,

$$h = h_c \equiv 2Jd, \quad (4.60)$$

the state with $\eta = -1$ becomes unstable, leading to the system's jump into the only remaining state with opposite magnetization, $\eta = +1$ – see the arrow in Fig. 7a. Application of the similar external field of the opposite polarity leads to the similar switching, back to $\eta = -1$, at the field $h = -h_c$, so that the full field dependence of η follows the hysteretic pattern shown in Fig. 7b.³⁶

Such a pattern is the most visible experimental feature of actual ferromagnetic materials, with the *coercive magnetic field* \mathcal{H}_c of the order of 10^3 A/m, and the *saturated* (or “remnant”) *magnetization* corresponding to fields \mathcal{B} of the order of a few teslas. The most important property of these materials, also called *permanent magnets*, is their stability, i.e. the ability to retain the history-determined direction of magnetization in the absence of an external field, for a very long time. In particular, this property is the basis of all magnetic systems for data recording, including the now-ubiquitous hard disk drives with their incredible information density, currently approaching 1 Terabit per square inch.³⁷

So, this simplest mean-field theory (59) does give a (crude) description of the ferromagnetic ordering. However, this theory grossly overestimates the stability of these states with respect to thermal fluctuations. Indeed, in this theory, there is no thermally-induced randomness at all, until T becomes comparable with the height of the energy barrier separating two stable states,

$$\Delta F \equiv F(\eta = 0) - F(\eta = \pm 1) = NJd, \quad (4.61)$$

which is proportional to the number of particles. At $N \rightarrow \infty$, this value diverges, and in this sense, the critical temperature is infinite, while numerical experiments and more refined theories of the Ising model show that actually its ferromagnetic phase is suppressed at $T > T_c \sim Jd$ – see below.

The accuracy of this theory may be dramatically improved by even an approximate account for thermally-induced randomness. In this approach (suggested in 1907 by Pierre-Ernest Weiss), called the *molecular-field theory*,³⁸ random deviations of individual spin values from the lattice average,

³⁵ The fact that the stable states always correspond to $\eta = \pm 1$, partly justifies the treatment, in this crude approximation, of the order parameter η as a continuous variable.

³⁶ Since these magnetization jumps are accompanied by (negative) jumps of the free energy F , they are sometimes called the first-order phase transitions. Note, however, that in this simple theory, these transitions are between two physically similar *fully-ordered* phases.

³⁷ For me, it was always shocking how little my graduate students knew about this fascinating (and very important) field of modern engineering, which involves so much interesting physics and fantastic electromechanical technology. For getting acquainted with it, I may recommend, for example, the monograph by C. Mee and E. Daniel, *Magnetic Recording Technology*, 2nd ed., McGraw-Hill, 1996.

³⁸ In some texts, this approximation is called the “mean-field theory”. This terminology may lead to confusion, because the molecular-field theory belongs to a different, deeper level of the theoretical hierarchy than, say, the (more phenomenological) Landau-style mean-field theories. For example, for a given microscopic model, the molecular-field approach may be used for the (approximate) calculation of the parameters a , b , and T_c participating in Eq. (46) – the starting point of the Landau theory.

$$\tilde{s}_k \equiv s_k - \eta, \quad \text{with } \eta \equiv \langle s_k \rangle, \quad (4.62)$$

are allowed, but considered small, $|\tilde{s}_k| \ll \eta$. This assumption allows us, after plugging the resulting expression $s_k = \eta + \tilde{s}_k$ to the first term on the right-hand side of Eq. (23),

$$E_m = -J \sum_{\{k,k'\}} (\eta + \tilde{s}_k)(\eta + \tilde{s}_{k'}) - h \sum_k s_k \equiv -J \sum_{\{k,k'\}} [\eta^2 + \eta(\tilde{s}_k + \tilde{s}_{k'}) + \tilde{s}_k \tilde{s}_{k'}] - h \sum_k s_k, \quad (4.63)$$

ignore the last term in the square brackets. Making the replacement (62) in the terms proportional to \tilde{s}_k , we may rewrite the result as

$$E_m \approx E'_m \equiv (N J d) \eta^2 - h_{\text{ef}} \sum_k s_k, \quad (4.64)$$

where h_{ef} is defined as the sum

$$h_{\text{ef}} \equiv h + (2 J d) \eta. \quad (4.65)$$

This sum may be interpreted as the *effective* external field, which takes into account (besides the genuine external field h) the effect that *would be* exerted on spin s_k by its $2d$ next neighbors if they all had non-fluctuating (but possibly continuous) spin values $s_{k'} = \eta$. Such addition to the external field,

Weiss
molecular
field

$$h_{\text{mol}} \equiv h_{\text{ef}} - h = (2 J d) \eta, \quad (4.66)$$

is called the *molecular field* – giving its name to the Weiss theory.

From the point of view of statistical physics, at fixed parameters of the system (including the order parameter η), the first term on the right-hand side of Eq. (64) is merely a constant energy offset, and h_{ef} is just another constant, so that

$$E'_m = \text{const} + \sum_k \varepsilon_k, \quad \text{with } \varepsilon_k = -h_{\text{ef}} s_k \equiv \begin{cases} -h_{\text{ef}}, & \text{for } s_k = +1, \\ +h_{\text{ef}}, & \text{for } s_k = -1. \end{cases} \quad (4.67)$$

Such separability of the energy means that in the molecular-field approximation the fluctuations of different spins are independent of each other, and their statistics may be examined individually, using the energy spectrum ε_k . But this is exactly the two-level system that was the subject of Problems 2.2-2.4. Actually, its statistics is so simple that it is easier to redo this fundamental problem starting from scratch, rather than to use the results of those exercises (which would require changing notation).

Indeed, according to the Gibbs distribution (2.58)-(2.59), the equilibrium probabilities of the states $s_k = \pm 1$ may be found as

$$W_{\pm} = \frac{1}{Z} e^{\pm h_{\text{ef}}/T}, \quad \text{with } Z = \exp\left\{+\frac{h_{\text{ef}}}{T}\right\} + \exp\left\{-\frac{h_{\text{ef}}}{T}\right\} \equiv 2 \cosh \frac{h_{\text{ef}}}{T}. \quad (4.68)$$

From here, we may readily calculate $F = -T \ln Z$ and all other thermodynamic variables, but let us immediately use Eq. (68) to calculate the statistical average of s_j , i.e. the order parameter:

$$\eta \equiv \langle s_j \rangle = (+1) W_+ + (-1) W_- = \frac{e^{+h_{\text{ef}}/T} - e^{-h_{\text{ef}}/T}}{2 \cosh(h_{\text{ef}}/T)} \equiv \tanh \frac{h_{\text{ef}}}{T}. \quad (4.69)$$

Now comes the punch line of the Weiss' approach: plugging this result back into Eq. (65), we may write the condition of *self-consistency* of the molecular-field theory:

$$h_{\text{ef}} - h = 2Jd \tanh \frac{h_{\text{ef}}}{T}. \quad (4.70)$$

Self-consistency equation

This is a transcendental equation, which evades an explicit analytical solution, but whose properties may be readily analyzed by plotting both its sides as functions of the same argument, so that the stationary state(s) of the system corresponds to the intersection point(s) of these plots.

First of all, let us explore the field-free case ($h = 0$), when $h_{\text{ef}} = h_{\text{mol}} \equiv 2dJ\eta$, so that Eq. (70) is reduced to

$$\eta = \tanh\left(\frac{2Jd}{T}\eta\right), \quad (4.71)$$

giving one of the patterns sketched in Fig. 8, depending on the dimensionless parameter $2Jd/T$.

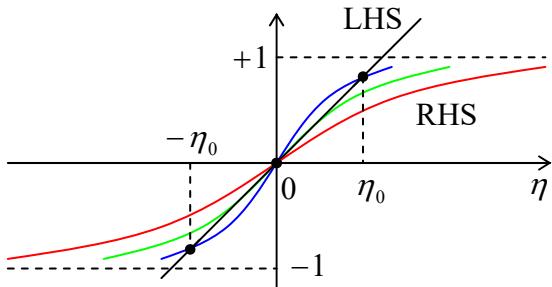

Fig. 4.8. The ferromagnetic phase transition in Weiss' molecular-field theory: two sides of Eq. (71) sketched as functions of η for three different temperatures: above T_c (red), below T_c (blue), and equal to T_c (green).

If this parameter is small, the right-hand side of Eq. (71) grows slowly with η (see the red line in Fig. 8), and there is only one intersection point with the left-hand side plot, at $\eta = 0$. This means that the spin system has no spontaneous magnetization; this is the so-called *paramagnetic phase*. However, if the parameter $2Jd/T$ exceeds 1, i.e. if T is decreased below the following critical value,

$$T_c = 2Jd, \quad (4.72)$$

Critical ("Curie") temperature

the right-hand side of Eq. (71) grows, at small η , faster than its left-hand side, so that their plots intersect it in 3 points: $\eta = 0$ and $\eta = \pm\eta_0$ – see the blue line in Fig. 8. It is almost evident that the former stationary point is unstable, while the two latter points are stable. (This fact may be readily verified by using Eq. (68) to calculate F . Now the condition $\partial F / \partial \eta|_{h=0} = 0$ returns us to Eq. (71), while calculating the second derivative, for $T < T_c$ we get $\partial^2 F / \partial \eta^2 > 0$ at $\eta = \pm\eta_0$, and $\partial^2 F / \partial \eta^2 < 0$ at $\eta = 0$). Thus, below T_c the system is in the ferromagnetic phase, with one of two possible directions of the average spontaneous magnetization, so that the critical (*Curie*³⁹) temperature, given by Eq. (72), marks the transition between the paramagnetic and ferromagnetic phases. (Since the stable minimum value of the free energy F is a continuous function of temperature at $T = T_c$, this phase transition is continuous.)

Now let us repeat this graphics analysis to examine how each of these phases responds to an external magnetic field $h \neq 0$. According to Eq. (70), the effect of h is just a horizontal shift of the

³⁹ Named after Pierre Curie, rather than his (more famous) wife Marie Skłodowska-Curie.

straight-line plot of its left-hand side – see Fig. 9. (Note a different, here more convenient, normalization of both axes.)

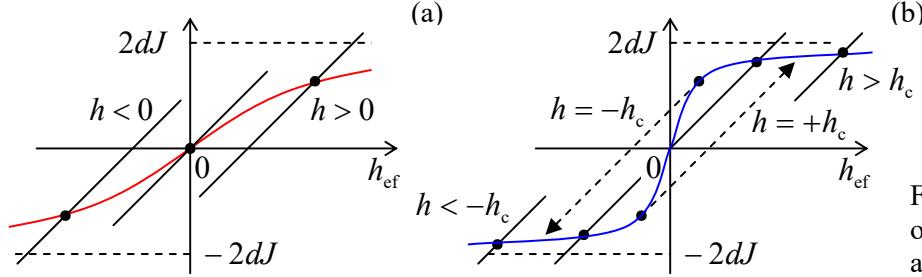

Fig. 4.9 External field effects on: (a) a paramagnet ($T > T_c$), and (b) a ferromagnet ($T < T_c$).

In the paramagnetic case (Fig. 9a) the resulting dependence $h_{\text{ef}}(h)$ is evidently continuous, but the coupling effect ($J > 0$) makes it steeper than it would be without spin interaction. This effect may be quantified by the calculation of the low-field susceptibility defined by Eq. (29). To calculate it, let us notice that for small h , and hence small h_{ef} , the function \tanh in Eq. (70) is approximately equal to its argument so that Eq. (70) is reduced to

$$h_{\text{ef}} - h = \frac{2Jd}{T} h_{\text{ef}}, \quad \text{for } \left| \frac{2Jd}{T} h_{\text{ef}} \right| \ll 1. \quad (4.73)$$

Solving this equation for h_{ef} , and then using Eq. (72), we get

$$h_{\text{ef}} = \frac{h}{1 - 2Jd/T} = \frac{h}{1 - T_c/T}. \quad (4.74)$$

Recalling Eq. (66), we can rewrite this result for the order parameter:

$$\eta = \frac{h_{\text{ef}} - h}{T_c} = \frac{h}{T - T_c}, \quad (4.75)$$

so that the low-field susceptibility

$$\chi \equiv \frac{\partial \eta}{\partial h} \Big|_{h=0} = \frac{1}{T - T_c}, \quad \text{for } T > T_c. \quad (4.76)$$

This is the famous *Curie-Weiss law*, which shows that the susceptibility diverges at the approach to the Curie temperature T_c .

In the ferromagnetic case, the graphical solution (Fig. 9b) of Eq. (70) gives a qualitatively different result. A field increase leads, depending on the spontaneous magnetization, either to the further saturation of h_{mol} (with the order parameter η gradually approaching 1), or, if the initial η was negative, to a jump to positive η at some critical (coercive) field h_c . In contrast with the crude approximation (59), at $T > 0$ the coercive field is smaller than that given by Eq. (60), and the magnetization saturation is gradual, in a good (semi-qualitative) accordance with experiment.

To summarize, the Weiss molecular-field theory gives an approximate but realistic description of the ferromagnetic and paramagnetic phases in the Ising model, and a very simple prediction (72) of the temperature of the phase transition between them, for an arbitrary dimensionality d of the cubic lattice. It also enables calculation of other parameters of Landau's mean-field theory for this model – an easy

exercise left for the reader. Moreover, the molecular-field approach allows one to obtain analytical (if approximate) results for other models of phase transitions – see, e.g., Problem 18.

4.5. Ising model: Exact and numerical results

In order to evaluate the main prediction (72) of the Weiss theory, let us now discuss the exact (analytical) and quasi-exact (numerical) results obtained for the Ising model, going from the lowest value of dimensionality, $d = 0$, to its higher values. Zero dimensionality means that the spin has no nearest neighbors at all, so that the first term of Eq. (23) vanishes. Hence Eq. (64) is exact, with $h_{\text{ef}} = h$, and so is its solution (69). Now we can simply use Eq. (76), with $J = 0$, i.e. $T_c = 0$, reducing this result to the so-called *Curie law*:

$$\chi = \frac{1}{T}. \quad (4.77)$$

Curie
law

It shows that the system is paramagnetic at any temperature. One may say that for $d = 0$ the Weiss molecular-field theory is exact – or even trivial. (However, in some sense it is more general than the Ising model, because as we know from Chapter 2, it gives the exact result for a fully quantum-mechanical treatment of any two-level system, including spin-½.) Experimentally, the Curie law is approximately valid for many so-called *paramagnetic materials*, i.e. 3D systems with sufficiently weak interaction between particle spins.

The case $d = 1$ is more complex but has an exact analytical solution. A simple (though not the simplest!) way to obtain it is to use the so-called *transfer matrix approach*.⁴⁰ For this, first of all, we may argue that most properties of a 1D system of $N \gg 1$ spins (say, put at equal distances on a straight line) should not change noticeably if we bend that line gently into a closed ring (Fig. 10), assuming that spins s_1 and s_N interact exactly as all other next-neighbor pairs. Then the energy (23) becomes

$$E_m = -(J s_1 s_2 + J s_2 s_3 + \dots + J s_N s_1) - (h s_1 + h s_2 + \dots + h s_N). \quad (4.78)$$

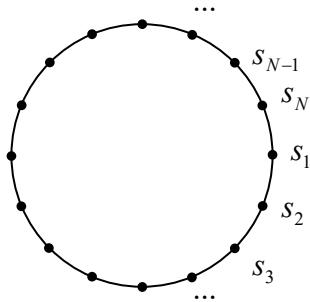

Fig. 4.10. The closed-ring version of the 1D Ising system.

Let us regroup the terms of this sum in the following way:

$$E_m = - \left[\left(\frac{h}{2} s_1 + J s_1 s_2 + \frac{h}{2} s_2 \right) + \left(\frac{h}{2} s_2 + J s_2 s_3 + \frac{h}{2} s_3 \right) + \dots + \left(\frac{h}{2} s_N + J s_N s_1 + \frac{h}{2} s_1 \right) \right], \quad (4.79)$$

⁴⁰ It was developed in 1941 by H. Kramers and G. Wannier. I am following this method here because it is very close to the one used in quantum mechanics (see, e.g., QM Sec. 2.5), and may be applied to other problems as well. For a simpler approach to the 1D Ising problem, which gives an explicit solution even for an “open-end” system with a finite number of spins, see the model solution of Problem 5.5.

so that the group inside each pair of parentheses depends only on the state of two adjacent spins. The corresponding statistical sum,

$$Z = \sum_{\substack{s_k=\pm 1, \text{for} \\ k=1,2,\dots,N}} \exp\left\{h \frac{s_1}{2T} + J \frac{s_1 s_2}{T} + h \frac{s_2}{2T}\right\} \exp\left\{h \frac{s_2}{2T} + J \frac{s_2 s_3}{T} + h \frac{s_3}{2T}\right\} \dots \exp\left\{h \frac{s_N}{2T} + J \frac{s_N s_1}{T} + h \frac{s_1}{2T}\right\}, \quad (4.80)$$

still has 2^N terms, each corresponding to a certain combination of signs of N spins. However, each operand of the product under the sum may take only four values, corresponding to four different combinations of its two arguments:

$$\exp\left\{h \frac{s_k}{2T} + J \frac{s_k s_{k+1}}{T} + h \frac{s_{k+1}}{2T}\right\} = \begin{cases} \exp\{(J+h)/T\}, & \text{for } s_k = s_{k+1} = +1, \\ \exp\{(J-h)/T\}, & \text{for } s_k = s_{k+1} = -1, \\ \exp\{-J/T\}, & \text{for } s_k = -s_{k+1} = \pm 1. \end{cases} \quad (4.81)$$

These values do not depend on the site number k ,⁴¹ and may be represented as the elements $M_{j,j'}$ (with $j, j' = 1, 2$) of the so-called *transfer matrix*

$$M \equiv \begin{pmatrix} \exp\{(J+h)/T\} & \exp\{-J/T\} \\ \exp\{-J/T\} & \exp\{(J-h)/T\} \end{pmatrix}, \quad (4.82)$$

so that the whole statistical sum (80) may be recast as a product:

$$Z = \sum_{j_k=1,2} M_{j_1 j_2} M_{j_2 j_3} \dots M_{j_{N-1} j_N} M_{j_N j_1}. \quad (4.83)$$

According to the basic rule of matrix multiplication, this sum is just

$$Z = \text{Tr}(M^N). \quad (4.84)$$

Linear algebra tells us that this trace may be represented just as

$$Z = \lambda_+^N + \lambda_-^N, \quad (4.85)$$

where λ_{\pm} are the eigenvalues of the transfer matrix M , i.e. the roots of its characteristic equation,

$$\begin{vmatrix} \exp\{(J+h)/T\} - \lambda & \exp\{-J/T\} \\ \exp\{-J/T\} & \exp\{(J-h)/T\} - \lambda \end{vmatrix} = 0. \quad (4.86)$$

A straightforward calculation yields

$$\lambda_{\pm} = \exp\left\{\frac{J}{T}\right\} \left[\cosh \frac{h}{T} \pm \left(\sinh^2 \frac{h}{T} + \exp\left\{-\frac{4J}{T}\right\} \right)^{1/2} \right]. \quad (4.87)$$

The last simplification comes from the condition $N \gg 1$ – which we need anyway, to make the ring model sufficiently close to the infinite linear 1D system. In this limit, even a small difference of the exponents, $\lambda_+ > \lambda_-$, makes the second term in Eq. (85) negligible, so that we finally get

⁴¹ This is a result of the “translational” (or rather rotational) symmetry of the system, i.e. its invariance to the index replacement $k \rightarrow k + 1$ in all terms of Eq. (78).

$$Z = \lambda_+^N = \exp\left\{\frac{NJ}{T}\right\} \left[\cosh \frac{h}{T} + \left(\sinh^2 \frac{h}{T} + \exp\left\{-\frac{4J}{T}\right\} \right)^{1/2} \right]^N. \quad (4.88)$$

From here, we can find the free energy per particle:

$$\frac{F}{N} = \frac{T}{N} \ln \frac{1}{Z} = -J - T \ln \left[\cosh \frac{h}{T} + \left(\sinh^2 \frac{h}{T} + \exp\left\{-\frac{4J}{T}\right\} \right)^{1/2} \right], \quad (4.89)$$

and then use thermodynamics to calculate such variables as entropy – see the first of Eqs. (1.35).

However, we are mostly interested in the order parameter defined by Eq. (25): $\eta \equiv \langle s_j \rangle$. The conceptually simplest approach to the calculation of this statistical average would be to use the sum (2.7), with the Gibbs probabilities $W_m = Z^{-1} \exp\{-E_m/T\}$. However, the number of terms in this sum is 2^N , so that for $N \gg 1$ this approach is completely impracticable. Here the analogy between the canonical pair $\{-P, V\}$ and other generalized force-coordinate pairs $\{\mathcal{F}, q\}$, in particular $\{\mu_0 \mathcal{H}(\mathbf{r}_k), m_k\}$ for the magnetic field, discussed in Secs. 1.1 and 1.4, becomes invaluable – see in particular Eq. (1.3b). (In our normalization (22), and for a uniform field, the pair $\{\mu_0 \mathcal{H}(\mathbf{r}_k), m_k\}$ becomes $\{h, s_k\}$.) Indeed, in this analogy the last term of Eq. (23), i.e. the sum of N products $(-hs_k)$ for all spins, with the statistical average $(-Nh\eta)$, is similar to the product PV , i.e. the difference between the thermodynamic potentials F and $G \equiv F + PV$ in the usual “ P - V thermodynamics”. Hence, the free energy F given by Eq. (89) may be understood as the Gibbs energy of the Ising system in the external field, and the equilibrium value of the order parameter may be found from the last of Eqs. (1.39) with the replacements $-P \rightarrow h$, $V \rightarrow N\eta$:

$$N\eta = -\left(\frac{\partial F}{\partial h} \right)_T, \quad \text{i.e. } \eta = -\left[\frac{\partial(F/N)}{\partial h} \right]_T. \quad (4.90)$$

Note that this formula is valid for any model of ferromagnetism, of any dimensionality, if it has the same form of interaction with the external field as the Ising model.

For the 1D Ising ring with $N \gg 1$, Eqs. (89) and (90) yield

$$\eta = \sinh \frac{h}{T} \left/ \left(\sinh^2 \frac{h}{T} + \exp\left\{-\frac{4J}{T}\right\} \right)^{1/2} \right., \quad \text{giving } \chi \equiv \frac{\partial \eta}{\partial h} \Big|_{h=0} = \frac{1}{T} \exp\left\{\frac{2J}{T}\right\}. \quad (4.91)$$

This result means that the 1D Ising model does *not* exhibit a phase transition, i.e., in this model $T_c = 0$. However, its susceptibility grows, at $T \rightarrow 0$, much faster than the Curie law (77). This gives us a hint that at low temperatures the system is “virtually ferromagnetic”, i.e. has the ferromagnetic order with some rare random violations. (Such violations are commonly called *low-temperature excitations*.) This interpretation may be confirmed by the following approximate calculation. It is almost evident that the lowest-energy excitation of the ferromagnetic state of an open-end 1D Ising chain at $h = 0$ is the reversal of signs of all spins in one of its parts – see Fig. 11.

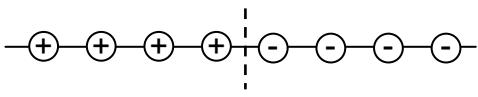

Fig. 4.11. A Bloch wall in an open-end 1D Ising system.

Indeed, such an excitation (called the *Bloch wall*⁴²) involves the change of sign of just one product $s_k s_{k'}$, so that according to Eq. (23), its energy E_W (defined as the difference between the values of E_m with and without the excitation) equals $2J$, regardless of the wall's position.⁴³ Since in the ferromagnetic Ising model, the parameter J is positive, $E_W > 0$. If the system “tried” to minimize its internal energy, having any wall in the system would be energy-disadvantageous. However, thermodynamics tells us that at $T \neq 0$, the system’s thermal equilibrium corresponds to the minimum of the free energy $F \equiv E - TS$, rather than just energy E .⁴⁴ Hence, we have to calculate the Bloch wall’s contribution F_W to the free energy. Since in an open-end linear chain of $N \gg 1$ spins, the wall can take $(N - 1) \approx N$ positions with the same energy E_W , we may claim that the entropy S_W associated with this excitation is $\ln N$, so that

$$F_W \equiv E_W - TS_W \approx 2J - T \ln N. \quad (4.92)$$

This result tells us that in the limit $N \rightarrow \infty$, and at $T \neq 0$, walls are always free-energy-beneficial, thus explaining the absence of the perfect ferromagnetic order in the 1D Ising system. Note, however, that since the logarithmic function changes extremely slowly at large values of its argument, one may argue that a large but finite 1D system should still feature a quasi-critical temperature

$$\text{"}T_c\text{"} = \frac{2J}{\ln N}, \quad (4.93)$$

below which it would be in a virtually complete ferromagnetic order. (The exponentially large susceptibility (91) is another manifestation of this fact.)

Now let us apply a similar approach to estimate T_c of a 2D Ising model, with open borders. Here the Bloch wall is a line of a certain total length L – see Fig. 12. (For the example presented in that figure, counting from the left to the right, $L = 2 + 1 + 4 + 2 + 3 = 12$ lattice periods.) Evidently, the additional energy associated with such a wall is $E_W = 2JL$, while the wall’s entropy S_W may be estimated using the following reasoning. Let the wall be formed along the path of a “Manhattan pedestrian” traveling between its nodes. (The dashed line in Fig. 12 is an example of such a path.) At each junction, the pedestrian may select 3 choices of 4 possible directions (except the one that leads backward), so that there are approximately $3^{(L-1)} \approx 3^L$ options for a walk starting from a certain point. Now taking into account that the open borders of a square-shaped lattice with N spins have a length of the order of $N^{1/2}$, and the Bloch wall may start from any of them, there are approximately $M \sim N^{1/2}3^L$ different walks between two borders. Again estimating S_W as $\ln M$, we get

$$F_W = E_W - TS_W \approx 2JL - T \ln(N^{1/2}3^L) \equiv L(2J - T \ln 3) - (T/2) \ln N. \quad (4.94)$$

(Actually, since L scales as $N^{1/2}$ or higher, at $N \rightarrow \infty$ the last term in Eq. (94) is negligible.) We see that the sign of the derivative $\partial F_W / \partial L$ depends on whether the temperature is higher or lower than the following critical value:

⁴² Named after Felix Bloch who was the first one to discuss such excitations in ferromagnetism.

⁴³ For the closed-ring model (Fig. 10) such analysis gives an almost similar prediction, with the difference that in that system, the Bloch walls may appear only in pairs, so that $E_W = 4J$, and $S_W = \ln[N(N-1)] \approx 2\ln N$.

⁴⁴ This is a very vivid application of one of the core results of thermodynamics. If the reader is still uncomfortable with it, they are strongly encouraged to revisit Eq. (1.42) and its discussion.

$$T_c = \frac{2J}{\ln 3} \approx 1.82 J. \quad (4.95)$$

At $T < T_c$, the free energy's minimum corresponds to $L \rightarrow 0$, i.e. the Bloch walls are free-energy-detrimental, and the system is in the purely ferromagnetic phase.

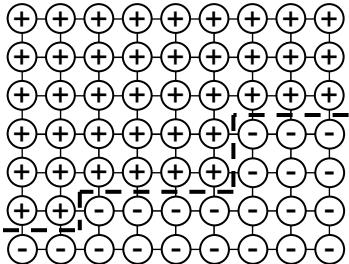

Fig. 4.12. A Bloch wall in a 2D Ising system.

So, for $d = 2$ the estimates predict a non-zero critical temperature of the same order as the Weiss theory (according to Eq. (72), in this case $T_c = 4J$). The major approximation implied in our calculation leading to Eq. (95) is disregarding possible self-crossings of the “Manhattan walk”. The accurate counting of such self-crossings is rather difficult. It had been carried out in 1944 by L. Onsager; since then his calculations have been redone in several easier ways, but even they are rather cumbersome, and I will not have time to discuss them.⁴⁵ The final result, however, is surprisingly simple:

$$T_c = \frac{2J}{\ln(1 + \sqrt{2})} \approx 2.269 J, \quad (4.96)$$

Onsager's exact result

i.e. showing that the simple estimate (95) is off the mark by only ~20%.

The Onsager solution, as well as all alternative solutions of the problem that were found later, are so “artificial” (2D-specific) that they do not give a clear way towards their generalization to other (higher) dimensions. As a result, the 3D Ising problem is still unsolved analytically. Nevertheless, we do know T_c for it with extremely high precision – at least to the 6th decimal place. This has been achieved by numerical methods; they deserve a thorough discussion because of their importance for the solution of other similar problems as well.

Conceptually, this task is rather simple: just compute, to the desired precision, the statistical sum of the system (23):

$$Z = \sum_{\substack{s_k = \pm 1, \text{ for} \\ k=1,2,\dots,N}} \exp \left\{ \frac{J}{T} \sum_{\{k,k'\}} s_k s_{k'} + \frac{h}{T} \sum_k s_k \right\}. \quad (4.97)$$

As soon as this has been done for a sufficient number of values of the dimensionless parameters J/T and h/T , everything becomes easy; in particular, we can compute the dimensionless function

$$F/T = -\ln Z, \quad (4.98)$$

⁴⁵ For that, the interested reader may be referred to either Sec. 151 in the textbook by Landau and Lifshitz, or Chapter 15 in the text by Huang, both cited above.

and then find the ratio J/T_c as the smallest value of the parameter J/T at that the ratio F/T (as a function of h/T) has a minimum at zero field. However, for any system of a reasonable size N , the “exact” computation of the statistical sum (97) is impossible, because it contains too many terms for any supercomputer to handle. For example, let us take a relatively small 3D lattice with $N = 10 \times 10 \times 10 = 10^3$ spins, which still feature substantial boundary artifacts even using the periodic boundary conditions, so that its phase transition is smeared about T_c by $\sim 3\%$. Still, even for such a crude model, Z would include $2^{1,000} \equiv (2^{10})^{100} \approx (10^3)^{100} \equiv 10^{300}$ terms. Let us suppose we are using a modern exaflops-scale supercomputer performing 10^{18} floating-point operations per second, i.e. $\sim 10^{26}$ such operations per year. With those resources, the computation of just one statistical sum would require $\sim 10^{(300-26)} = 10^{274}$ years. To call such a number “astronomic” would be a strong understatement. (As a reminder, the age of our Universe is close to 1.3×10^{10} years – a very humble number in comparison.)

This situation may be improved dramatically by noticing that any statistical sum,

$$Z = \sum_m \exp\left\{-\frac{E_m}{T}\right\}, \quad (4.99)$$

is dominated by terms with lower values of E_m . To find those lowest-energy states, we may use the following powerful approach (belonging to a broad class of numerical *Monte-Carlo techniques*), which essentially mimics one (randomly selected) path of the system’s evolution in time. One could argue that for that we would need to know the exact laws of evolution of statistical systems,⁴⁶ that may differ from one system to another, even if their energy spectra E_m are the same. This is true, but since the genuine value of Z should be independent of these details, it may be evaluated using *any* reasonable kinetic model that satisfies certain general rules. In order to reveal these rules, let us start from a system with just two states, with energies E_m and $E_{m'} = E_m + \Delta$ – see Fig. 13.

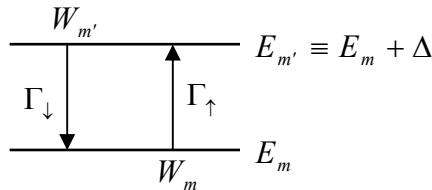

Fig. 4.13. Deriving the detailed balance relation.

In the absence of quantum coherence between the states (see Sec. 2.1), the equations for the time evolution of the corresponding probabilities W_m and $W_{m'}$ should depend only on the probabilities (plus certain constant coefficients). Moreover, since the equations of quantum mechanics are linear, these *master equations* should be also linear. Hence, it is natural to expect them to have the following form,

$$\frac{dW_m}{dt} = W_{m'}\Gamma_\downarrow - W_m\Gamma_\uparrow, \quad \frac{dW_{m'}}{dt} = W_m\Gamma_\uparrow - W_{m'}\Gamma_\downarrow, \quad (4.100)$$

where the coefficients Γ_\uparrow and Γ_\downarrow have the physical sense of the *rates* of the corresponding transitions (see Fig. 13); for example, $\Gamma_\uparrow dt$ is the probability of the system’s transition into the state m' during an infinitesimal time interval dt , provided that at the beginning of that interval it was in the state m with full certainty: $W_m = 1$, $W_{m'} = 0$.⁴⁷ Since for the system with just two energy levels, the time derivatives of the

⁴⁶ Discussion of such laws in the task of *physical kinetics*, which will be briefly reviewed in Chapter 6.

⁴⁷ The calculation of these rates for several particular cases is described in QM Secs. 6.6, 6.7, and 7.6 – see, e.g., QM Eq. (7.196), which is valid for a very general model of a quantum system.

probabilities have to be equal and opposite, Eqs. (100) describe an (irreversible) redistribution of the probabilities while keeping their sum $W = W_m + W_{m'}$ constant. According to Eqs. (100), at $t \rightarrow \infty$ the probabilities settle to their stationary values related as

$$\frac{W_{m'}}{W_m} = \frac{\Gamma_{\uparrow}}{\Gamma_{\downarrow}}. \quad (4.101)$$

Now let us require these stationary values to obey the Gibbs distribution (2.58); from it

$$\frac{W_{m'}}{W_m} = \exp\left\{\frac{E_m - E_{m'}}{T}\right\} = \exp\left\{-\frac{\Delta}{T}\right\} < 1. \quad (4.102)$$

Comparing these two expressions, we see that the rates have to satisfy the following *detailed balance relation*:

$$\frac{\Gamma_{\uparrow}}{\Gamma_{\downarrow}} = \exp\left\{-\frac{\Delta}{T}\right\}. \quad (4.103)$$
Detailed balance

Now comes the final step: since the rates of transition between two particular states should not depend on other states and their occupation, Eq. (103) has to be valid for *each* pair of states of any multi-state system. (By the way, this relation may serve as an important sanity check: the rates calculated using any reasonable model of a quantum system have to satisfy it.)

The detailed balance yields only one equation for two rates Γ_{\uparrow} and Γ_{\downarrow} ; if our only goal is the calculation of Z , the choice of the other equation is not too important. A very simple choice is

$$\Gamma(\Delta) \propto \gamma(\Delta) \equiv \begin{cases} 1, & \text{if } \Delta < 0, \\ \exp\{-\Delta/T\}, & \text{otherwise,} \end{cases} \quad (4.104)$$

where Δ is the energy change resulting from the transition. This model, which evidently satisfies the detailed balance relation (103), is very popular (despite the unphysical cusp this function has at $\Delta = 0$), because it enables the following simple *Metropolis algorithm* (Fig. 14).

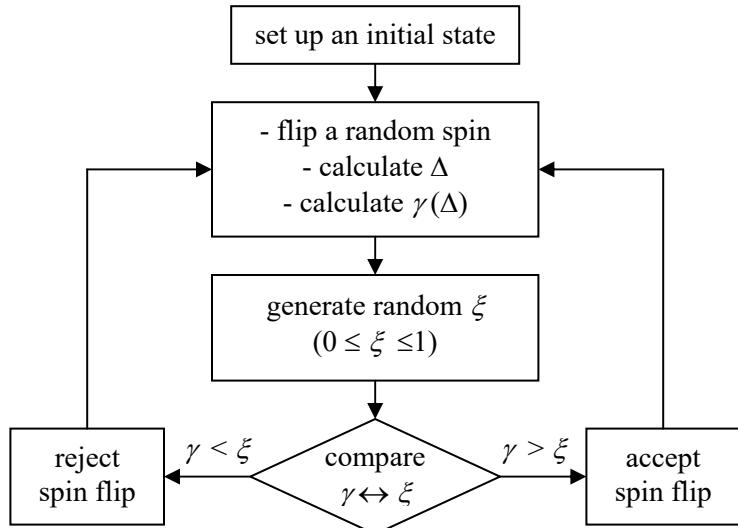

Fig. 4.14. A crude scheme of the Metropolis algorithm for the Ising model simulation.

The calculation starts by setting a certain initial state of the system. At relatively high temperatures, the state may be generated randomly; for example, in the Ising system, the initial state of each spin s_k may be selected independently, with a 50% probability. At low temperatures, starting the calculations from the lowest-energy state (in particular, for the Ising model, from the ferromagnetic state $s_k = \text{sgn}(h) = \text{const}$) may give the fastest convergence. Now one spin is flipped at random, the corresponding change Δ of the energy is calculated,⁴⁸ and plugged into Eq. (104) to calculate $\gamma(\Delta)$. Next, a pseudo-random number generator is used to generate a random number ξ , with the probability density being constant on the segment $[0, 1]$. (Such functions are available in virtually any numerical library.) If the resulting ξ is less than $\gamma(\Delta)$, the transition is accepted, while if $\xi > \gamma(\Delta)$, it is rejected. Physically, this means that any transition down the energy spectrum ($\Delta < 0$) is always accepted, while those up the energy profile ($\Delta > 0$) are accepted with the probability proportional to $\exp\{-\Delta/T\}$.⁴⁹ After sufficiently many such steps, the statistical sum (99) may be calculated approximately as a partial sum over the states passed by the system. (It may be better to discard the contributions from a few first steps, to avoid the effects of the initial state choice.)

This algorithm is extremely efficient. Even with modest computers available in the 1980s, it has allowed simulating a 3D Ising system of $(128)^3$ spins to get the following result: $J/T_c \approx 0.221650 \pm 0.000005$. For all practical purposes, this result is exact – so that perhaps the largest benefit of the possible future analytical solution of the infinite 3D Ising problem will be a virtually certain Nobel Prize for its author. Table 2 summarizes the values of T_c for the Ising model. Very visible is the fast improvement of the prediction accuracy of the molecular-field theory – which is asymptotically correct at $d \rightarrow \infty$.

Table 4.2. The critical temperature T_c (in the units of J) of the Ising model of a ferromagnet ($J > 0$), for several values of dimensionality d

d	Molecular-field theory – Eq. (72)	Exact value	Exact value's source
0	0	0	Gibbs distribution
1	2	0	Transfer matrix theory
2	4	2.269...	Onsager's solution
3	6	4.513...	Numerical simulation

Finally, I need to mention the *renormalization-group* (“RG”) approach,⁵⁰ despite its low efficiency for the Ising-type problems. The basic idea of this approach stems from the scaling law (30)–(31): at $T = T_c$ the correlation radius r_c diverges. Hence, the critical temperature may be found from the requirement for the system to be *spatially self-similar*. Namely, let us form larger and larger groups (“blocks”) of adjacent spins, and require that all properties of the resulting system of the blocks approach those of the initial system, as T approaches T_c .

⁴⁸ Note that a flip of a single spin changes the signs of only $(2d + 1)$ terms in the sum (23), i.e. does not require the re-calculation of all $(2d + 1)N$ terms of the sum, so that the computation of Δ takes just a few multiply-and-accumulate operations even at $N \gg 1$.

⁴⁹ The latter step is necessary to avoid the system’s trapping in local minima of its multidimensional energy profile $E_m(s_1, s_2, \dots, s_N)$.

⁵⁰ Initially developed in the quantum field theory in the 1950s, it was adapted to statistics by L. Kadanoff in 1966, with a spectacular solution of the so-called *Kubo problem* by K. Wilson in 1972, later awarded with a Nobel Prize.

Let us see how this idea works for the simplest nontrivial (1D) case, described by the statistical sum (80). Assuming N to be even (which does not matter at $N \rightarrow \infty$), and adding an inconsequential constant C to each exponent (for the purpose that will be clear soon), we may rewrite this expression as

$$Z = \sum_{s_k=\pm 1} \prod_{k=1,2,\dots,N} \exp \left\{ \frac{h}{2T} s_k + \frac{J}{T} s_k s_{k+1} + \frac{h}{2T} s_{k+1} + C \right\}. \quad (4.105)$$

Let us group each pair of adjacent exponents to recast this expression as a product over only *even* numbers k ,

$$Z = \sum_{s_k=\pm 1} \prod_{k=2,4,\dots,N} \exp \left\{ \frac{h}{2T} s_{k-1} + s_k \left[\frac{J}{T} (s_{k-1} + s_{k+1}) + \frac{h}{T} \right] + \frac{h}{2T} s_{k+1} + 2C \right\}, \quad (4.106)$$

and carry out the summation over two possible states of the internal spin s_k explicitly:

$$\begin{aligned} Z &= \sum_{s_k=\pm 1} \prod_{k=2,4,\dots,N} \left[\exp \left\{ \frac{h}{2T} s_{k-1} + \frac{J}{T} (s_{k-1} + s_{k+1}) + \frac{h}{T} + \frac{h}{2T} s_{k+1} + 2C \right\} \right. \\ &\quad \left. + \exp \left\{ \frac{h}{2T} s_{k-1} - \frac{J}{T} (s_{k-1} + s_{k+1}) - \frac{h}{T} + \frac{h}{2T} s_{k+1} + 2C \right\} \right] \\ &\equiv \sum_{s_k=\pm 1} \prod_{k=2,4,\dots,N} 2 \cosh \left\{ \frac{J}{T} (s_{k-1} + s_{k+1}) + \frac{h}{T} \right\} \exp \left\{ \frac{h}{2T} (s_{k-1} + s_{k+1}) + 2C \right\}. \end{aligned} \quad (4.107)$$

Now let us require this statistical sum (and hence all statistical properties of the system of 2-spin blocks) to be identical to that of the Ising system of $N/2$ spins, numbered by odd k :

$$Z' = \sum_{s_k=\pm 1} \prod_{k=2,4,\dots,N} \exp \left\{ \frac{J'}{T} s_{k-1} s_{k+1} + \frac{h'}{T} s_{k+1} + C' \right\}, \quad (4.108)$$

with some different parameters h' , J' , and C' , for all four possible values of $s_{k-1} = \pm 1$ and $s_{k+1} = \pm 1$. Since the right-hand side of Eq. (107) depends only on the sum $(s_{k-1} + s_{k+1})$, this requirement yields only three (rather than four) independent equations for finding h' , J' , and C' . Of them, the equations for h' and J' depend only on h and J (but not on C),⁵¹ and may be represented in an especially simple form,

$$x' = \frac{x(1+y)^2}{(x+y)(1+xy)}, \quad y' = \frac{y(x+y)}{1+xy}, \quad (4.109)$$

RG
equations
for 1D Ising
model

if the following notation is used:

$$x \equiv \exp \left\{ -4 \frac{J}{T} \right\}, \quad y \equiv \exp \left\{ -2 \frac{h}{T} \right\}. \quad (4.110)$$

Now the grouping procedure may be repeated, with the same result (109)-(110). Hence these equations may be considered as recurrence relations describing repeated doubling of the spin block size. Figure 15 shows (schematically) the *trajectories* of this dynamic system on the phase plane $[x, y]$. (Each trajectory is defined by the following property: for each of its points $\{x, y\}$, the point $\{x', y'\}$ defined by

⁵¹ This might be expected because physically C is just a certain constant addition to the system's energy. However, the introduction of that constant is mathematically necessary, because Eqs. (107) and (108) may be reconciled only if $C' \neq C$.

the “mapping” Eq. (109) is also on the same trajectory.) For ferromagnetic coupling ($J > 0$) and $h > 0$, we may limit the analysis to the unit square $0 \leq x, y \leq 1$. If this *flow diagram* had a stable fixed point with $x' = x = x_\infty \neq 0$ (i.e. $T/J < \infty$) and $y' = y = 1$ (i.e. $h = 0$), then the first of Eqs. (110) would immediately give us the critical temperature of the phase transition in the field-free system:

$$T_c = \frac{4J}{\ln(1/x_\infty)}. \quad (4.111)$$

However, Fig. 15 shows that the only fixed point of the 1D system is $x = y = 0$, which (at a finite coupling J) should be interpreted as $T_c = 0$. This is of course in agreement with the exact result of the transfer-matrix analysis, but does not provide any additional information.

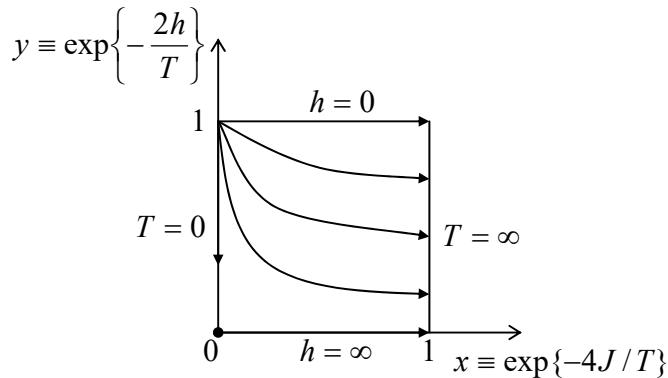

Fig. 4.15. The RG flow diagram of the 1D Ising system (schematically).

Unfortunately, for higher dimensionalities, the renormalization-group approach rapidly becomes rather cumbersome and requires certain approximations, whose accuracy cannot be easily controlled. For the 2D Ising system, such approximations lead to the prediction $T_c \approx 2.55 J$, i.e. to a substantial difference from the exact result (96).

4.6. Exercise problems

4.1. Compare the third virial coefficient $C(T)$ that follows from the van der Waals equation, with its value for the hardball model of particle interactions (whose calculation was the subject of Problem 3.28), and comment.

4.2. Calculate the entropy and the internal energy of the van der Waals gas, and discuss the results.

4.3. Use two different approaches to calculate the so-called *Joule-Thomson coefficient* $(\partial E/\partial V)_T$ for the van der Waals gas, and the change of temperature of such a gas, with a temperature-independent C_V , at its fast expansion.

4.4. Calculate the difference $C_P - C_V$ for the van der Waals gas, and compare the result with that for an ideal classical gas.

4.5. Calculate the temperature dependence of the phase-equilibrium pressure $P_0(T)$ and the latent heat $\Lambda(T)$, for the van der Waals model, in the low-temperature limit $T \ll T_c$.

4.6. Perform the same tasks as in the previous problem in the opposite limit – in close vicinity of the critical point T_c .

4.7. Calculate the critical values P_c , V_c , and T_c for the so-called *Redlich-Kwong model* of the real gas, with the following equation of state:⁵²

$$P + \frac{a}{V(V + Nb)T^{1/2}} = \frac{NT}{V - Nb},$$

with constant parameters a and b .

Hint: Be prepared to solve a cubic equation with particular (numerical) coefficients.

4.8. Calculate the critical values P_c , V_c , and T_c for the phenomenological *Dieterici model*, with the following equation of state:⁵³

$$P = \frac{NT}{V - b} \exp\left\{-\frac{a}{NTV}\right\},$$

with constant parameters a and b . Compare the value of the dimensionless factor $P_c V_c / NT_c$ with those given by the van der Waals and Redlich-Kwong models.

4.9. In the crude sketch shown in Fig. 3b, the derivatives dP/dT of the phase transitions liquid-gas (“vaporization”) and solid-gas (“sublimation”), at the triple point, are different, with

$$\left(\frac{dP_v}{dT}\right)_{T=T_t} < \left(\frac{dP_s}{dT}\right)_{T=T_t}.$$

Is this occasional? What relation between these derivatives can be obtained from thermodynamics?

4.10. Use the Clapeyron-Clausius formula (17) to calculate the latent heat Λ of the Bose-Einstein condensation, and compare the result with that obtained in the solution of Problem 3.21.

4.11.

(i) Write the effective Hamiltonian for that the usual single-particle stationary Schrödinger equation coincides with the Gross-Pitaevski equation (58).

(ii) Use this *Gross-Pitaevskii Hamiltonian*, with the trapping potential $U(\mathbf{r}) = m\omega^2 r^2/2$, to calculate the energy E of $N \gg 1$ trapped particles, assuming the trial solution $\psi \propto \exp\{-r^2/2r_0^2\}$, as a function of the parameter r_0 .⁵⁴

⁵² This equation of state, suggested in 1948, describes most real gases better than not only the original van der Waals model, but also other two-parameter alternatives, such as the *Berthelot*, *modified-Berthelot*, and *Dieterici* models, though some approximations with more fitting parameters (such as the *Soave-Redlich-Kwong model*) work even better.

⁵³ This model is currently less popular than the Redlich-Kwong one (also with two fitting parameters), whose analysis was the task of the previous problem.

⁵⁴ This task is essentially the first step of the variational method of quantum mechanics – see, e.g., QM Sec. 2.9.

(iii) Explore the function $E(r_0)$ for positive and negative values of the constant b , and interpret the results.

(iv) For small $b < 0$, estimate the largest number N of particles that may form a metastable Bose-Einstein condensate.

4.12. Superconductivity may be suppressed by a sufficiently strong magnetic field. In the simplest case of a bulk, long cylindrical sample of a type-I superconductor, placed into an external magnetic field \mathcal{H}_{ext} parallel to its surface, this suppression takes a simple form of a simultaneous transition of the whole sample from the superconducting state to the “normal” (non-superconducting) state at a certain value $\mathcal{H}_c(T)$ of the field’s magnitude. This *critical field* gradually decreases with temperature from its maximum value $\mathcal{H}_c(0)$ at $T \rightarrow 0$ to zero at the critical temperature T_c . Assuming that the function $\mathcal{H}_c(T)$ is known, calculate the latent heat of this phase transition as a function of temperature, and spell out its values at $T \rightarrow 0$ and $T = T_c$.

Hint: In this context, “bulk sample” means a sample much larger than the intrinsic length scales of the superconductor (such as the London penetration depth δ_L and the coherence length ξ).⁵⁵ For such bulk superconductors, magnetic properties of the superconducting phase may be well described just as the perfect diamagnetism, with $\mathcal{B} = 0$ inside it.

4.13. In some textbooks, the discussion of thermodynamics of superconductivity is started with displaying, as self-evident, the following formula:

$$F_n(T) - F_s(T) = \frac{\mu_0 \mathcal{H}_c^2(T)}{2} V,$$

where F_s and F_n are the free energy values in the superconducting and non-superconducting (“normal”) phases, and $\mathcal{H}_c(T)$ is the critical value of the magnetic external field. Is this formula correct, and if not, what qualification is necessary to make it valid? Assume that all conditions of the simultaneous field-induced phase transition in the whole sample, spelled out in the previous problem, are satisfied.

4.14. In Sec. 4, we have discussed Weiss’ molecular-field approach to the Ising model, in which the average $\langle s_j \rangle$ plays the role of the order parameter η . Use the results of that analysis to calculate the coefficients a and b in the corresponding Landau expansion (46) of the free energy. List the critical exponents α and β , defined by Eqs. (26) and (28), within this approach.

4.15. Consider a ring of $N = 3$ Ising “spins” ($s_k = \pm 1$), with similar ferromagnetic coupling J between all sites, in thermal equilibrium.

(i) Calculate the order parameter η and the low-field susceptibility $\chi \equiv \partial \eta / \partial h|_{h=0}$.

(ii) Use the low-temperature limit of the result for χ to predict it for a ring with an arbitrary N , and verify your prediction by a direct calculation (in this limit).

(iii) Discuss the relation between the last result, in the limit $N \rightarrow \infty$, and Eq. (91).

⁵⁵A discussion of these parameters, as well as of the difference between the type-I and type-II superconductivity, may be found in EM Secs. 6.4-6.5. However, those details are not needed for the solution of this problem.

4.16. Calculate the average energy, entropy, and heat capacity of a three-site ring of Ising-type “spins” ($s_k = \pm 1$), with *anti*-ferromagnetic coupling (of magnitude J) between the sites, in thermal equilibrium at temperature T , with no external magnetic field. Find the asymptotic behavior of its heat capacity for low and high temperatures, and give an interpretation of the results.

4.17. Using the results discussed in Sec. 5, calculate the average energy, free energy, entropy, and heat capacity (all per spin) as functions of temperature T and external field h , for the infinite 1D Ising model. Sketch the temperature dependence of the heat capacity for various values of ratio h/J , and give a physical interpretation of the result.

4.18. Use the molecular-field theory to calculate the critical temperature and the low-field susceptibility of a d -dimensional cubic lattice of spins, described by the so-called *classical Heisenberg model*:⁵⁶

$$E_m = -J \sum_{\{k, k'\}} \mathbf{s}_k \cdot \mathbf{s}_{k'} - \sum_k \mathbf{h} \cdot \mathbf{s}_k .$$

Here, in contrast to the (otherwise, very similar) Ising model (23), the spin of each site is modeled by a classical 3D vector $\mathbf{s}_k = \{s_{xk}, s_{yk}, s_{zk}\}$ of unit length: $s_k^2 = 1$.

⁵⁶ This classical model is formally similar to the generalization of the genuine (quantum) Heisenberg model (21) to arbitrary spin s , and serves as its infinite-spin limit.

Chapter 5. Fluctuations

This chapter discusses fluctuations of macroscopic variables, mostly at thermodynamic equilibrium. In particular, it describes the intimate connection between fluctuations and dissipation (damping) in dynamic systems weakly coupled to multi-particle environments, which culminates in the Einstein relation between the diffusion coefficient and mobility, the Nyquist formula, and its quantum-mechanical generalization – the fluctuation-dissipation theorem. An alternative approach to the same problem, based on the Smoluchowski and Fokker-Planck equations, is also discussed in brief.

5.1. Characterization of fluctuations

At the beginning of Chapter 2, we have discussed the notion of averaging, $\langle f \rangle$, of a variable f over a statistical ensemble – see Eqs. (2.7) and (2.10). Now, the *fluctuation* of the variable is defined simply as its deviation from such average:

$$\tilde{f} \equiv f - \langle f \rangle; \quad (5.1)$$

this deviation is, generally, also a random variable. The most important property of any fluctuation is that its average (over the same statistical ensemble) equals zero:

$$\langle \tilde{f} \rangle = \langle f - \langle f \rangle \rangle = \langle f \rangle - \langle \langle f \rangle \rangle = \langle f \rangle - \langle f \rangle = 0. \quad (5.2)$$

As a result, such an average cannot characterize fluctuations' *intensity*, and the simplest characteristic of the intensity is the *variance* (sometimes called "dispersion"):

$$\langle \tilde{f}^2 \rangle = \langle (f - \langle f \rangle)^2 \rangle. \quad (5.3)$$

The following simple property of the variance is frequently convenient for its calculation:

$$\langle \tilde{f}^2 \rangle = \langle (f - \langle f \rangle)^2 \rangle = \langle f^2 - 2f\langle f \rangle + \langle f \rangle^2 \rangle = \langle f^2 \rangle - 2\langle f \rangle^2 + \langle f \rangle^2, \quad (5.4a)$$

so that, finally:

$$\langle \tilde{f}^2 \rangle = \langle f^2 \rangle - \langle f \rangle^2. \quad (5.4b)$$

As the simplest example, consider a variable that takes only two values, ± 1 , with equal probabilities $W_j = 1/2$. For such a variable, the basic Eq. (2.7) yields

$$\begin{aligned} \langle f \rangle &= \sum_j W_j f_j = \frac{1}{2}(+1) + \frac{1}{2}(-1) = 0, \quad \text{but } \langle f^2 \rangle = \sum_j W_j f_j^2 = \frac{1}{2}(+1)^2 + \frac{1}{2}(-1)^2 = 1 \neq 0, \\ &\text{so that } \langle \tilde{f}^2 \rangle = \langle f^2 \rangle - \langle f \rangle^2 = 1. \end{aligned} \quad (5.5)$$

The square root of the variance,

$$\delta f \equiv \langle \tilde{f}^2 \rangle^{1/2}, \quad (5.6)$$

is called the *root-mean-square (r.m.s.) fluctuation*. An advantage of this measure is that it has the same dimensionality as the variable itself, so that the ratio $\delta f / \langle f \rangle$ is dimensionless, and may be used to characterize the *relative intensity* of fluctuations.

As has been mentioned in Chapter 1, all results of thermodynamics are valid only if the fluctuations of thermodynamic variables (internal energy E , entropy S , etc.) are relatively small.¹ Let us make a simple estimate of the relative intensity of fluctuations for an example of a system of N independent, similar particles, and an extensive variable

$$\mathcal{F} \equiv \sum_{k=1}^N f_k . \quad (5.7)$$

where all single-particle functions f_k are similar, besides that each of them depends on the state of only “its own” (k^{th}) particle. The statistical average of such \mathcal{F} is evidently

$$\langle \mathcal{F} \rangle = \sum_{k=1}^N \langle f \rangle = N \langle f \rangle, \quad (5.8)$$

while its fluctuation variance is

$$\langle \tilde{\mathcal{F}}^2 \rangle \equiv \langle \tilde{\mathcal{F}} \tilde{\mathcal{F}} \rangle \equiv \left\langle \sum_{k=1}^N \tilde{f}_k \sum_{k'=1}^N \tilde{f}_{k'} \right\rangle \equiv \left\langle \sum_{k,k'=1}^N \tilde{f}_k \tilde{f}_{k'} \right\rangle \equiv \sum_{k,k'=1}^N \langle \tilde{f}_k \tilde{f}_{k'} \rangle. \quad (5.9)$$

Now we may use the fact that for two independent variables

$$\langle \tilde{f}_k \tilde{f}_{k'} \rangle = 0, \quad \text{for } k' \neq k; \quad (5.10)$$

indeed, this relation may be considered as the mathematical definition of their independence. Hence, only the terms with $k' = k$ make substantial contributions to the sum (9):

$$\langle \tilde{\mathcal{F}}^2 \rangle = \sum_{k,k'=1}^N \langle \tilde{f}_k^2 \rangle \delta_{k,k'} = N \langle \tilde{f}^2 \rangle. \quad (5.11)$$

Comparing Eqs. (8) and (11), we see that the relative intensity of fluctuations of the variable \mathcal{F} ,

$$\frac{\delta \mathcal{F}}{\langle \mathcal{F} \rangle} = \frac{1}{N^{1/2}} \frac{\delta f}{\langle f \rangle}, \quad (5.12)$$

Relative fluctuation estimate

tends to zero as the system size grows ($N \rightarrow \infty$). It is this fact that justifies the thermodynamic approach to typical physical systems, with the number N of particles of the order of the Avogadro number $N_A \sim 10^{24}$. Nevertheless, in many situations even small fluctuations of variables are important, and in this chapter we will calculate their basic properties, starting with the variance.

It should be comforting for the reader to notice that for some simple (but very important) cases, such calculation has already been done in our course. In particular, for any generalized coordinate q and generalized momentum p that give quadratic contributions of the type (2.46) to the system’s

¹ Let me remind the reader that up to this point, the averaging signs $\langle \dots \rangle$ were dropped in most formulas, for the sake of notation simplicity. In this chapter, I have to restore these signs to avoid confusion. The only exception will be temperature – whose average, following (probably, bad :-) tradition, will be still called just T everywhere, besides the last part of Sec. 3, where temperature fluctuations are discussed explicitly.

Hamiltonian (as in a harmonic oscillator), we have derived the equipartition theorem (2.48), valid in the classical limit. Since the average values of these variables, in the thermodynamic equilibrium, equal zero, Eq. (6) immediately yields their r.m.s. fluctuations:

$$\delta p = (mT)^{1/2}, \quad \delta q = \left(\frac{T}{\kappa} \right)^{1/2} \equiv \left(\frac{T}{m\omega^2} \right)^{1/2}, \quad \text{where } \omega = \left(\frac{\kappa}{m} \right)^{1/2}. \quad (5.13)$$

The generalization of these classical relations to the quantum-mechanical case ($T \sim \hbar\omega_j$) is provided by Eqs. (2.78) and (2.81):

$$\delta p = \left[\frac{\hbar m \omega}{2} \coth \frac{\hbar \omega}{2T} \right]^{1/2}, \quad \delta q = \left[\frac{\hbar}{2m\omega} \coth \frac{\hbar \omega}{2T} \right]^{1/2}. \quad (5.14)$$

However, the intensity of fluctuations in other systems requires special calculations. Moreover, only a few cases allow for general, model-independent results. Let us review some of them.

5.2. Energy and the number of particles

First of all, note that fluctuations of macroscopic variables depend on particular conditions.² For example, in a mechanically- and thermally-insulated system with a fixed number of particles, i.e. a member of a *microcanonical* ensemble, the internal energy does not fluctuate: $\delta E = 0$. However, if such a system is in thermal contact with the environment, i.e. is a member of a *canonical* ensemble (Fig. 2.6), the situation is different. Indeed, for such a system we may apply the general Eq. (2.7), with W_m given by the Gibbs distribution (2.58)-(2.59), not only to E but also to E^2 . As we already know from Sec. 2.4, the first average,

$$\langle E \rangle = \sum_m W_m E_m, \quad W_m = \frac{1}{Z} \exp \left\{ -\frac{E_m}{T} \right\}, \quad Z = \sum_m \exp \left\{ -\frac{E_m}{T} \right\}, \quad (5.15)$$

yields Eq. (2.61b), which may be rewritten in the form

$$\langle E \rangle = \frac{1}{Z} \frac{\partial Z}{\partial(-\beta)}, \quad \text{where } \beta \equiv \frac{1}{T}, \quad (5.16)$$

more convenient for our current purposes. Let us carry out a similar calculation for E^2 :

$$\langle E^2 \rangle = \sum_m W_m E_m^2 = \frac{1}{Z} \sum_m E_m^2 \exp \left\{ -\beta E_m \right\}. \quad (5.17)$$

It is straightforward to verify, by double differentiation, that the last expression may be rewritten in a form similar to Eq. (16):

$$\langle E^2 \rangle = \frac{1}{Z} \frac{\partial^2}{\partial(-\beta)^2} \sum_m \exp \left\{ -\beta E_m \right\} \equiv \frac{1}{Z} \frac{\partial^2 Z}{\partial(-\beta)^2}. \quad (5.18)$$

Now it is easy to use Eqs. (4) to calculate the variance of energy fluctuations:

$$\langle \tilde{E}^2 \rangle = \langle E^2 \rangle - \langle E \rangle^2 = \frac{1}{Z} \frac{\partial^2 Z}{\partial(-\beta)^2} - \left(\frac{1}{Z} \frac{\partial Z}{\partial(-\beta)} \right)^2 \equiv \frac{\partial}{\partial(-\beta)} \left(\frac{1}{Z} \frac{\partial Z}{\partial(-\beta)} \right) = \frac{\partial \langle E \rangle}{\partial(-\beta)}. \quad (5.19)$$

² Unfortunately, even in some popular textbooks, certain formulas pertaining to fluctuations are either incorrect or given without specifying the conditions of their applicability, so that the reader's caution is advised.

Since Eqs. (15)-(19) are valid only if the system's volume V is fixed (because its change may affect the energy spectrum E_m), it is customary to rewrite this important result as follows:

$$\langle \tilde{E}^2 \rangle = \frac{\partial \langle E \rangle}{\partial (-1/T)} = T^2 \left(\frac{\partial \langle E \rangle}{\partial T} \right)_V \equiv C_V T^2. \quad (5.20)$$

Fluctuations
of E

This is a remarkably simple, fundamental result. As a sanity check, for a system of N similar, independent particles, $\langle E \rangle$ and hence C_V are proportional to N , so that $\delta E \propto N^{1/2}$ and $\delta E/\langle E \rangle \propto N^{-1/2}$, in agreement with Eq. (12). Let me emphasize that the classically-looking Eq. (20) is based on the general Gibbs distribution, and hence is valid for any system (either classical or quantum) in thermal equilibrium.

Some corollaries of this result will be discussed in the next section, and now let us carry out a very similar calculation for a system whose number N of particles in a system is not fixed, because they may go to, and come from its environment at will. If the chemical potential μ of the environment and its temperature T are fixed, i.e. we are dealing with the *grand canonical ensemble* (Fig. 2.13), we may use the grand canonical distribution (2.106)-(2.107):

$$W_{m,N} = \frac{1}{Z_G} \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\}, \quad Z_G = \sum_{N,m} \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\}. \quad (5.21)$$

Acting exactly as we did above for the internal energy, we get

$$\langle N \rangle = \frac{1}{Z_G} \sum_{m,N} N \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\} = \frac{T}{Z_G} \frac{\partial Z_G}{\partial \mu}, \quad (5.22)$$

$$\langle N^2 \rangle = \frac{1}{Z_G} \sum_{m,N} N^2 \exp \left\{ \frac{\mu N - E_{m,N}}{T} \right\} = \frac{T^2}{Z_G} \frac{\partial^2 Z_G}{\partial \mu^2}, \quad (5.23)$$

so that the particle number's variance is

$$\langle \tilde{N}^2 \rangle = \langle N^2 \rangle - \langle N \rangle^2 = \frac{T^2}{Z_G} \frac{\partial Z_G}{\partial \mu} - \frac{T^2}{Z_G^2} \left(\frac{\partial Z_G}{\partial \mu} \right)^2 = T \frac{\partial}{\partial \mu} \left(\frac{T}{Z_G} \frac{\partial Z_G}{\partial \mu} \right) = T \frac{\partial \langle N \rangle}{\partial \mu}, \quad (5.24)$$

Fluctuations
of N

in full analogy with Eq. (19).

In particular, for an ideal classical gas, we may combine the last result with Eq. (3.32b). (As was already emphasized in Sec. 3.2, though that result has been obtained for the canonical ensemble, in which the number of particles N is fixed, at $N \gg 1$ the fluctuations of N in the grand canonical ensemble should be relatively small, so that the same relation should be valid for the *average* $\langle N \rangle$ in that ensemble.) Easily solving Eq. (3.32b) for $\langle N \rangle$, we get

$$\langle N \rangle = \text{const} \times \exp \left\{ \frac{\mu}{T} \right\}, \quad (5.25)$$

where “const” means a factor constant at the partial differentiation of $\langle N \rangle$ over μ , required by Eq. (24). Performing the differentiation and then using Eq. (25) again,

$$\frac{\partial \langle N \rangle}{\partial \mu} = \text{const} \times \frac{1}{T} \exp\left\{\frac{\mu}{T}\right\} = \frac{\langle N \rangle}{T}, \quad (5.26)$$

we get from Eq. (24) a very simple result:

Fluctuations
of N :
classical gas

$$\langle \tilde{N}^2 \rangle = \langle N \rangle, \quad \text{i.e. } \delta N = \langle N \rangle^{1/2}. \quad (5.27)$$

This relation is so important that I will also show how it may be derived differently. As a by-product of this new derivation, we will prove that this result is valid for systems with an arbitrary (say, small) N , and also get more detailed information about the statistics of fluctuations of that number. Let us consider an ideal classical gas of N_0 particles in a volume V_0 , and calculate the probability W_N to have exactly $N \leq N_0$ of these particles in its part of volume $V \leq V_0$ – see Fig. 1.

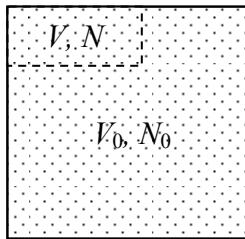

Fig. 5.1. Deriving the binomial and Poisson distributions.

For one particle such probability is $W = V/V_0 = \langle N \rangle/N_0 \leq 1$, while the probability to have that particle in the remaining part of the volume is $W' = 1 - W = 1 - \langle N \rangle/N_0$. If all particles were distinguishable, the probability of having $N \leq N_0$ specific particles in volume V and $(N - N_0)$ specific particles in volume $(V - V_0)$, would be $W^N W'^{(N_0-N)}$. However, if we do not want to distinguish the particles, we should multiply this probability by the number of possible particle combinations keeping the numbers N and N_0 constant, i.e. by the binomial coefficient $N_0!/N!(N_0 - N)!$.³ As the result, the required probability is

Binomial distribution

$$W_N = W^N W'^{(N_0-N)} \frac{N_0!}{N!(N_0 - N)!} = \left(\frac{\langle N \rangle}{N_0} \right)^N \left(1 - \frac{\langle N \rangle}{N_0} \right)^{N_0 - N} \frac{N_0!}{N!(N_0 - N)!}. \quad (5.28)$$

This is the so-called *binomial probability distribution*, valid for any $\langle N \rangle$ and N_0 .⁴

Still keeping $\langle N \rangle$ arbitrary, we can simplify the binomial distribution by assuming that the whole volume V_0 , and hence N_0 , are very large:

$$N_0 \gg N, \quad (5.29)$$

where N means all values of interest, including $\langle N \rangle$. Indeed, in this limit we can neglect N in comparison with N_0 in the second exponent of Eq. (28), and also approximate the fraction $N_0!/(N_0 - N)!$, i.e. the product of N terms, $(N_0 - N + 1)(N_0 - N + 2)\dots(N_0 - 1)N_0$, by just N_0^N . As a result, we get

$$W_N \approx \left(\frac{\langle N \rangle}{N_0} \right)^N \left(1 - \frac{\langle N \rangle}{N_0} \right)^{N_0} \frac{N_0^N}{N!} \equiv \frac{\langle N \rangle^N}{N!} \left(1 - \frac{\langle N \rangle}{N_0} \right)^{N_0} = \frac{\langle N \rangle^N}{N!} \left[(1 - W)^{\frac{1}{W}} \right]^{\langle N \rangle}, \quad (5.30)$$

³ See, e.g., MA Eq. (2.2).

⁴ It was derived by Jacob Bernoulli (1655-1705).

where, as before, $W = \langle N \rangle / N_0$. In the limit (29), $W \rightarrow 0$, so that the factor inside the square brackets tends to $1/e$, the reciprocal of the natural logarithm base.⁵ Thus, we get an expression independent of N_0 :

$$W_N = \frac{\langle N \rangle^N}{N!} e^{-\langle N \rangle}. \quad (5.31)$$

Poisson distribution

This is the much-celebrated *Poisson distribution*⁶ which describes a very broad family of random phenomena. Figure 2 shows this distribution for several values of $\langle N \rangle$ – which, in contrast to N , are not necessarily integer.

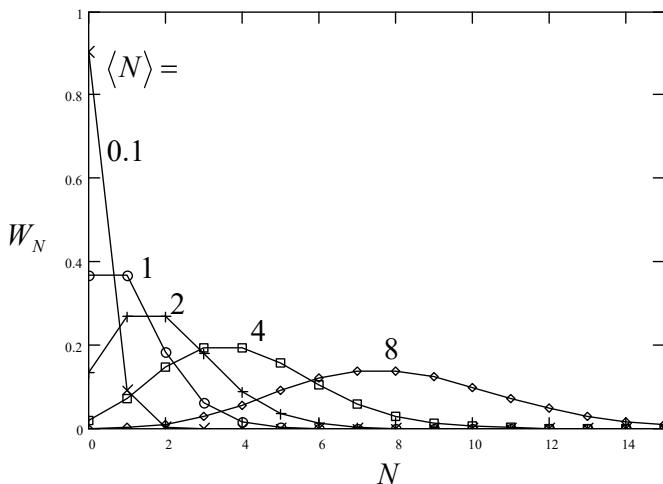

Fig. 5.2. The Poisson distribution for several values of $\langle N \rangle$. In contrast to that average, the argument N may take only integer values, so that the lines in these plots are only guides for the eye.

In the limit of very small $\langle N \rangle$, the function $W_N(N)$ is close to an exponent, $W_N \approx W^N \propto \langle N \rangle^N$, while in the opposite limit, $\langle N \rangle \gg 1$, it rapidly approaches the *Gaussian* (or “normal”) *distribution*⁷

$$W_N = \frac{1}{(2\pi)^{1/2} \delta N} \exp\left\{-\frac{(N - \langle N \rangle)^2}{2(\delta N)^2}\right\}. \quad (5.32)$$

Gaussian distribution

(Note that the Gaussian distribution is also valid if both N and N_0 are large, regardless of the relation between them – see Fig. 3.)

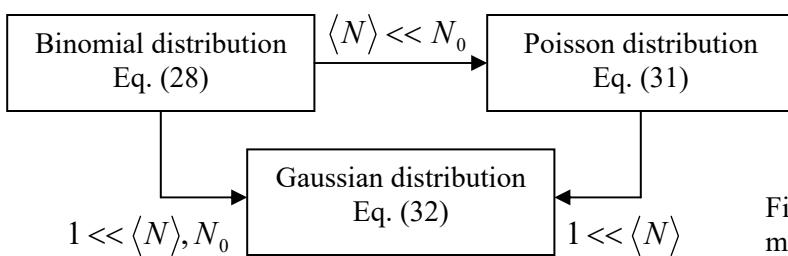

Fig. 5.3. The hierarchy of three major probability distributions.

⁵ Indeed, this is just the most popular definition of that major mathematical constant – see, e.g., MA Eq. (1.2a) with $n = -1/W$.

⁶ Named after the same Siméon Denis Poisson (1781-1840) who is also responsible for other mathematical tools and results used in this series, including the Poisson equation – see Sec. 6.4 below.

⁷ Named after Carl Friedrich Gauss (1777-1855), though Pierre-Simone Laplace (1749-1827) is credited for substantial contributions to its development.

A major property of the Poisson (and hence of the Gaussian) distribution is that it has the same variance as given by Eq. (27):

$$\langle \tilde{N}^2 \rangle \equiv \langle (N - \langle N \rangle)^2 \rangle = \langle N \rangle. \quad (5.33)$$

(This is not true for the general binomial distribution.) For our current purposes, this means that for the ideal classical gas, Eq. (27) is valid for *any* number of particles.

5.3. Volume and temperature

What are the r.m.s. fluctuations of other thermodynamic variables – like V , T , etc.? Again, the answer depends on specific conditions. For example, if the volume V occupied by a gas is externally fixed (say, by rigid walls), it evidently does not fluctuate at all: $\delta V = 0$. On the other hand, the volume may fluctuate in the situation when the average pressure is fixed – see, e.g., Fig. 1.5. A formal calculation of these fluctuations, using the approach applied in the last section, is complicated by the fact that it is physically impracticable to fix its conjugate variable, P , i.e. suppress its fluctuations. For example, the force $\mathcal{F}(t)$ exerted by an ideal classical gas on a container's wall (whose measure the pressure is) is the result of individual, independent hits of the wall by particles (Fig. 4), with the time scale $\tau_c \sim r_B/\langle v^2 \rangle^{1/2} \sim r_B/(T/m)^{1/2} \sim 10^{-16}$ s, so that its frequency spectrum extends to very high frequencies, virtually impossible to control.

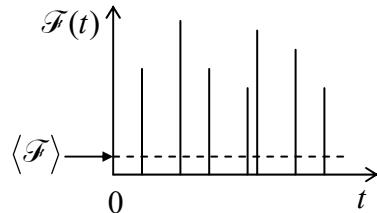

Fig. 5.4. The force exerted by gas particles on a container's wall, as a function of time (schematically).

However, we can use the following trick, very typical for the theory of fluctuations. It is almost evident that the r.m.s. fluctuations of the gas volume are independent of the shape of the container. Let us consider a particular situation similar to that shown in Fig. 1.5, with the container of a cylindrical shape, with the base area A .⁸ Then the coordinate of the piston is just $q = V/A$, while the average force exerted by the gas on the cylinder is $\mathcal{F} = PA$ – see Fig. 5. Now if the piston is sufficiently massive, its free oscillation frequency ω near the equilibrium position is small enough to satisfy the following three conditions.

First, besides balancing the average force $\langle \mathcal{F} \rangle$ and thus sustaining the average pressure $\langle P \rangle = \langle \mathcal{F} \rangle / A$ of the gas, the interaction between the heavy piston and the relatively light particles of the gas is weak, because of a relatively short duration of the particle hits (Fig. 4). As a result, the full energy of the system may be represented as a sum of those of the particles and the piston, with a quadratic contribution to the piston's potential energy by small deviations from the equilibrium:

⁸ As a math reminder, the term “cylinder” does not necessarily mean the “circular cylinder”; the shape of its base may be arbitrary; it just should not change with height.

$$U_p = \frac{\kappa}{2} \tilde{q}^2, \quad \text{where } \tilde{q} \equiv q - \langle q \rangle = \frac{\tilde{V}}{A}, \quad (5.34)$$

and κ is the effective spring constant arising from the finite compressibility of the gas.

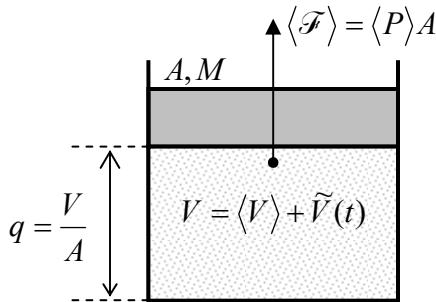

Fig. 5.5. Deriving Eq. (37).

Second, at $\omega \rightarrow 0$, this spring constant may be calculated just as for constant variations of the volume, with the gas remaining in quasi-equilibrium at all times:

$$\kappa = -\frac{\partial \langle \mathcal{F} \rangle}{\partial q} = A^2 \left(-\frac{\partial \langle P \rangle}{\partial \langle V \rangle} \right). \quad (5.35)$$

This partial derivative⁹ should be calculated at whatever the given thermal conditions are, e.g., with $S = \text{const}$ for adiabatic conditions (i.e., a thermally insulated gas), or with $T = \text{const}$ for isothermal conditions (including a good thermal contact between the gas and a heat bath), etc. With that constant denoted as X , Eqs. (34)-(35) give

$$U_p = \frac{1}{2} \left(-A^2 \frac{\partial \langle P \rangle}{\partial \langle V \rangle} \right)_X \left(\frac{\tilde{V}}{A} \right)^2 \equiv \frac{1}{2} \left(-\frac{\partial \langle P \rangle}{\partial \langle V \rangle} \right)_X \tilde{V}^2. \quad (5.36)$$

Finally, assuming that $\omega = (\kappa/M)^{1/2}$ is sufficiently small (namely, $\hbar\omega \ll T$) because of a sufficiently large piston mass M , we may apply, to the piston's fluctuations, the classical equipartition theorem: $\langle U_p \rangle = T/2$, giving¹⁰

$$\boxed{\langle \tilde{V}^2 \rangle_X = T \left(-\frac{\partial \langle V \rangle}{\partial \langle P \rangle} \right)_X.} \quad (5.37a) \quad \text{Fluctuations of } V$$

Since this result is valid for any A and ω , it should not depend on the system's geometry and piston's mass, provided that it is large in comparison with the effective mass of a single system component (say, a gas molecule) – the condition that is naturally fulfilled in most experiments. For the

⁹ As already was discussed in Sec. 4.1 in the context of the van der Waals equation, for the mechanical stability of a gas (or liquid), the derivative $\partial P/\partial V$ has to be negative, so that κ is positive.

¹⁰ One may meet statements that a similar formula,

$$\langle \tilde{P}^2 \rangle_X = T \left(-\frac{\partial \langle P \rangle}{\partial \langle V \rangle} \right)_X, \quad \text{(WRONG!)}$$

is valid for pressure fluctuations. However, a such statement does not take into account a different physical nature of pressure (Fig. 4), with its very broad frequency spectrum. This issue will be discussed later in this chapter.

particular case of fluctuations at constant temperature ($X = T$),¹¹ we may use the definition (3.58) of the isothermal bulk compressibility K_T of the gas to rewrite Eq. (37a) as

$$\langle \tilde{V}^2 \rangle_T = \frac{TV}{K_T}. \quad (5.37b)$$

For an ideal classical gas of N particles, with the equation of state $\langle V \rangle = NT/\langle P \rangle$, it is easier to use directly Eq. (37a), again with $X = T$, to get

$$\langle \tilde{V}^2 \rangle_T = -T \left(-\frac{NT}{\langle P \rangle^2} \right) = \frac{\langle V \rangle^2}{N}, \quad \text{i.e. } \frac{\delta V_T}{\langle V \rangle} = \frac{1}{N^{1/2}}, \quad (5.38)$$

in full agreement with the general trend given by Eq. (12).

Now let us proceed to fluctuations of temperature, for simplicity focusing on the case $V = \text{const}$. Let us again assume that the system we are considering is weakly coupled to a heat bath of temperature T_0 , in the sense that the time τ of temperature equilibration between the two is much larger than the time of internal equilibration, called *thermalization*. Then we may assume that, on the former time scale, T changes virtually simultaneously in the whole system, and consider it a function of time alone:

$$T = \langle T \rangle + \tilde{T}(t). \quad (5.39)$$

Moreover, due to the (relatively) large τ , we may use the stationary relation between small fluctuations of temperature and the internal energy of the system:

$$\tilde{T}(t) = \frac{\tilde{E}(t)}{C_V}, \quad \text{so that } \delta T = \frac{\delta E}{C_V}. \quad (5.40)$$

With those assumptions, Eq. (20) immediately yields the famous expression for the so-called *thermodynamic fluctuations of temperature*:

$$\delta T = \frac{\delta E}{C_V} = \frac{\langle T \rangle}{C_V^{1/2}}. \quad (5.41)$$

The most straightforward application of this result is to analyses of so-called *bolometers* – broadband detectors of electromagnetic radiation in microwave and infrared frequency bands. (In particular, they are used for measurements of the CMB radiation, which was discussed in Sec. 2.6). In such a detector (Fig. 6), the incoming radiation is focused on a small sensor (e.g., either a small piece of a germanium crystal or a superconductor thin film at temperature $T \approx T_c$, etc.), which is well isolated thermally from the environment. As a result, the absorption of an even small radiation power \mathcal{P} leads to a noticeable change ΔT of the sensor's average temperature $\langle T \rangle$ and hence of its electric resistance R , which is probed up by low-noise external electronics.¹² If the power does not change in time too fast, ΔT is a certain function of \mathcal{P} , turning to 0 at $\mathcal{P} = 0$. Hence, if ΔT is much lower than the environment temperature T_0 , we may keep only the main, linear term in its Taylor expansion in \mathcal{P} .

¹¹ In this case, we may also use the second of Eqs. (1.39) to rewrite Eq. (37) via the second derivative $(\partial^2 G / \partial P^2)_T$.

¹² Besides low internal electric noise, a good sensor should have a sufficiently large *temperature responsivity* dR/dT , making the noise contribution by the readout electronics insignificant – see below.

$$\Delta T \equiv \langle T \rangle - T_0 = \frac{\mathcal{P}}{\mathcal{G}}, \quad (5.42)$$

where the coefficient $\mathcal{G} \equiv \partial \mathcal{P} / \partial T$ is called the *thermal conductance* of the (perhaps small but unavoidable) thermal coupling between the sensor and the heat bath – see Fig. 6.

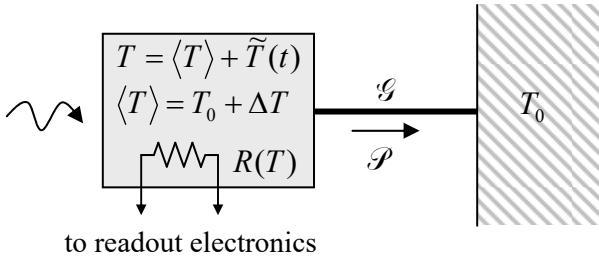

Fig. 5.6. The conceptual scheme of a bolometer.

The power may be detected if the electric signal from the sensor, which results from the change ΔT , is not drowned in spontaneous fluctuations. In practical systems, these fluctuations are contributed by several sources including electronic amplifiers. However, in modern systems, these “technical” contributions to noise are successfully suppressed,¹³ and the dominating noise source is the fundamental sensor temperature fluctuations, described by Eq. (41). In this case, the so-called *noise-equivalent power* (“NEP”), defined as the level of \mathcal{P} that produces the signal equal to the r.m.s. value of noise, may be calculated by equating the expressions (41) (with $\langle T \rangle = T_0$) and (42):

$$\text{NEP} \equiv \mathcal{P} \Big|_{\Delta T = \delta T} = \frac{T_0 \mathcal{G}}{C_V^{1/2}}. \quad (5.43)$$

This expression shows that to decrease the NEP, i.e. improve the detector’s sensitivity, both the environment temperature T_0 and the thermal conductance \mathcal{G} should be reduced. In modern receivers of radiation, their typical values are of the order of 0.1 K and 10^{-10} W/K, respectively.

On the other hand, Eq. (43) implies that to increase the bolometer’s sensitivity, i.e. to reduce the NEP, the C_V of the sensor, and hence its mass, should be *increased*. This conclusion is valid only to a certain extent, because due to technical reasons (parameter drifts and the so-called *1/f noise* of the sensor and external electronics), the incoming power has to be modulated with as high frequency ω as technically possible (in practical receivers, the cyclic frequency $\nu = \omega/2\pi$ of the modulation is between 10 and 1,000 Hz), so that the electrical signal might be picked up from the sensor at that frequency. As a result, the C_V may be increased only until the thermal constant of the sensor,

$$\tau = \frac{C_V}{\mathcal{G}}, \quad (5.44)$$

becomes close to $1/\omega$, because at $\omega\tau \gg 1$ the useful signal drops faster than noise. So, the lowest (i.e. the best) values of the NEP,

¹³ An important modern trend in this progress [see, e.g., P. Day *et al.*, *Nature* **425**, 817 (2003)] is the replacement of the resistive temperature sensors $R(T)$ with thin and narrow superconducting strips with temperature-sensitive kinetic inductance $L_k(T)$ – see the model solution of EM Problem 6.19. Such inductive sensors have zero dc resistance, and hence vanishing Johnson-Nyquist noise at typical signal pickup frequencies of a few kHz – see Eq. (81) and its discussion below.

$$(NEP)_{\min} = \alpha T_0 \mathcal{G}^{1/2} \nu^{1/2}, \quad \text{with } \alpha \sim 1, \quad (5.45)$$

are reached at $\nu\tau \approx 1$. (The exact values of the optimal product $\omega\tau$, and of the numerical constant $\alpha \sim 1$ in Eq. (45), depend on the exact law of the power modulation in time, and the readout signal processing procedure.) With the parameters cited above, this estimate yields $(NEP)_{\min}/\nu^{1/2} \sim 3 \times 10^{-17} \text{ W/Hz}^{1/2}$ – a very low power indeed.

However, perhaps counter-intuitively, the power modulation allows the bolometric (and other broadband) receivers to register radiation with power much lower than this NEP! Indeed, picking up the sensor signal at the modulation frequency ω , we can use the subsequent electronics stages to filter out all the noise besides its components within a very narrow band, of width $\Delta\nu \ll \nu$, around the modulation frequency (Fig. 7). This is the idea of a *microwave radiometer*,¹⁴ currently used in all sensitive broadband receivers of radiation.

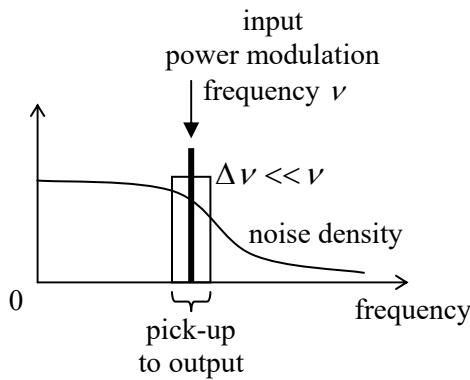

Fig. 5.7. The basic idea of the Dicke radiometer.

In order to analyze this opportunity, we need to develop theoretical tools for a quantitative description of the spectral distribution of fluctuations. Another motivation for that description is a need for analysis of variables dominated by fast (high-frequency) components, such as pressure – please have one more look at Fig. 4. Finally, during such an analysis, we will run into the fundamental relation between fluctuations and dissipation, which is one of the main results of statistical physics as a whole.

5.4. Fluctuations as functions of time

In the previous sections, the averaging $\langle \dots \rangle$ of any function was assumed to be over an appropriate statistical ensemble of many similar systems. However, as was discussed in Sec. 2.1, most physical systems of interest are ergodic. If such a system is also *stationary*, i.e. the statistical averages of its variables do not change with time, the averaging may be also understood as that over a sufficiently long time interval. In this case, we may think about fluctuations of any variable f as of a random process taking place in just one system, but developing in time: $\tilde{f} = \tilde{f}(t)$.

There are two mathematically equivalent approaches to the description of such random functions of time, called the *time-domain* picture and the *frequency-domain* picture, their relative convenience

¹⁴ It was pioneered in the 1950s by Robert Henry Dicke, so that the device is frequently called the *Dicke radiometer*. Note that the optimal strategy of using similar devices for time- and energy-resolved detection of single high-energy photons is different – though even it is essentially based on Eq. (41). For a recent brief review of such detectors see, e.g., K. Morgan, *Phys. Today* **71**, 29 (Aug. 2018), and references therein.

depending on the particular problem to be solved. In the time domain, we need to characterize a *random* fluctuation $\tilde{f}(t)$ by some *deterministic* function of time. Evidently, the average $\langle \tilde{f}(t) \rangle$ cannot be used for this purpose, because it equals zero – see Eq. (2). Of course, the variance (3) does not equal zero, but if the system is stationary, that average cannot depend on time either. Because of that, let us consider the following average:

$$\langle \tilde{f}(t)\tilde{f}(t') \rangle. \quad (5.46)$$

Generally, this is a function of two arguments. However, in a stationary system, the average like (46) may depend only on the difference,

$$\tau \equiv t' - t, \quad (5.47)$$

between the two observation times. In this case, the average (46) is called the *correlation function* of the variable f :

$$K_f(\tau) \equiv \langle \tilde{f}(t)\tilde{f}(t+\tau) \rangle. \quad (5.48)$$

Correlation
function

Again, here the averaging may be understood as that either over a statistical ensemble of macroscopically similar systems or over a sufficiently long interval of the time argument t , with the argument τ kept constant. The correlation function's name¹⁵ catches the idea of this notion very well: $K_f(\tau)$ characterizes the mutual relation between the fluctuations of the variable f at two times separated by the given interval τ . Let us list the basic properties of this function.¹⁶

First of all, $K_f(\tau)$ has to be an even function of the time delay τ . Indeed, we may write

$$K_f(-\tau) = \langle \tilde{f}(t)\tilde{f}(t-\tau) \rangle \equiv \langle \tilde{f}(t-\tau)\tilde{f}(t) \rangle = \langle \tilde{f}(t')\tilde{f}(t'+\tau) \rangle, \quad (5.49)$$

with $t' \equiv t - \tau$. For stationary processes, this average cannot depend on the common shift of two observation times, so that the averages (48) and (49) have to be equal:

$$K_f(-\tau) = K_f(\tau). \quad (5.50)$$

Second, at $\tau \rightarrow 0$ the correlation function tends to the variance:

$$K_f(0) = \langle \tilde{f}(t)\tilde{f}(t) \rangle = \langle \tilde{f}^2 \rangle \geq 0. \quad (5.51)$$

In the opposite limit, when τ is much larger than certain characteristic *correlation time* τ_c of the system,¹⁷ the correlation function has to tend to zero because the fluctuations separated by such time interval are virtually independent (*uncorrelated*). As a result, the correlation function typically looks like one of the plots sketched in Fig. 8.

¹⁵ Another term, the *autocorrelation function*, is sometimes used for the average (48) to distinguish it from the *mutual correlation function*, $\langle f_1(t)f_2(t+\tau) \rangle$, of two different stationary processes.

¹⁶ Please notice that this correlation function is the direct temporal analog of the spatial correlation function briefly discussed in Sec. 4.2 – see Eq. (4.30).

¹⁷ Note that the correlation time τ_c is the direct temporal analog of the correlation radius r_c that was discussed in Sec. 4.2 – see the same Eq. (4.30).

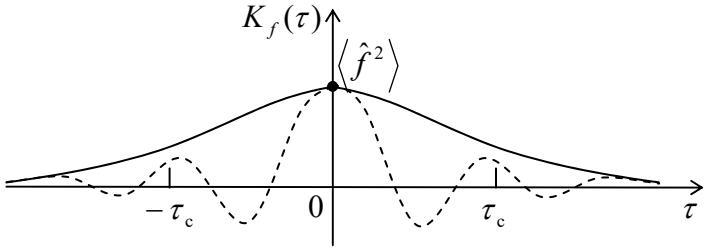

Fig. 5.8. The correlation function of fluctuations: two typical examples.

Note that on a time scale much longer than τ_c , any physically-realistic correlation function may be well approximated with a delta function of τ . (For example, for a process which is a sum of independent very short pulses, e.g., the gas pressure force exerted on the container wall (Fig. 4), such approximation is legitimate on time scales much longer than the single pulse duration, e.g., the time of particle's interaction with on the wall at the impact.)

In the reciprocal, frequency domain, the same process $\tilde{f}(t)$ is represented as a Fourier integral,¹⁸

$$\tilde{f}(t) = \int_{-\infty}^{+\infty} f_\omega e^{-i\omega t} d\omega, \quad (5.52)$$

with the reciprocal transform being

$$f_\omega = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \tilde{f}(t) e^{i\omega t} dt. \quad (5.53)$$

If the function $\tilde{f}(t)$ is random (as it is in the case of fluctuations), with zero average, its Fourier transform f_ω is also a random function (now of frequency), also with a vanishing statistical average. Indeed, now thinking of the operation $\langle \dots \rangle$ as an ensemble averaging, we may write

$$\langle f_\omega \rangle = \left\langle \frac{1}{2\pi} \int_{-\infty}^{+\infty} \tilde{f}(t) e^{i\omega t} dt \right\rangle = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \langle \tilde{f}(t) \rangle e^{i\omega t} dt = 0. \quad (5.54)$$

The simplest non-zero average may be formed similarly to Eq. (46), but with due respect to the complex-variable character of the Fourier images:

$$\langle f_\omega f_{\omega'}^* \rangle = \frac{1}{(2\pi)^2} \int_{-\infty}^{+\infty} dt' \int_{-\infty}^{+\infty} dt \langle \tilde{f}(t) \tilde{f}(t') \rangle e^{i(\omega' t' - \omega t)}. \quad (5.55)$$

It turns out that for a stationary process, the averages (46) and (55) are directly related. Indeed, since the integration over t' in Eq. (55) is in infinite limits, we may replace it with the integration over $\tau \equiv t' - t$ (at fixed t), also in infinite limits. Replacing t' with $t + \tau$ in the expressions under the integral, we see that the average is just the correlation function $K_f(\tau)$, while the time exponent is equal to $\exp\{i(\omega' - \omega)t\}\exp\{i\omega'\tau\}$. As a result, changing the order of integration, we get

$$\langle f_\omega f_{\omega'}^* \rangle = \frac{1}{(2\pi)^2} \int_{-\infty}^{+\infty} dt \int_{-\infty}^{+\infty} d\tau K_f(\tau) e^{i(\omega - \omega')t} e^{i\omega'\tau} \equiv \frac{1}{(2\pi)^2} \int_{-\infty}^{+\infty} K_f(\tau) e^{i\omega'\tau} d\tau \int_{-\infty}^{+\infty} e^{i(\omega - \omega')t} dt. \quad (5.56)$$

But the last integral is just $2\pi\delta(\omega - \omega')$,¹⁹ so that we finally get

¹⁸ The argument of the function f_ω is represented as its index with a purpose to emphasize that this function is different from $\tilde{f}(t)$, while (very conveniently) still using the same letter for the same variable.

$$\langle f_\omega f_{\omega'}^* \rangle = S_f(\omega) \delta(\omega - \omega'), \quad (5.57)$$

where the real function of frequency,

$$S_f(\omega) \equiv \frac{1}{2\pi} \int_{-\infty}^{+\infty} K_f(\tau) e^{i\omega\tau} d\tau = \frac{1}{\pi} \int_0^\infty K_f(\tau) \cos \omega\tau d\tau, \quad (5.58)$$

Spectral density of fluctuations

is called the *spectral density of fluctuations at frequency ω* . According to Eq. (58), the spectral density is just the Fourier image of the correlation function, and hence the reciprocal Fourier transform is:²⁰⁻²¹

$$K_f(\tau) = \int_{-\infty}^{+\infty} S_f(\omega) e^{-i\omega\tau} d\omega = 2 \int_0^\infty S_f(\omega) \cos \omega\tau d\omega. \quad (5.59)$$

Wiener-Khinchin theorem

In particular, for the fluctuation variance, Eq. (59) yields

$$\langle \tilde{f}^2 \rangle \equiv K_f(0) = \int_{-\infty}^{+\infty} S_f(\omega) d\omega \equiv 2 \int_0^\infty S_f(\omega) d\omega. \quad (5.60)$$

The last relation shows that the term “spectral density” describes the physical sense of the function $S_f(\omega)$ very well. Indeed, if a random signal $f(t)$ had been passed through a frequency filter with a small bandwidth $\Delta\nu \ll \nu$ of positive cyclic frequencies, the integral in the last form of Eq. (60) could be limited to the interval $\Delta\omega = 2\pi\Delta\nu$, i.e. the variance of the filtered signal would become

$$\langle \tilde{f}^2 \rangle_{\Delta\nu} = 2S_f(\omega)\Delta\omega \equiv 4\pi S_f(\omega)\Delta\nu. \quad (5.61)$$

(A popular alternative definition of the spectral density is $\mathcal{S}(\nu) \equiv 4\pi S_f(\omega)$, making the average (61) equal to just $\mathcal{S}(\nu)\Delta\nu$.)

To conclude this introductory (mostly mathematical) section, let me note an important particular case. If the spectral density of some process is nearly constant within all the frequency range of interest, $S_f(\omega) = \text{const} = S_f(0)$,²² Eq. (59) shows that its correlation function may be well approximated with a delta function:

$$K_f(\tau) = S_f(0) \int_{-\infty}^{+\infty} e^{-i\omega\tau} d\omega = 2\pi S_f(0) \delta(\tau). \quad (5.62)$$

From this relation stems another popular name of the white noise, the *delta-correlated process*. We have already seen that this is a very reasonable approximation, for example, for the gas pressure force fluctuations (Fig. 4). Of course, for the spectral density of a realistic, limited physical variable the approximation of constant spectral density cannot be true for *all* frequencies (otherwise, for example,

¹⁹ See, e.g., MA Eq. (14.4).

²⁰ The second form of Eq. (59) uses the fact that, according to Eq. (58), $S_f(\omega)$ is an even function of frequency – just as $K_f(\tau)$ is an even function of time.

²¹ Although Eqs. (58) and (59) look not much more than straightforward corollaries of the Fourier transform, they bear a special name of the *Wiener-Khinchin theorem* – after the mathematicians N. Wiener and A. Khinchin who have proved that these relations are valid even for the functions $f(t)$ that are not square-integrable, so that from the point of view of standard mathematics, their Fourier transforms are not well defined.

²² Such process is frequently called the *white noise*, because it consists of all frequency components with equal amplitudes, reminding the white light, which consists of many monochromatic components with close amplitudes.

the integral (60) would diverge, giving an unphysical, infinite value of its variance), and may be valid only at frequencies much lower than $1/\tau_c$.

5.5. Fluctuations and dissipation

Now we are equipped mathematically to address one of the most important issues of statistical physics, the relation between fluctuations and dissipation. This relation is especially simple for the following hierarchical situation: a relatively “heavy”, slowly moving system, weakly interacting with an environment consisting of rapidly moving, “light” components. A popular theoretical term for such a system is the *Brownian particle*, named after botanist Robert Brown who was first to notice (in 1827) the random motion of small particles (in his case, pollen grains), caused by their random hits by fluid’s molecules, under a microscope. However, the family of such systems is much broader than that of small mechanical particles. Just for a few examples, such description is valid for an atom interacting with electromagnetic field modes of the surrounding space, a clock pendulum interacting with molecules of the air around it, current and voltage in electric circuits, etc.²³

One more important assumption of this theory is that the system’s motion does not violate the thermal equilibrium of the environment – well fulfilled in many cases. (Think, for example, about a typical mechanical pendulum – its motion does not overheat the air around it to any noticeable extent.) In this case, the averaging over a statistical ensemble of *similar environments*, at a fixed, specific motion of the system of interest, may be performed assuming their thermal equilibrium.²⁴ I will denote such a “primary” averaging by the usual angle brackets $\langle \dots \rangle$. At a later stage, we may carry out additional, “secondary” averaging, over an ensemble of many similar systems of interest, coupled to similar environments. When we do, such double averaging will be denoted by double angle brackets $\langle\langle \dots \rangle\rangle$.

Let me start from a simple classical system, a 1D harmonic oscillator whose equation of evolution may be represented as

$$m\ddot{q} + \kappa q = \mathcal{F}_{\text{det}}(t) + \mathcal{F}_{\text{env}}(t) \equiv \mathcal{F}_{\text{det}}(t) + \langle \mathcal{F} \rangle + \tilde{\mathcal{F}}(t), \quad \text{with } \langle \tilde{\mathcal{F}}(t) \rangle = 0, \quad (5.63)$$

where q is the (generalized) coordinate of the oscillator, $\mathcal{F}_{\text{det}}(t)$ is the deterministic external force, while both components of the force $\mathcal{F}_{\text{env}}(t)$ represent the impact of the environment on the oscillator’s motion. Again, on the time scale of the fast-moving environmental components, the oscillator’s motion is slow. The average component $\langle \mathcal{F} \rangle$ of the force exerted by the environment on such a slowly moving object is frequently independent of its coordinate q but does depend on its velocity \dot{q} . For most such systems, the Taylor expansion of the force in small velocity has a non-zero linear term:

$$\langle \mathcal{F} \rangle = -\eta \dot{q}, \quad (5.64)$$

where the constant η is usually called the *drag* (or “kinematic friction”, or “damping”) *coefficient*, so that Eq. (63) may be rewritten as

²³ To emphasize this generality, in the forthcoming discussion of the 1D case, I will use the letter q rather than x for the system’s displacement.

²⁴ For a usual (ergodic) environment, the primary averaging may be interpreted as that over relatively short time intervals, $\tau_c \ll \Delta t \ll \tau$, where τ_c is the correlation time of the environment, while τ is the characteristic time scale of motion of our “heavy” system of interest.

$$m\ddot{q} + \eta\dot{q} + \kappa q = \mathcal{F}_{\text{det}}(t) + \tilde{\mathcal{F}}(t). \quad (5.65)$$

This method of describing the environmental effects on an otherwise Hamiltonian system is called the *Langevin equation*.²⁵ Due to the linearity of the differential equation (65), its general solution may be represented as a sum of two independent parts: the deterministic motion of the damped linear oscillator due to the external force $\mathcal{F}_{\text{det}}(t)$, and its random fluctuations due to the random force $\tilde{\mathcal{F}}(t)$ exerted by the environment. The former effects are well known from classical dynamics,²⁶ so let us focus on the latter part by taking $\mathcal{F}_{\text{det}}(t) = 0$. The remaining term on the right-hand side of Eq. (65) describes the fluctuating part of the environmental force; in contrast to the average component (64), its intensity (read: its spectral density at relevant frequencies $\omega \sim \omega_0 \equiv (\kappa/m)^{1/2}$) does not vanish at $q(t) = 0$, and hence may be evaluated ignoring the system's motion.²⁷

Plugging into Eq. (65) the representation of both variables in the Fourier form similar to Eq. (52), and requiring the coefficients before the same $\exp\{-i\omega t\}$ to be equal on both sides of the equation, for their Fourier images we get the following relation:

$$-m\omega^2 q_\omega - i\omega\eta q_\omega + \kappa q_\omega = \mathcal{F}_\omega, \quad (5.66)$$

which immediately gives us q_ω , i.e. the (random) complex amplitude of the coordinate fluctuations:

$$q_\omega = \frac{\mathcal{F}_\omega}{(\kappa - m\omega^2) - i\eta\omega} \equiv \frac{\mathcal{F}_\omega}{m(\omega_0^2 - \omega^2) - i\eta\omega}. \quad (5.67)$$

Now multiplying Eq. (67) by its complex conjugate for another frequency (say, ω'), averaging both parts of the resulting equation, and using the formulas similar to Eq. (57) for each of them,²⁸ we get the following relation between spectral densities of the oscillations and the random force:²⁹

$$S_q(\omega) = \frac{1}{m^2(\omega_0^2 - \omega^2)^2 + \eta^2\omega^2} S_{\mathcal{F}}(\omega). \quad (5.68)$$

In the so-called low-damping limit ($\eta \ll m\omega_0$), the fraction on the right-hand side of Eq. (68) has a sharp peak near the oscillator's own frequency ω_0 (describing the well-known effect of high- Q resonance), and may be well approximated in that vicinity as

²⁵ Named after Paul Langevin, whose 1908 work was the first systematic development of A. Einstein's ideas on Brownian motion (see below) using this formalism. A detailed discussion of this approach, with numerical examples of its application, may be found, e.g., in the monograph by W. Coffey, Yu. Kalmykov, and J. Waldron, *The Langevin Equation*, World Scientific, 1996.

²⁶ See, e.g., CM Sec. 5.1. Here I assume that the variable $f(t)$ is classical, with the discussion of the quantum case postponed until the end of the section.

²⁷ Note that the direct secondary statistical averaging of Eq. (65) with $\mathcal{F}_{\text{det}} = 0$ yields $\langle\langle q \rangle\rangle = 0$! This, perhaps a bit counter-intuitive result becomes less puzzling if we recognize that this is the averaging over a large statistical ensemble of random sinusoidal oscillations with all values of their phase, and that the (equally probable) oscillations with opposite phases give mutually canceling contributions to the sum in Eq. (2.6).

²⁸ At this stage, we restrict our analysis to random, stationary processes $q(t)$, so that Eq. (57) is valid for this variable as well, if the averaging in it is understood in the $\langle\langle \dots \rangle\rangle$ sense.

²⁹ Regardless of the physical sense of such a function of ω , and of whether its maximum is situated at a finite frequency ω_0 as in Eq. (68) or at $\omega = 0$, it is often referred to as the *Lorentzian* (or "Breit-Wigner") *line*.

$$\frac{1}{m^2(\omega_0^2 - \omega^2)^2 + (\eta\omega)^2} \approx \frac{1}{\eta^2\omega_0^2(\xi^2 + 1)}, \quad \text{with } \xi \equiv \frac{2m(\omega - \omega_0)}{\eta}. \quad (5.69)$$

In contrast, the spectral density $S_{\mathcal{F}}(\omega)$ of fluctuations of a typical environment is changing relatively slowly, so that for the purpose of integration over frequencies near ω_0 we may replace $S_{\mathcal{F}}(\omega)$ with $S_{\mathcal{F}}(\omega_0)$. As a result, the variance of the environment-imposed random oscillations may be calculated, using Eq. (60), as³⁰

$$\langle\langle \tilde{q}^2 \rangle\rangle = 2 \int_0^\infty S_q(\omega) d\omega \approx 2 \int_{\omega \approx \omega_0} S_q(\omega) d\omega = 2S_{\mathcal{F}}(\omega_0) \frac{1}{\eta^2\omega_0^2} \frac{\eta}{2m} \int_{-\infty}^{+\infty} \frac{d\xi}{\xi^2 + 1}. \quad (5.70)$$

This is a well-known table integral,³¹ equal to π , so that, finally:

$$\langle\langle \tilde{q}^2 \rangle\rangle = 2S_{\mathcal{F}}(\omega_0) \frac{1}{\eta^2\omega_0^2} \frac{\eta}{2m} \pi \equiv \frac{\pi}{m\omega_0^2\eta} S_{\mathcal{F}}(\omega_0) \equiv \frac{\pi}{\kappa\eta} S_{\mathcal{F}}(\omega_0). \quad (5.71)$$

But on the other hand, the weak interaction with the environment should keep the oscillator in thermodynamic equilibrium at the same temperature T . Since our analysis has been based on the classical Langevin equation (65), we may only use it in the classical limit $\hbar\omega_0 \ll T$, in which we may use the equipartition theorem (2.48). In our current notation, it yields

$$\frac{\kappa}{2} \langle\langle \tilde{q}^2 \rangle\rangle = \frac{T}{2}. \quad (5.72)$$

Comparing Eqs. (71) and (72), we see that the spectral density of the random force exerted by the environment has to be fundamentally related to the damping it provides:

$$S_{\mathcal{F}}(\omega_0) = \frac{\eta}{\pi} T. \quad (5.73a)$$

Now we may argue (rather convincingly :-) that since this relation does not depend on oscillator's parameters m and κ , and hence its eigenfrequency $\omega_0 = (\kappa/m)^{1/2}$, it should be valid at any relatively low frequency ($\omega\tau_c \ll 1$). Using Eq. (58) with $\omega \rightarrow 0$, it may be also rewritten as a formula for the effective low-frequency drag coefficient:

$$\eta = \frac{1}{T} \int_0^\infty K_{\mathcal{F}}(\tau) d\tau \equiv \frac{1}{T} \int_0^\infty \langle\langle \tilde{\mathcal{F}}(0)\tilde{\mathcal{F}}(\tau) \rangle\rangle d\tau. \quad (5.73b)$$

Formulas (73) reveal an intimate, fundamental relation between the fluctuations and the dissipation provided by a thermally-equilibrium environment. Parroting the famous political slogan, there is “no dissipation without fluctuation” – and vice versa. This means in particular that the phenomenological description of dissipation barely by the drag force in classical mechanics³² is

³⁰ Since in this case the process in the oscillator is entirely due to its environment, its variance should be obtained by statistical averaging over an ensemble of many similar (oscillator + environment) systems, and hence, following our convention, it is denoted by double angular brackets.

³¹ See, e.g. MA Eq. (6.5a).

³² See, e.g., CM Sec. 5.1.

(approximately) valid only when the energy scale of the process is much larger than T . To the best of my knowledge, this fact was first recognized in 1905 by A. Einstein,³³ for the following particular case.

Let us apply our result (73) to a free 1D Brownian particle, by taking $\kappa = 0$ and $\mathcal{F}_{\text{det}}(t) = 0$. In this case, both relations (71) and (72) give infinities. To understand the reason for that divergence, let us go back to the Langevin equation (65) with not only $\kappa = 0$ and $\mathcal{F}_{\text{det}}(t) = 0$, but also $m \rightarrow 0$ – just for the sake of simplicity. (The latter approximation, frequently called the *overdamping limit*, is quite appropriate, for example, for the motion of small particles in viscous fluids – such as in R. Brown's experiments.) In this approximation, Eq. (65) is reduced to a simple equation,

$$\eta \dot{q} = \tilde{\mathcal{F}}(t), \quad \text{with } \langle \tilde{\mathcal{F}}(t) \rangle = 0, \quad (5.74)$$

which may be readily integrated to give the particle's displacement during a finite time interval t :

$$\Delta q(t) \equiv q(t) - q(0) = \frac{1}{\eta} \int_0^t \tilde{\mathcal{F}}(t') dt'. \quad (5.75)$$

Evidently, at the full statistical averaging of the displacement, the fluctuation effects vanish, but this does not mean that the particle does not move – just that it has equal probabilities to be shifted in either of two possible directions. To see that, let us calculate the variance of the displacement:

$$\langle \langle \Delta \tilde{q}^2(t) \rangle \rangle = \frac{1}{\eta^2} \int_0^t dt' \int_0^t dt'' \langle \tilde{\mathcal{F}}(t') \tilde{\mathcal{F}}(t'') \rangle \equiv \frac{1}{\eta^2} \int_0^t dt' \int_0^t dt'' K_{\mathcal{F}}(t' - t''). \quad (5.76)$$

As we already know, at times $\tau \gg \tau_c$, the correlation function may be well approximated by the delta function – see Eq. (62). In this approximation, with $S_{\mathcal{F}}(0)$ expressed by Eq. (73a), we get

$$\langle \langle \Delta \tilde{q}^2(t) \rangle \rangle = \frac{2\pi}{\eta^2} S_{\mathcal{F}}(0) \int_0^t dt' \int_0^t dt'' \delta(t'' - t') = \frac{2\pi}{\eta^2} \frac{\eta T}{\pi} \int_0^t dt' = \frac{2T}{\eta} t \equiv 2Dt, \quad (5.77)$$

with

$$D = \frac{T}{\eta}. \quad (5.78)$$

Einstein's relation

The final form of Eq. (77) describes the well-known law of *diffusion* (“random walk”) of a 1D system, with the r.m.s. deviation from the point of origin growing as $(2Dt)^{1/2}$. The coefficient D is this relation is called the *coefficient of diffusion*, and Eq. (78) describes the extremely simple and important³⁴ *Einstein's relation* between that coefficient and the drag coefficient. Often this relation is rewritten, in the SI units of temperature, as $D = \mu k_B T_K$, where $\mu \equiv 1/\eta$ is the *mobility* of the particle. The physical sense of μ becomes clear from the expression for the deterministic velocity (particle's “drift”), which follows from the averaging of both sides of Eq. (74) after the restoration of the term $\mathcal{F}_{\text{det}}(t)$ in it:

³³ It was published in one of the three papers of Einstein's celebrated 1905 “triad”. As a reminder, another paper started the (special) relativity theory, and one more was the quantum description of the photoelectric effect, essentially starting the quantum mechanics. Not too bad for one year, one young scientist!

³⁴ In particular, in 1908, i.e. very soon after Einstein's publication, it was used by J. Perrin for an accurate determination of the Avogadro number N_A . (It was Perrin who graciously suggested naming this constant after A. Avogadro, honoring his pioneering studies of gases in the 1810s.)

$$v_{\text{drift}} \equiv \langle \langle \dot{q}(t) \rangle \rangle = \frac{1}{\eta} \mathcal{F}_{\text{det}}(t) \equiv \mu \mathcal{F}_{\text{det}}(t), \quad (5.79)$$

so that the mobility is just the drift velocity given to the particle by a unit force.³⁵

Another famous embodiment of the general Eq. (73) is the *thermal* (or “Johnson”, or “Johnson-Nyquist”, or just “Nyquist”) *noise* in resistive electron devices. Let us consider a two-terminal, dissipation-free “probe” circuit, playing the role of the harmonic oscillator in our analysis carried out above, connected to a resistive device (Fig. 9), playing the role of the probe circuit’s environment. (The noise is generated by the thermal motion of numerous electrons, randomly moving inside the resistive device.) For this system, one convenient choice of the conjugate variables (the generalized coordinate and generalized force) is, respectively, the electric charge $Q \equiv \int I(t)dt$ that has passed through the “probe” circuit by time t , and the voltage \mathcal{V} across its terminals, with the polarity shown in Fig. 9. (Indeed, the product $\mathcal{V}dQ$ is the elementary work $d\mathcal{W}$ done by the environment on the probe circuit.)

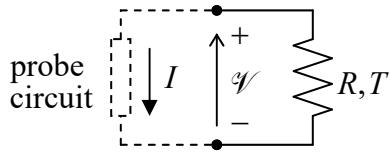

Fig. 5.9. A resistive device as a dissipative environment of a two-terminal probe circuit.

Making the corresponding replacements, $q \rightarrow Q$ and $\mathcal{F} \rightarrow \mathcal{V}$ in Eq. (64), we see that it becomes

$$\langle \mathcal{V} \rangle = -\eta \dot{Q} \equiv -\eta I. \quad (5.80)$$

Comparing this relation with Ohm’s law, $\mathcal{V} = R(-I)$,³⁶ we see that in this case, the coefficient η has the physical sense of the usual Ohmic resistance R of our dissipative device,³⁷ so that Eq. (73a) becomes

$$S_{\mathcal{V}}(\omega) = \frac{R}{\pi} T. \quad (5.81a)$$

Using last equality in Eq. (61), and transferring to the SI units of temperature ($T = k_B T_K$), we may bring this famous *Nyquist formula*³⁸ to its most popular form:

$$\langle \tilde{\mathcal{V}}^2 \rangle_{\Delta\nu} = 4k_B T_K R \Delta\nu. \quad (5.81b)$$

Nyquist formula

³⁵ Note that in solid-state physics and electronics, the charge carrier mobility is usually defined as $|\mathbf{v}_{\text{drift}}/\mathcal{E}| = e v_{\text{drift}}/|\mathcal{F}_{\text{det}}| \equiv e |\mu|$ (where \mathcal{E} is the applied electric field), and is traditionally measured in $\text{cm}^2/\text{V}\cdot\text{s}$.

³⁶ The minus sign is due to the fact that in our notation, the current flowing in the resistor, from the positive terminal to the negative one, is $(-I)$ – see Fig. 9.

³⁷ Due to this fact, Eq. (64) is often called the *Ohmic model* of the environment’s response, even if the physical nature of the variables q and \mathcal{F} is completely different from the electric charge and voltage.

³⁸ It is named after Harry Nyquist who derived this formula in 1928 (independently of the prior work by A. Einstein, M. Smoluchowski, and P. Langevin) to describe the noise that had been just discovered experimentally by his Bell Labs’ colleague John Bertrand Johnson. The derivation of Eq. (73) and hence Eq. (81) in these notes is essentially a twist of the derivation used by H. Nyquist.

Note that according to Eq. (65), this result is only valid at a negligible speed of change of the coordinate q (in our current case, negligible current I), i.e. Eq. (81) expresses the voltage fluctuations as would be measured by a virtually ideal *voltmeter*, with its input resistance much higher than R .

On the other hand, using a different choice of generalized coordinate and force, $q \rightarrow \Phi$, $\mathcal{F} \rightarrow I$ (where $\Phi \equiv \int \mathcal{V}(t)dt$ is the generalized magnetic flux, so that $d\mathcal{W} = I\mathcal{V}(t)dt \equiv Id\Phi$), we get $\eta \rightarrow 1/R$, and Eq. (73) yields the thermal fluctuations of the current through the resistive device, as measured by a virtually ideal *ammeter*, i.e. at $\mathcal{V} \rightarrow 0$:

$$S_I(\omega) = \frac{1}{\pi R} T, \quad \text{i.e. } \langle \tilde{I}^2 \rangle_{\Delta\nu} = \frac{4k_B T_K}{R} \Delta\nu. \quad (5.81c)$$

The nature of Eqs. (81) is so fundamental that they may be used, in particular, for the so-called *Johnson noise thermometry*.³⁹ Note, however, that these relations are valid for noise in thermal equilibrium only. In electric circuits that may be readily driven out of equilibrium by an applied voltage \mathcal{V} , other types of noise are frequently important, notably the *shot noise*, which arises in short conductors, e.g., tunnel junctions, at applied voltages with $|\mathcal{V}| \gg T/q$, due to the discreteness of charge carriers.⁴⁰ A straightforward analysis (left for the reader's exercise) shows that this noise may be characterized by current fluctuations with the following low-frequency spectral density:

$$S_I(\omega) = \frac{|q\bar{I}|}{2\pi}, \quad \text{i.e. } \langle \tilde{I}^2 \rangle_{\Delta\nu} = 2|q\bar{I}|\Delta\nu, \quad (5.82)$$

Schottky formula

where q is the electric charge of a single current carrier. This is the *Schottky formula*,⁴¹ valid for any relation between the average I and \mathcal{V} . The comparison of Eqs. (81c) and (82) for a device that obeys the Ohm law shows that the shot noise has the same intensity as the thermal noise with the effective temperature

$$T_{\text{ef}} = \frac{|q\mathcal{V}|}{2} \gg T. \quad (5.83)$$

This relation may be interpreted as a result of charge carrier overheating by the applied electric field, and explains why the Schottky formula (82) is only valid in conductors much shorter than the energy relaxation length l_e of the charge carriers.⁴² (Another mechanism of shot noise suppression, which may become noticeable in highly conductive nanoscale devices, is the Fermi-Dirac statistics of electrons.⁴³)

Now let us return for a minute to the bolometric Dicke radiometer (see Figs. 6-7 and their discussion in Sec. 4), and use the Langevin formalism to finalize its analysis. For this system, the Langevin equation is an extension of the usual equation of heat balance:

³⁹ See, e.g., J. Crossno *et al.*, *Appl. Phys. Lett.* **106**, 023121 (2015), and references therein.

⁴⁰ Another practically important type of fluctuations in electronic devices is the low-frequency *1/f noise* that was already mentioned in Sec. 3 above. I will briefly discuss it in Sec. 8.

⁴¹ It was derived by Walter Hans Schottky as early as 1918, i.e. even before Nyquist's work.

⁴² See, e.g., Y. Naveh *et al.*, *Phys. Rev. B* **58**, 15371 (1998). In practically used metals, l_e is of the order of 30 nm even at liquid-helium temperatures (and much shorter at room temperatures), so that the usual "macroscopic" resistors do not exhibit the shot noise.

⁴³ For a review of this effect see, e.g., Ya. Blanter and M. Büttiker, *Phys. Repts.* **336**, 1 (2000).

$$C_V \frac{dT}{dt} + \mathcal{G}(T - T_0) = \mathcal{P}_{\text{det}}(t) + \tilde{\mathcal{P}}(t), \quad (5.84)$$

where $\mathcal{P}_{\text{det}} \equiv \langle \mathcal{P} \rangle$ describes the (deterministic) power of the absorbed radiation and $\tilde{\mathcal{P}}$ represents the effective source of temperature fluctuations. Now we can use Eq. (84) to carry out a calculation of the spectral density $S_T(\omega)$ of temperature fluctuations absolutely similarly to how this was done with Eq. (65), assuming that the frequency spectrum of the fluctuation source is much broader than the intrinsic bandwidth $1/\tau = \mathcal{G}/C_V$ of the bolometer, so that its spectral density at frequencies $\omega\tau \sim 1$ may be well approximated by its low-frequency value $S_{\mathcal{P}}(0)$:

$$S_T(\omega) = \left| \frac{1}{-i\omega C_V + \mathcal{G}} \right|^2 S_{\mathcal{P}}(0). \quad (5.85)$$

Then, requiring the variance of temperature fluctuations, calculated from this formula and Eq. (60),

$$\begin{aligned} (\delta T)^2 &\equiv \langle \tilde{T}^2 \rangle = 2 \int_0^\infty S_T(\omega) d\omega = 2 S_{\mathcal{P}}(0) \int_0^\infty \left| \frac{1}{-i\omega C_V + \mathcal{G}} \right|^2 d\omega \\ &\equiv 2 S_{\mathcal{P}}(0) \frac{1}{C_V^2} \int_0^\infty \frac{d\omega}{\omega^2 + (\mathcal{G}/C_V)^2} = \frac{\pi S_{\mathcal{P}}(0)}{\mathcal{G} C_V}, \end{aligned} \quad (5.86)$$

to coincide with our earlier “thermodynamic fluctuation” result (41), we get

$$S_{\mathcal{P}}(0) = \frac{\mathcal{G}}{\pi} T_0^2. \quad (5.87)$$

The r.m.s. value of the “power noise” within a bandwidth $\Delta\nu \ll 1/\tau$ (see Fig. 7) becomes equal to the deterministic signal power \mathcal{P}_{det} (or more exactly, the main harmonic of its modulation law) at

$$\mathcal{P} = \mathcal{P}_{\text{min}} \equiv \left(\langle \tilde{\mathcal{P}}^2 \rangle_{\Delta\nu} \right)^{1/2} = (2 S_{\mathcal{P}}(0) \Delta\nu)^{1/2} = 2(\mathcal{G} \Delta\nu)^{1/2} T_0. \quad (5.88)$$

This result shows that our earlier prediction (45) may be improved by a substantial factor of the order of $(\Delta\nu/\nu)^{1/2}$, where the reduction of the output bandwidth is limited only by the signal accumulation time $\Delta t \sim 1/\Delta\nu$, while the increase of ν is limited by the speed of (typically, mechanical) devices performing the power modulation. In practical systems this factor may improve the sensitivity by a couple of orders of magnitude, enabling observation of extremely weak radiation. Maybe the most spectacular example is the recent measurements of the CMB radiation, which corresponds to blackbody temperature $T_K \approx 2.726$ K, with accuracy $\delta T_K \sim 10^{-6}$ K, using microwave receivers with the physical temperature of all their components much higher than δT . The observed weak ($\sim 10^{-5}$ K) anisotropy of the CMB radiation is a major experimental basis of all modern cosmology.⁴⁴

Returning to the discussion of our main result, Eq. (73), let me note that it may be readily generalized to the case when the environment’s response is different from the Ohmic form (64). This opportunity is virtually evident from Eq. (66): by its derivation, the second term on its left-hand side is just the Fourier component of the average response of the environment to the system’s displacement:

⁴⁴ See, e.g., a concise book by A. Balbi, *The Music of the Big Bang*, Springer, 2008.

$$\langle \hat{\mathcal{F}}_\omega \rangle = i\omega\eta q_\omega. \quad (5.89)$$

Now let the response be still linear, but have an arbitrary frequency dispersion,

$$\langle \hat{\mathcal{F}}_\omega \rangle = \chi(\omega)q_\omega, \quad (5.90)$$

where the function $\chi(\omega)$, called the *generalized susceptibility* (in our case, of the environment) may be complex, i.e. have both the imaginary and real parts:

$$\chi(\omega) = \chi'(\omega) + i\chi''(\omega). \quad (5.91)$$

Then Eq. (73) remains valid with the replacement $\eta \rightarrow \chi''(\omega)/\omega$.⁴⁵

$$S_{\hat{\mathcal{F}}}(\omega) = \frac{\chi''(\omega)}{\pi\omega} T. \quad (5.92)$$

This fundamental relation⁴⁶ may be used not only to calculate the fluctuation intensity from the known generalized responsibility (i.e. the deterministic response of the system to a small perturbation), but also in reverse – to calculate such linear response from the known fluctuations. The latter use is especially attractive at numerical simulations of complex systems, e.g., those based on molecular-dynamics approaches, because it circumvents the need in extracting a weak response to a small perturbation out of a noisy background.

Now let us discuss what generalization of Eq. (92) is necessary to make that fundamental result suitable for arbitrary temperatures, $T \sim \hbar\omega$. The calculations we had performed were based on the apparently classical equation of motion, Eq. (63). However, quantum mechanics shows⁴⁷ that a similar equation is valid for the corresponding Heisenberg-picture operators, so that repeating all the arguments leading to the Langevin equation (65), we may write its quantum-mechanical version

$$m\ddot{\hat{q}} + \eta\dot{\hat{q}} + \kappa\hat{q} = \hat{\mathcal{F}}_{\text{det}} + \hat{\mathcal{F}}. \quad (5.93)$$

Heisenberg-Langevin equation

This is the so-called *Heisenberg-Langevin* (or “quantum Langevin”) *equation* – in this particular case, for a harmonic oscillator.

The further operations, however, require certain caution, because the right-hand side of the equation is now an operator, and has some nontrivial properties. For example, the “values” of the Heisenberg operator, representing the same variable $f(t)$ at different times, do not necessarily commute:

$$\hat{f}(t)\hat{f}(t') \neq \hat{f}(t')\hat{f}(t), \quad \text{if } t' \neq t. \quad (5.94)$$

⁴⁵ Reviewing the calculations leading to Eq. (73), we may see that the possible real part $\chi'(\omega)$ of the susceptibility just adds up to $(k - m\omega^2)$ in the denominator of Eq. (67), resulting in a change of the oscillator’s frequency ω_0 . This renormalization is insignificant if the oscillator-to-environment coupling is weak, i.e. if the susceptibility $\chi(\omega)$ is small – as had been assumed at the derivation of Eq. (69) and hence Eq. (73).

⁴⁶ It is sometimes called the Green-Kubo (or just the Kubo) formula. This is hardly fair, because, as the reader could see, Eq. (92) is just an elementary generalization of the Nyquist formula (81). Moreover, the corresponding works of M. Green and R. Kubo were published, respectively, in 1954 and 1957, i.e. after the 1951 paper by H. Callen and T. Welton, where a more general result (98) had been derived. Much more adequately, the Green/Kubo names are associated with Eq. (102) below.

⁴⁷ See, e.g., QM Sec. 4.6.

As a result, the function defined by Eq. (46) may not be a symmetric function of the time delay $\tau \equiv t' - t$ even for a stationary process, making it inadequate for the representation of the actual correlation function – which has to obey Eq. (50). This technical difficulty may be overcome by the introduction of the following *symmetrized correlation function*⁴⁸

$$K_f(\tau) \equiv \frac{1}{2} \left\langle \hat{\tilde{f}}(t) \hat{\tilde{f}}(t+\tau) + \hat{\tilde{f}}(t+\tau) \hat{\tilde{f}}(t) \right\rangle \equiv \frac{1}{2} \left\langle \left\{ \hat{\tilde{f}}(t), \hat{\tilde{f}}(t+\tau) \right\} \right\rangle, \quad (5.95)$$

(where $\{ \dots, \dots \}$ denotes the anticommutator of the two operators), and, similarly, the symmetrical spectral density $S_f(\omega)$, defined by the following relation:

$$S_f(\omega) \delta(\omega - \omega') \equiv \frac{1}{2} \left\langle \hat{f}_\omega \hat{f}_{\omega'}^* + \hat{f}_{\omega'}^* \hat{f}_\omega \right\rangle \equiv \frac{1}{2} \left\langle \left\{ \hat{f}_\omega, \hat{f}_{\omega'}^* \right\} \right\rangle, \quad (5.96)$$

with $K_f(\tau)$ and $S_f(\omega)$ still related by the Fourier transform (59).

Now we may repeat all the analysis that was carried out for the classical case, and get Eq. (71) again, but now this expression has to be compared not with the equipartition theorem, but with its quantum-mechanical generalization (14), which, in our current notation, reads

$$\left\langle \left\langle \tilde{q}^2 \right\rangle \right\rangle = \frac{\hbar\omega_0}{2\kappa} \coth \frac{\hbar\omega_0}{2T}. \quad (5.97)$$

As a result, we get the following quantum-mechanical generalization of Eq. (92):

FDT

$$S_{\mathcal{F}}(\omega) = \frac{\hbar\chi''(\omega)}{2\pi} \coth \frac{\hbar\omega}{2T}. \quad (5.98)$$

This is the much-celebrated *fluctuation-dissipation theorem*, usually referred to just as the FDT, first derived in 1951 by Herbert Bernard Callen and Theodore A. Welton – in a somewhat different way.

As natural as it seems, this generalization of the relation between fluctuations and dissipation poses a very interesting conceptual dilemma. Let, for the sake of clarity, temperature be relatively low, $T \ll \hbar\omega$; then Eq. (98) gives a temperature-independent result

$$S_{\mathcal{F}}(\omega) = \frac{\hbar\chi''(\omega)}{2\pi}, \quad (5.99)$$

Quantum noise

which describes what is frequently called *quantum noise*. According to the quantum Langevin equation (93), nothing but the random force exerted by the environment, with the spectral density (99) proportional to the imaginary part of susceptibility (i.e. damping), is the source of the ground-state “fluctuations” of the coordinate and momentum of a quantum harmonic oscillator, with the r.m.s. values

$$\delta q \equiv \left\langle \left\langle \tilde{q}^2 \right\rangle \right\rangle^{1/2} = \left(\frac{\hbar}{2m\omega_0} \right)^{1/2}, \quad \delta p \equiv \left\langle \left\langle \tilde{p}^2 \right\rangle \right\rangle^{1/2} = \left(\frac{\hbar m\omega_0}{2} \right)^{1/2}, \quad (5.100)$$

⁴⁸ Here (and to the end of this section) the averaging $\langle \dots \rangle$ should be understood in the general quantum-statistical sense – see Eq. (2.12). As was discussed in Sec. 2.1, for the classical-mixture state of the system, this does not create any difference in either the mathematical treatment of the averages or their physical interpretation.

and the total energy $\hbar\omega_0/2$. On the other hand, the basic quantum mechanics tells us that exactly these formulas describe the ground state of a *dissipation-free* oscillator, not coupled to any environment, and are a direct corollary of the basic commutation relation

$$[\hat{q}, \hat{p}] = i\hbar. \quad (5.101)$$

So, what is the genuine source of the uncertainty described by Eqs. (100)?

The best resolution of this paradox I can offer is that *either* interpretation of Eqs. (100) is legitimate, with their relative convenience depending on the particular application. One may say that since the right-hand side of the quantum Langevin equation (93) is a quantum-mechanical operator, rather than a classical force, it “carries the uncertainty relation within itself”. However, this (admittedly, opportunistic :-) resolution leaves the following question open: is the quantum noise (99) of the environment’s observable \mathcal{F} directly, without any probe oscillator subjected to it? An experimental resolution of this dilemma is not quite simple, because usual scientific instruments have their own ground-state uncertainty, i.e. their own quantum fluctuations, which may be readily confused with those of the system under study. Fortunately, this difficulty may be overcome, for example, using unique frequency-mixing (“down-conversion”) properties of Josephson junctions. Special low-temperature experiments using such down-conversion⁴⁹ have confirmed that the noise (99) is real and measurable.

Finally, let me mention an alternative derivation⁵⁰ of the fluctuation-theorem (98) from the general quantum mechanics of open systems. This derivation is substantially longer than that presented above, but gives an interesting sub-product, the *Green-Kubo formula*

$$\left\langle \left[\hat{\mathcal{F}}(t), \hat{\mathcal{F}}(t + \tau) \right] \right\rangle = i\hbar \mathcal{G}(\tau), \quad (5.102)$$

where $\mathcal{G}(\tau)$ is the temporal Green’s function of the environment, defined by the following relation:

$$\langle \mathcal{F}(t) \rangle = \int_0^\infty \mathcal{G}(\tau) q(t - \tau) d\tau \equiv \int_{-\infty}^t \mathcal{G}(t - t') q(t') dt'. \quad (5.103)$$

Plugging the Fourier transforms of all three functions of time participating in Eq. (103) into this relation, it is straightforward to check that this Green’s function is just the Fourier image of the complex susceptibility $\chi(\omega)$ defined by Eq. (90):

$$\int_0^\infty \mathcal{G}(\tau) e^{i\omega\tau} d\tau = \chi(\omega); \quad (5.104)$$

here 0 is used as the lower limit instead of $(-\infty)$ just to emphasize that due to the causality principle, Green’s function has to be equal zero for $\tau < 0$.⁵¹

In order to reveal the real beauty of Eq. (102), we may use the Wiener-Khinchin theorem (59) to rewrite the fluctuation-dissipation theorem (98) in a similar time-domain form:

⁴⁹ R. Koch *et al.*, *Phys. Rev. B* **26**, 74 (1982), and references therein.

⁵⁰ See, e.g., QM Sec. 7.4.

⁵¹ See, e.g., CM Sec. 5.1.

$$\left\langle \left\{ \hat{\mathcal{F}}(t), \hat{\mathcal{F}}(t+\tau) \right\} \right\rangle = 2K_{\mathcal{F}}(\tau), \quad (5.105)$$

where the symmetrized correlation function $K_{\mathcal{F}}(\tau)$ is most simply described by its Fourier transform, which is, according to Eq. (58), equal to $\pi S_{\mathcal{F}}(\omega)$, so that using the FDT, we get

$$\int_0^\infty K_{\mathcal{F}}(\tau) \cos \omega \tau d\tau = \frac{\hbar \chi''(\omega)}{2} \coth \frac{\hbar \omega}{2T}. \quad (5.106)$$

The comparison of Eqs. (102) and (104), on one hand, and Eqs (105)-(106), on the other hand, shows that both the commutation and anticommutation properties of the Heisenberg-Langevin force operator at different moments of time are determined by the same generalized susceptibility $\chi(\omega)$ of the environment. However, the averaged anticommutator also depends on temperature, while the averaged commutator does not – at least explicitly, because the complex susceptibility of an environment may be temperature-dependent as well.

5.6. The Kramers problem and the Smoluchowski equation

Returning to the classical case, it is evident that Langevin equations of the type (65) provide means not only for the analysis of stationary fluctuations, but also for the description of arbitrary time evolution of (classical) systems coupled to their environments – which, again, may provide both dissipation and fluctuations. However, this approach to evolution analysis suffers from two major handicaps.

First, the Langevin equation does enable a straightforward calculation of the statistical average of the variable q , and its fluctuation variance – i.e., in the common mathematical terminology, the first and second *moments* of the probability density $w(q, t)$ – as functions of time, but not of the probability distribution as such. Admittedly, this is rarely a big problem, because in most cases the distribution is Gaussian – see, e.g., Eq. (2.77).

The second, more painful drawback of the Langevin approach is that it is instrumental only for “linear” systems – i.e., the systems whose dynamics may be described by linear differential equations, such as Eq. (65). However, as we know from classical dynamics, many important problems (for example, the Kepler problem of planetary motion⁵²) are reduced to motion in substantially non-harmonic potentials $U_{\text{ef}}(q)$, leading to nonlinear equations of motion. If the energy of interaction between the system and its random environment is factorable – i.e. is a product of variables belonging to these subsystems (as it is very frequently the case), we may repeat all arguments of the last section to derive the following generalized version of the 1D Langevin equation:⁵³

$$m\ddot{q} + \eta \dot{q} + \frac{\partial U(q, t)}{\partial q} = \tilde{\mathcal{F}}(t), \quad (5.107)$$

⁵² See, e.g., CM Secs. 3.4-3.6.

⁵³ The generalization of Eq. (107) to higher spatial dimensionality is also straightforward, with the scalar variable q replaced with a multi-dimensional vector \mathbf{q} , and the scalar derivative dU/dq replaced with the vector ∇U , where ∇ is the del vector-operator in the \mathbf{q} -space.

valid for an arbitrary, possibly time-dependent potential $U(q, t)$. Unfortunately, the solution of this equation may be very hard. Indeed, its Fourier analysis carried out in the last section was essentially based on the linear superposition principle, which is invalid for nonlinear equations.

If the fluctuation intensity is low, $|\delta q| \ll \langle q \rangle$, where $\langle q \rangle(t)$ is the deterministic solution of Eq. (107) in the absence of fluctuations, this equation may be linearized⁵⁴ with respect to small fluctuations $\tilde{q} \equiv q - \langle q \rangle$ to get a linear equation,

$$m\ddot{\tilde{q}} + \eta \dot{\tilde{q}} + \kappa(t)\tilde{q} = \tilde{\mathcal{F}}(t), \quad \text{with } \kappa(t) \equiv \frac{\partial^2}{\partial q^2} U(\langle q \rangle(t), t). \quad (5.108)$$

This equation differs from Eq. (65) only by the time dependence of the effective spring constant $\kappa(t)$, and may be solved by the Fourier expansion of both the fluctuations and the function $\kappa(t)$. Such calculations may be more cumbersome than those performed above, but still be doable (especially if the unperturbed motion $\langle q \rangle(t)$ is periodic), and sometimes give useful analytical results.⁵⁵

However, some important problems cannot be solved by linearization. Perhaps, the most apparent (and practically very important) example is the so-called *Kramers problem*⁵⁶ of finding the lifetime of a metastable state of a 1D classical system in a potential well separated from the region of unlimited motion with a potential barrier – see Fig. 10.

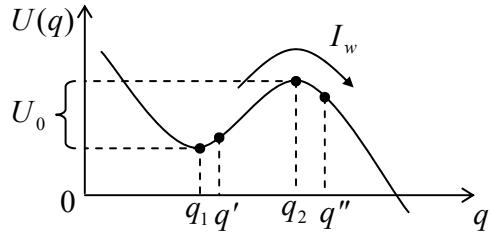

Fig. 5.10. The Kramers problem.

In the absence of fluctuations, the system, initially placed close to the well's bottom (in Fig. 10, at $q \approx q_1$), would stay there forever. Fluctuations result not only in a finite spread of the probability density $w(q, t)$ around that point but also in a gradual decrease of the total probability

$$W(t) = \int_{\text{well's bottom}} w(q, t) dq \quad (5.109)$$

to find the system in the well, because of a non-zero rate of its escape from it, over the potential barrier, due to thermal activation. What may be immediately expected of the situation is that if the barrier height,

$$U_0 \equiv U(q_2) - U(q_1), \quad (5.110)$$

⁵⁴ See, e.g., CM Secs. 3.2, 5.2, and beyond.

⁵⁵ See, e.g., QM Problem 7.8, and also Chapters 5 and 6 in the monograph by W. Coffey *et al.*, cited above.

⁵⁶ It was named after Hendrik Anthony (“Hans”) Kramers who, besides solving this conceptually important problem in 1940, has made several other seminal contributions to physics, including the famous Kramers-Kronig dispersion relations (see, e.g., EM Sec. 7.4) and the WKB (Wentzel-Kramers-Brillouin) approximation in quantum mechanics – see, e.g., QM Sec. 2.4.

is much larger than temperature T ,⁵⁷ the Boltzmann distribution $w \propto \exp\{-U(q)/T\}$ should be still approximately valid in most of the well, so that the probability for the system to overcome the barrier should scale as $\exp\{-U_0/T\}$. From these handwaving arguments, one may reasonably expect that if the probability $W(t)$ of the system's still residing in the well by time t obeys the usual “decay law”

$$\dot{W} = -\frac{W}{\tau}, \quad (5.111a)$$

then the lifetime τ has to obey the general Arrhenius law:

$$\tau = \tau_A \exp\left\{\frac{U_0}{T}\right\}. \quad (5.111b)$$

However, these relations need to be proved, and the pre-exponential coefficient τ_A (usually called the *attempt time*) needs to be calculated. This cannot be done by the linearization of Eq. (107), because this approximation is equivalent to a quadratic approximation of the potential $U(q)$, which evidently cannot describe the potential well *and* the potential barrier simultaneously – see Fig. 10 again.

This and other essentially nonlinear problems may be addressed using an alternative approach to fluctuations, dealing directly with the time evolution of the probability density $w(q, t)$. Due to the shortage of time/space, I will review this approach using mostly handwaving arguments, and refer the interested reader to special literature⁵⁸ for strict mathematical proofs. Let us start from the diffusion of a free classical 1D particle with inertial effects negligible in comparison with damping. It is described by the Langevin equation (74) with $\mathcal{F}_{\text{det}} = 0$. Let us assume that at all times the probability distribution stays Gaussian:

$$w(q, t) = \frac{1}{(2\pi)^{1/2} \delta q(t)} \exp\left\{-\frac{(q - q_0)^2}{2\delta q^2(t)}\right\}, \quad (5.112)$$

where q_0 is the initial position of the particle, and $\delta q(t)$ is the time-dependent distribution width, whose growth in time is described, as we already know, by Eq. (77):

$$\delta q(t) = (2Dt)^{1/2}. \quad (5.113)$$

Then it is straightforward to verify, by substitution, that this solution satisfies the following simple partial differential equation,⁵⁹

$$\frac{\partial w}{\partial t} = D \frac{\partial^2 w}{\partial q^2}, \quad (5.114)$$

with the delta-functional initial condition

$$w(q, 0) = \delta(q - q_0). \quad (5.115)$$

⁵⁷ If U_0 is comparable with T , the system's behavior also depends substantially on the initial probability distribution, i.e., does not follow the simple law (111).

⁵⁸ See, e.g., either R. Stratonovich, *Topics in the Theory of Random Noise*, vol. 1., Gordon and Breach, 1963, or Chapter 1 in the monograph by W. Coffey *et al.*, cited above.

⁵⁹ By the way, the goal of the traditional definition (78) of the diffusion coefficient, leading to the front coefficient 2 in Eq. (77), is exactly to have the fundamental equations (114) and (116) free of numerical coefficients.

The simple and important *equation of diffusion* (114) may be naturally generalized to the 3D motion:⁶⁰

$$\boxed{\frac{\partial w}{\partial t} = D \nabla^2 w.} \quad (5.116)$$

Equation
of diffusion

Now let us compare this equation with the probability conservation law,⁶¹

$$\frac{\partial w}{\partial t} + \nabla \cdot \mathbf{j}_w = 0, \quad (5.117a)$$

where the vector \mathbf{j}_w has the physical sense of the probability current density. (The validity of this relation is evident from its integral form,

$$\frac{d}{dt} \int_V w d^3 r + \oint_S \mathbf{j}_w \cdot d^2 \mathbf{q} = 0, \quad (5.117b)$$

which results from the integration of Eq. (117a) over an arbitrary time-independent volume V limited by surface S , and applying the divergence theorem⁶² to the second term.) The continuity relation (117a) coincides with Eq. (116), with D given by Eq. (78), only if we take

$$\mathbf{j}_w = -D \nabla w = -\frac{T}{\eta} \nabla w. \quad (5.118)$$

The first form of this relation allows a simple interpretation: the probability flow is proportional to the spatial gradient of the probability density (i.e., in application to $N \gg 1$ similar and independent particles, just to the gradient of their concentration $n = Nw$), with the sign corresponding to the flow from the higher to lower concentrations. This flow is the very essence of the effect of diffusion. The second form of Eq. (118) is also not very surprising: the diffusion speed scales as temperature and is inversely proportional to the viscous drag.

The fundamental Eq. (117) has to be satisfied also in the case of a force-driven particle at negligible diffusion ($D \rightarrow 0$); in this case

$$\mathbf{j}_w = w \mathbf{v}, \quad (5.119)$$

where \mathbf{v} is the deterministic velocity of the particle. In the high-damping limit we are considering right now, \mathbf{v} has to be just the *drift velocity*:

$$\mathbf{v} = \frac{1}{\eta} \mathcal{F}_{\text{det}} = -\frac{1}{\eta} \nabla U(\mathbf{q}), \quad (5.120)$$

where \mathcal{F}_{det} is the deterministic force described by the potential energy $U(\mathbf{q})$.

Now that we have descriptions of \mathbf{j}_w due to both the drift *and* the diffusion separately, we may rationally assume that in the general case when both effects are present, the corresponding components (118) and (119) of the probability current just add up, so that

⁶⁰ As will be discussed in Chapter 6, the equation of diffusion also describes several other physical phenomena – in particular, the heat propagation in a uniform, isotropic solid, and in this context is called the *heat conduction equation* or (rather inappropriately) just the “heat equation”.

⁶¹ Both forms of Eq. (117) are similar to the mass conservation law in classical dynamics (see, e.g., CM Sec. 8.2), the electric charge conservation law in electrodynamics (see, e.g., EM Sec. 4.1), and the probability conservation law in quantum mechanics (see, e.g., QM Sec. 1.4).

⁶² See, e.g., MA Eq. (12.2),

$$\mathbf{j}_w = \frac{1}{\eta} [w(-\nabla U) - T\nabla w], \quad (5.121)$$

and Eq. (117a) takes the form

Smoluchowski
equation

$$\eta \frac{\partial w}{\partial t} = \nabla(w\nabla U) + T\nabla^2 w. \quad (5.122)$$

This is the *Smoluchowski equation*,⁶³ which is closely related to the *drift-diffusion equation* in multi-particle kinetics – to be discussed in the next chapter.

As a sanity check, let us see what the Smoluchowski equation gives in the stationary limit, $\partial w/\partial t \rightarrow 0$ (which evidently may be eventually achieved only if the deterministic potential U is time-independent.) Then Eq. (117a) yields $\mathbf{j}_w = \text{const}$, where the constant describes the deterministic motion of the system as the whole. If such a motion is absent, $\mathbf{j}_w = 0$, then according to Eq. (121),

$$w\nabla U + T\nabla w = 0, \quad \text{i.e. } \frac{\nabla w}{w} = -\frac{\nabla U}{T}. \quad (5.123)$$

Since the left-hand side of the last relation is just $\nabla(\ln w)$, it may be easily integrated over \mathbf{q} , giving

$$\ln w = -\frac{U}{T} + \ln C, \quad \text{i.e. } w(\mathbf{r}) = C \exp\left\{-\frac{U(\mathbf{q})}{T}\right\}, \quad (5.124)$$

where C is a normalization constant. With both sides multiplied by the number N of similar, independent systems, with the spatial density $n(\mathbf{q}) = Nw(\mathbf{q})$, this equality becomes the Boltzmann distribution (3.26).

As a less trivial example of the Smoluchowski equation's applications, let us use it to solve the 1D Kramers problem (Fig. 10) in the corresponding high-damping limit, $m \ll \eta\tau_A$, where τ_A (still to be calculated) is some time scale of the particle's motion inside the well. It is straightforward to verify that the 1D version of Eq. (121),

$$I_w = \frac{1}{\eta} \left[w \left(-\frac{\partial U}{\partial q} \right) - T \frac{\partial w}{\partial q} \right], \quad (5.125a)$$

(where I_w is the probability current at a certain point q , rather than its density) is mathematically equivalent to

$$I_w = -\frac{T}{\eta} \exp\left\{-\frac{U(q)}{T}\right\} \frac{\partial}{\partial q} \left(w \exp\left\{\frac{U(q)}{T}\right\} \right), \quad (5.125b)$$

so that we may write

$$I_w \exp\left\{\frac{U(q)}{T}\right\} = -\frac{T}{\eta} \frac{\partial}{\partial q} \left(w \exp\left\{\frac{U(q)}{T}\right\} \right). \quad (5.126)$$

As was discussed above, the notion of metastable state's lifetime is well defined only for sufficiently low temperatures

⁶³ It is named after Marian Smoluchowski, who developed this formalism in 1906, apparently independently from the slightly earlier Einstein's work, but in much more detail. This equation has important applications in many fields of science – including such surprising topics as statistics of spikes in neural networks. (Note, however, that in some non-physical fields, Eq. (122) is referred to as the *Fokker-Planck equation*, while actually, the latter equation is much more general – see the next section.)

$$T \ll U_0. \quad (5.127)$$

when the lifetime is relatively long: $\tau \gg \tau_A$. Since according to Eq. (111a), the first term of the continuity equation (117b) has to be of the order of W/τ , in this limit the term, and hence the gradient of I_w , are exponentially small, so the probability current virtually does not depend on q in the potential barrier region. Let us use this fact at the integration of both sides of Eq. (126) over that region:

$$I_w \int_{q'}^{q''} \exp\left\{\frac{U(q)}{T}\right\} dq = -\frac{T}{\eta} \left(w \exp\left\{\frac{U(q)}{T}\right\} \right)_{q'}^{q''}, \quad (5.128)$$

where the integration limits q' and q'' (see Fig. 10) are selected so that

$$T \ll U(q') - U(q_1), U(q_2) - U(q'') \ll U_0. \quad (5.129)$$

(Obviously, such selection is only possible if the condition (127) is satisfied.) In this limit, the contribution from the point q'' to the right-hand side of Eq. (129) is negligible because the probability density behind the barrier is exponentially small. On the other hand, the probability at the point q' has to be close to the value given by its quasi-stationary Boltzmann distribution (124), so that

$$w(q') \exp\left\{\frac{U(q')}{T}\right\} = w(q_1) \exp\left\{\frac{U(q_1)}{T}\right\}, \quad (5.130)$$

and Eq. (128) yields

$$I_w = \frac{T}{\eta} w(q_1) \int_{q'}^{q''} \exp\left\{\frac{U(q) - U(q_1)}{T}\right\} dq. \quad (5.131)$$

Patience, my reader, we are almost done. The probability density $w(q_1)$ at the well's bottom may be expressed in terms of the total probability W of the particle being in the well by using the normalization condition

$$W = \int_{\text{well's bottom}} w(q_1) \exp\left\{\frac{U(q_1) - U(q)}{T}\right\} dq; \quad (5.132)$$

the integration here may be limited to the region where the difference $U(q) - U(q_1)$ is much smaller than U_0 – cf. Eq. (129). According to the Taylor expansion, the shape of virtually any smooth potential $U(q)$ near the point q_1 of its minimum may be well approximated with a quadratic parabola:

$$U(q \approx q_1) - U(q_1) \approx \frac{\kappa_1}{2}(q - q_1)^2, \quad \text{where } \kappa_1 \equiv \frac{d^2 U}{dq^2} \Big|_{q=q_1} > 0. \quad (5.133)$$

With this approximation, Eq. (132) is reduced to the standard Gaussian integral:⁶⁴

$$W = w(q_1) \int_{\text{well's bottom}} \exp\left\{-\frac{\kappa_1(q - q_1)^2}{2T}\right\} dq \approx w(q_1) \int_{-\infty}^{+\infty} \exp\left\{-\frac{\kappa_1 \tilde{q}^2}{2T}\right\} d\tilde{q} = w(q_1) \left(\frac{2\pi T}{\kappa_1}\right)^{1/2}. \quad (5.134)$$

To complete the calculation, we may use a similar approximation for the barrier top:

⁶⁴ If necessary, see MA Eq. (6.9b) again.

$$U(q \approx q_2) - U(q_1) \approx \left[U(q_2) - \frac{\kappa_2}{2} (q - q_2)^2 \right] - U(q_1) = U_0 - \frac{\kappa_2}{2} (q - q_2)^2, \quad (5.135)$$

where $\kappa_2 \equiv -\frac{d^2 U}{dq^2} \Big|_{q=q_2} > 0$,

and work out the remaining integral in Eq. (131), because in the limit (129) it is dominated by the contribution from a region very close to the barrier top, where the approximation (135) is asymptotically exact. As a result, we get

$$\int_{q'}^{q''} \exp\left\{-\frac{U(q) - U(q_1)}{T}\right\} dq \approx \exp\left\{-\frac{U_0}{T}\right\} \left(\frac{2\pi T}{\kappa_2}\right)^{1/2}. \quad (5.136)$$

Plugging Eq. (136), and the $w(q_1)$ expressed from Eq. (134), into Eq. (131), we finally get

$$I_w = W \frac{(\kappa_1 \kappa_2)^{1/2}}{2\pi\eta} \exp\left\{-\frac{U_0}{T}\right\}. \quad (5.137)$$

This expression should be compared with the 1D version of Eq. (117b) for the segment $[-\infty, q']$. Since this interval covers the region near q_1 where most of the probability density resides, and $I_q(-\infty) = 0$, this equation is merely

$$\frac{dW}{dt} + I_w(q') = 0. \quad (5.138)$$

In our approximation, $I_w(q')$ does not depend on the exact position of the point q' , and is given by Eq. (137), so that plugging it into Eq. (138), we recover the exponential decay law (111a), with the lifetime τ obeying the Arrhenius law (111b), and the following attempt time:

$$\tau_A = \frac{2\pi\eta}{(\kappa_1 \kappa_2)^{1/2}} \equiv 2\pi(\tau_1 \tau_2)^{1/2}, \quad \text{where } \tau_{1,2} \equiv \frac{\eta}{\kappa_{1,2}}. \quad (5.139)$$

Kramers formula for high damping

Thus the metastable state lifetime is indeed described by the Arrhenius law, with the attempt time scaling as the geometric mean of the system's "relaxation times" near the potential well bottom (τ_1) and the potential barrier top (τ_2).⁶⁵ Let me leave for the reader's exercise to prove that if the potential profile near well's bottom and/or top is sharp, the expression for the attempt time should be modified, but the Arrhenius decay law (111) is not affected.

5.7. The Fokker-Planck equation

Formula (139) is just a particular, high-damping limit of a more general result obtained by Kramers. In order to get all of it (and much more), we need to generalize the Smoluchowski equation to arbitrary values of damping η . In this case, the probability density w is a function of not only the particle's position \mathbf{q} (and time t) but also of its momentum \mathbf{p} – see Eq. (2.11). Thus the continuity equation (117) needs to be generalized to the 6D phase space $\{\mathbf{q}, \mathbf{p}\}$. Such generalization is natural:

⁶⁵ Actually, τ_2 describes the characteristic time of the exponential *growth* of small deviations from the unstable fixed point q_2 at the barrier top, rather than their *decay*, as near the stable point q_1 .

$$\frac{\partial w}{\partial t} + \nabla_q \cdot \mathbf{j}_q + \nabla_p \cdot \mathbf{j}_p = 0, \quad (5.140)$$

where \mathbf{j}_q (which was called \mathbf{j}_w in the last section) is the probability current density in the coordinate space, and ∇_q (which was denoted as ∇ in that section) is the usual vector operator in the space, while \mathbf{j}_p is the current density in the momentum space, and ∇_p is the similar vector operator in that space:

$$\nabla_q \equiv \sum_{j=1}^3 \mathbf{n}_j \frac{\partial}{\partial q_j}, \quad \nabla_p \equiv \sum_{j=1}^3 \mathbf{n}_j \frac{\partial}{\partial p_j}. \quad (5.141)$$

At negligible fluctuations ($T \rightarrow 0$), \mathbf{j}_p may be composed using the natural analogy with \mathbf{j}_q – see Eq. (119). In our new notation, that relation reads,

$$\mathbf{j}_q = w \dot{\mathbf{q}} = w \frac{\mathbf{p}}{m}, \quad (5.142)$$

so it is natural to take

$$\mathbf{j}_p = w \dot{\mathbf{p}} = w \langle \mathcal{F} \rangle, \quad (5.143a)$$

where the (statistical-ensemble) averaged force $\langle \mathcal{F} \rangle$ includes not only the contribution due to the potential's gradient, but also the drag force $-\eta \mathbf{v}$ provided by the environment – see Eq. (64) and its discussion:

$$\mathbf{j}_p = w(-\nabla_q U - \eta \mathbf{v}) = -w(\nabla_q U + \eta \frac{\mathbf{p}}{m}). \quad (5.143b)$$

As a sanity check, it is straightforward to verify that the diffusion-free equation resulting from the combination of Eqs. (140), (142) and (143),

$$\frac{\partial w}{\partial t} \Big|_{\text{drift}} = -\nabla_q \cdot \left(w \frac{\mathbf{p}}{m} \right) + \nabla_p \cdot \left[w \left(\nabla_q U + \eta \frac{\mathbf{p}}{m} \right) \right], \quad (5.144)$$

allows the following particular solution:

$$w(\mathbf{q}, \mathbf{p}, t) = \delta[\mathbf{q} - \langle \mathbf{q} \rangle(t)] \delta[\mathbf{p} - \langle \mathbf{p} \rangle(t)], \quad (5.145)$$

where the statistical-averaged coordinate and momentum satisfy the deterministic equations of motion,

$$\langle \dot{\mathbf{q}} \rangle = \frac{\langle \mathbf{p} \rangle}{m}, \quad \langle \dot{\mathbf{p}} \rangle = -\nabla_q U - \eta \frac{\langle \mathbf{p} \rangle}{m}, \quad (5.146)$$

describing the particle's drift, with the usual deterministic initial conditions.

In order to understand how the diffusion should be accounted for, let us consider a statistical ensemble of free ($\nabla_q U = 0$, $\eta \rightarrow 0$) particles that are uniformly distributed in the direct space \mathbf{q} (so that $\nabla_q w = 0$), but possibly localized in the momentum space. For this case, the right-hand side of Eq. (144) vanishes, i.e. the time evolution of the probability density w may be only due to diffusion. In the corresponding limit $\langle \mathcal{F} \rangle \rightarrow 0$, the Langevin equation (107) for each Cartesian coordinate is reduced to

$$m \ddot{q}_j = \tilde{\mathcal{F}}_j(t), \quad \text{i.e. } \dot{p}_j = \tilde{\mathcal{F}}_j(t). \quad (5.147)$$

The last equation is identical to the high-damping 1D equation (74) (with $\mathcal{F}_{\text{det}} = 0$), with the replacement $q \rightarrow p/\eta$, and hence the corresponding contribution to $\partial w/\partial t$ may be described by the last term of Eq. (122), with that replacement:

$$\frac{\partial w}{\partial t} \Big|_{\text{diffusion}} = D \nabla_{p/\eta}^2 w = \frac{T}{\eta} \eta^2 \nabla_p^2 w \equiv \eta T \nabla_p^2 w. \quad (5.148)$$

Now the reasonable assumption that in the arbitrary case the drift and diffusion contributions to $\partial w/\partial t$ just add up immediately leads us to the full *Fokker-Planck equation*:⁶⁶

Fokker-
Planck
equation

$$\frac{\partial w}{\partial t} = -\nabla_q \cdot \left(w \frac{\mathbf{p}}{m} \right) + \nabla_p \cdot \left[w \left(\nabla_q U + \eta \frac{\mathbf{p}}{m} \right) \right] + \eta T \nabla_p^2 w. \quad (5.149)$$

As a sanity check, let us use this equation to calculate the stationary probability distribution of the momentum of particles with an arbitrary damping η but otherwise free, in the momentum space, assuming (just for simplicity) their uniform distribution in the direct space, $\nabla_q = 0$. In this case, Eq. (149) is reduced to

$$\nabla_p \cdot \left[w \left(\eta \frac{\mathbf{p}}{m} \right) \right] + \eta T \nabla_p^2 w = 0, \quad \text{i.e. } \nabla_p \cdot \left(\frac{\mathbf{p}}{m} w + T \nabla_p w \right) = 0. \quad (5.150)$$

The first integration over the momentum space yields

$$\frac{\mathbf{p}}{m} w + T \nabla_p w = \mathbf{j}_w, \quad \text{i.e. } w \nabla_p \left(\frac{\mathbf{p}^2}{2m} \right) + T \nabla_p w = \mathbf{j}_w, \quad (5.151)$$

where \mathbf{j}_w is a vector constant describing a possible general probability flow in the system. In the absence of such flow, $\mathbf{j}_w = 0$, we get

$$\nabla_p \left(\frac{\mathbf{p}^2}{2m} \right) + T \frac{\nabla_p w}{w} \equiv \nabla_p \left(\frac{\mathbf{p}^2}{2m} + T \ln w \right) = 0, \quad \text{giving } w = \text{const} \times \exp \left\{ -\frac{\mathbf{p}^2}{2mT} \right\}, \quad (5.152)$$

i.e. the Maxwell distribution (3.5). However, the result (152) is more general than that obtained in Sec. 3.1, because it shows that the distribution stays the same even at non-zero damping. It is easy to verify that in the more general case of an arbitrary stationary potential $U(\mathbf{q})$, Eq. (149) is satisfied with the stationary solution (3.24), also giving $\mathbf{j}_w = 0$.

It is also straightforward to show that if the damping is large (in the sense assumed in the last section), the solution of the Fokker-Planck equation tends to the following product

$$w(\mathbf{q}, \mathbf{p}, t) \rightarrow \text{const} \times \exp \left\{ -\frac{\mathbf{p}^2}{2mT} \right\} \times \mathbf{w}(\mathbf{q}, t), \quad (5.153)$$

where the direct-space distribution $\mathbf{w}(\mathbf{q}, t)$ obeys the Smoluchowski equation (122).

Another important particular case is that of a quasi-periodic motion of a particle, with low damping, in a soft potential well. In this case, the Fokker-Planck equation describes both diffusion of the effective phase Θ of such (generally nonlinear, “anharmonic”) oscillator, and slow relaxation of its

⁶⁶ It was first derived by Adriaan Fokker in 1913 in his PhD thesis, and further elaborated by Max Planck in 1917. (Curiously, A. Fokker is more famous for his work on music theory, and the invention and construction of several new keyboard instruments, than for this and several other important contributions to theoretical physics.)

energy. If we are only interested in the latter process, Eq. (149) may be reduced to the so-called *energy diffusion equation*,⁶⁷ which is easier to solve.

However, in most practically interesting cases, solutions of Eq. (149) are rather complicated. (Indeed, the reader should remember that these solutions embody, in the particular case $T = 0$, all classical dynamics of a particle.) Because of this, I will present (rather than derive) only one more of them: the solution of the Kramers problem (Fig. 10). Acting almost exactly as in Sec. 6, one can show⁶⁸ that at virtually arbitrary damping (but still in the limit $T \ll U_0$), the metastable state's lifetime is again given by the Arrhenius formula (111b), with the attempt time again expressed by the first of Eqs. (139), but with the reciprocal time constants $1/\tau_{1,2}$ replaced with

$$\omega'_{1,2} \equiv \left[\omega_{1,2}^2 + \left(\frac{\eta}{2m} \right)^2 \right]^{1/2} - \frac{\eta}{2m} \rightarrow \begin{cases} \omega_{1,2}, & \text{for } \eta \ll m\omega_{1,2}, \\ 1/\tau_{1,2}, & \text{for } m\omega_{1,2} \ll \eta, \end{cases} \quad (5.154)$$

where $\omega_{1,2} \equiv (\kappa_{1,2}/m)^{1/2}$, and $\kappa_{1,2}$ are the effective spring constants defined by Eqs. (133) and (135). Thus, in the important particular limit of low damping, Eqs. (111b) and (154) give the famous formula

$$\tau = \frac{2\pi}{(\omega_1\omega_2)^{1/2}} \exp\left\{ \frac{U_0}{T} \right\}. \quad (5.155)$$

Kramers formula for low damping

This Kramers' result for the classical thermal activation of the dissipation-free system *over* a potential barrier may be compared with that for its quantum-mechanical tunneling *through* the barrier.⁶⁹ The WKB approximation for the latter effect gives the expression

$$\tau_Q = \tau_A \exp\left\{ -2 \int_{\kappa^2(q)>0} \kappa(q) dq \right\}, \quad \text{with } \frac{\hbar^2 \kappa^2(q)}{2m} \equiv U(q) - E, \quad (5.156)$$

showing that generally, the classical and quantum lifetimes of a metastable state have different dependences on the barrier shape. For example, for a nearly-rectangular potential barrier, the exponent that determines the classical lifetime (155) depends (linearly) only on the barrier *height* U_0 , while that defining the quantum lifetime (156) is proportional to the barrier *width* and to the square root of U_0 . However, in the important case of "soft" potential profiles, which are typical for the case of barely emerging (or nearly disappearing) quantum wells (Fig. 11), the classical and quantum results are closely related.

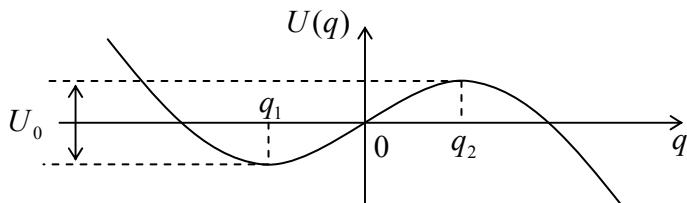

Fig. 5.11. Cubic-parabolic potential profile and its parameters.

⁶⁷ An example of such an equation, for the particular case of a harmonic oscillator, is given by QM Eq. (7.214). The Fokker-Planck equation, of course, can give only its classical limit, with $n, n_e \gg 1$.

⁶⁸ A detailed description of this calculation (first performed by H. Kramers in 1940) may be found, for example, in Sec. III.7 of the review paper by S. Chandrasekhar, *Rev. Mod. Phys.* **15**, 1 (1943).

⁶⁹ See, e.g., QM Secs. 2.4-2.6.

Indeed, such potential profile $U(q)$ may be well approximated by four leading terms of its Taylor expansion, with the highest term proportional to $(q - q_0)^3$, near any point q_0 in the vicinity of the well. In this approximation, the second derivative d^2U/dq^2 vanishes at the inflection point $q_0 = (q_1 + q_2)/2$, exactly between the well's bottom and the barrier's top (in Fig. 11, q_1 and q_2). Selecting the origin at this point, as this is done in Fig. 11, we may reduce the approximation to just two terms:⁷⁰

$$U(q) = aq - \frac{b}{3}q^3. \quad (5.157)$$

(For the particle's escape into the positive direction of the q -axis, we should have $a, b > 0$.) An easy calculation gives all essential parameters of this cubic parabola: the positions of its minimum and maximum:

$$q_2 = -q_1 = (a/b)^{1/2}, \quad (5.158)$$

the barrier height over the well's bottom:

$$U_0 \equiv U(q_2) - U(q_1) = \frac{4}{3} \left(\frac{a^3}{b} \right)^{1/2}, \quad (5.159)$$

and the effective spring constants at these points:

$$\kappa_1 = \kappa_2 \equiv \left| \frac{d^2U}{dq^2} \right|_{q_{1,2}} = 2(ab)^{1/2}. \quad (5.160)$$

The last expression shows that for this potential profile, the frequencies $\omega_{1,2}$ participating in Eq. (155) are equal to each other, so that this result may be rewritten as

$$\tau = \frac{2\pi}{\omega_0} \exp\left\{ \frac{U_0}{T} \right\}, \quad \text{with } \omega_0^2 \equiv \frac{2(ab)^{1/2}}{m}. \quad (5.161)$$

On the other hand, for the same profile, the WKB approximation (156) (which is accurate when the height of the metastable state energy over the well's bottom, $E - U(q_1) \approx \hbar\omega_0/2$, is much lower than the barrier height U_0) yields⁷¹

$$\tau_Q = \frac{2\pi}{\omega_0} \left(\frac{\hbar\omega_0}{864U_0} \right)^{1/2} \exp\left\{ \frac{36}{5} \frac{U_0}{\hbar\omega_0} \right\}. \quad (5.162)$$

The comparison of the dominating, exponential factors in these two results shows that the thermal activation yields a lower lifetime (i.e., dominates the metastable state decay) if the temperature is above the crossover value

$$T_c = \frac{36}{5} \hbar\omega_0 \equiv 7.2 \hbar\omega_0. \quad (5.163)$$

⁷⁰ As a reminder, a similar approximation arises for the $P(V)$ function, at the analysis of the van der Waals model near the critical temperature – see Problem 4.6.

⁷¹ The main, exponential factor in this result may be obtained simply by ignoring the difference between E and $U(q_1)$, but the correct calculation of the pre-exponential factor requires taking this difference, $\hbar\omega_0/2$, into account – see, e.g., the model solution of QM Problem 2.43.

This expression for the *cubic*-parabolic barrier may be compared with the similar crossover for a *quadratic*-parabolic barrier,⁷² for which $T_c = 2\pi \hbar\omega_0 \approx 6.28 \hbar\omega_0$. We see that the numerical factors for the quantum-to-classical crossover temperature for these two different soft potential profiles are close to each other – and much larger than 1, which could result from a naïve estimate.

5.8. Back to the correlation function

Unfortunately, I will not have time/space to either derive or even review solutions of other problems using the Smoluchowski and Fokker-Planck equations, but have to mention one conceptual issue. Since it is intuitively clear that the solution $w(\mathbf{q}, \mathbf{p}, t)$ of the Fokker-Planck equation for a system provides the complete statistical information about it, one may wonder how it may be used to find its temporal characteristics that were discussed in Secs. 4-5, using the Langevin formalism. For any statistical average of a function taken at the same time instant, the answer is clear – cf. Eq. (2.11):

$$\langle f[\mathbf{q}(t), \mathbf{p}(t)] \rangle = \int f(\mathbf{q}, \mathbf{p}) w(\mathbf{q}, \mathbf{p}, t) d^3 q d^3 p, \quad (5.164)$$

but what if the function depends on variables taken at *different* times, for example as in the correlation function $K(\tau)$ defined by Eq. (48)?

To answer this question, let us start from the discrete-variable case when Eq. (164) takes the form (2.7), which, for our current purposes, may be rewritten as

$$\langle f(t) \rangle = \sum_m f_m W_m(t). \quad (5.165)$$

In plain English, this is a sum of all possible values of the function, each multiplied by its probability as a function of time. But this implies that the average $\langle f(t)f(t') \rangle$ may be calculated as the sum of all possible products $f_m f_{m'}$, multiplied by the *joint probability* to measure outcome m at moment t , and outcome m' at moment t' . The joint probability may be represented as a product of $W_m(t)$ by the *conditional probability* $W(m', t' | m, t)$. Since the correlation function is well defined only for stationary systems, in the last expression we may take $t = 0$, i.e. look for the conditional probability as the solution, $W_m(\tau)$, of the equation describing the system's probability evolution, at time $\tau = t' - t$ (rather than t'), with the special initial condition

$$W_{m'}(0) = \delta_{m',m}. \quad (5.166)$$

On the other hand, since the average $\langle f(t)f(t+\tau) \rangle$ of a stationary process should not depend on t , instead of $W_m(0)$ we may take the stationary probability distribution $W_m(\infty)$, independent of the initial conditions, which may be found as the same special solution, but at time $\tau \rightarrow \infty$. As a result, we get

$$\langle f(t)f(t+\tau) \rangle = \sum_{m,m'} f_m W_m(\infty) f_{m'} W_{m'}(\tau). \quad (5.167)$$

Correlation
function:
discrete
system

This expression looks simple, but note that this recipe requires solving the time evolution equations for each $W_m(\tau)$ for all possible initial conditions (166). To see how this recipe works in practice, let us revisit the simplest two-level system (see, e.g., Fig. 4.13, which is reproduced in Fig. 12

⁷² See, e.g., QM Sec. 2.4.

below in a notation more convenient for our current purposes), and calculate the correlation function of its energy fluctuations.

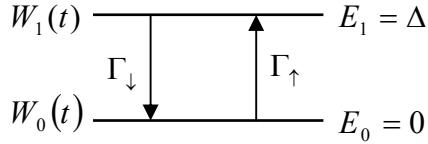

Fig. 5.12. Dynamics of a two-level system.

The stationary probabilities of the system's states (i.e. their probabilities for $\tau \rightarrow \infty$) have been calculated in problems of Chapter 2, and then again in Sec. 4.4 – see Eq. (4.68). In our current notation (Fig. 12),

$$W_0(\infty) = \frac{1}{1 + e^{-\Delta/T}}, \quad W_1(\infty) = \frac{1}{e^{\Delta/T} + 1}, \quad (5.168)$$

so that $\langle E(\infty) \rangle = W_0(\infty) \times 0 + W_1(\infty) \times \Delta = \frac{\Delta}{e^{\Delta/T} + 1}$.

To calculate the conditional probabilities $W_m(\tau)$ with the initial conditions (167) (according to Eq. (168), we need all four of them, for $\{m, m'\} = \{0, 1\}$), we may use the master equations (4.100), in our current notation reading

$$\frac{dW_1}{d\tau} = -\frac{dW_0}{d\tau} = \Gamma_\uparrow W_0 - \Gamma_\downarrow W_1. \quad (5.169)$$

Since Eq. (169) conserves the total probability, $W_0 + W_1 = 1$, only one probability (say, W_1) is an independent variable, and for it, Eq. (169) gives a simple, linear differential equation

$$\frac{dW_1}{d\tau} = \Gamma_\uparrow - \Gamma_\Sigma W_1, \quad \text{where } \Gamma_\Sigma \equiv \Gamma_\uparrow + \Gamma_\downarrow, \quad (5.170)$$

which may be readily integrated for an arbitrary initial condition:

$$W_1(\tau) = W_1(0)e^{-\Gamma_\Sigma\tau} + W_1(\infty)\left(1 - e^{-\Gamma_\Sigma\tau}\right), \quad (5.171)$$

where $W_1(\infty)$ is given by the second of Eqs. (168). (It is straightforward to verify that the solution for $W_0(\tau)$ may be represented in a similar form, with the corresponding change of the state index.)

Now everything is ready to calculate the average $\langle E(t)E(t+\tau) \rangle$ using Eq. (167), with $f_{m,m'} = E_{0,1}$. Thanks to our (smart :-) choice of the energy reference, of the four terms in the double sum (167), all three terms that include at least one factor $E_0 = 0$ vanish, and we have only one term left to calculate:

$$\begin{aligned} \langle E(t)E(t+\tau) \rangle &= E_1 W_1(\infty) E_1 W_1(\tau) \Big|_{W_1(0)=1} = E_1^2 W_1(\infty) \left[W_1(0) e^{-\Gamma_\Sigma\tau} + W_1(\infty) \left(1 - e^{-\Gamma_\Sigma\tau}\right) \right] \Big|_{W_1(0)=1} \\ &= \frac{\Delta^2}{e^{\Delta/T} + 1} \left[e^{-\Gamma_\Sigma\tau} + \frac{1}{e^{\Delta/T} + 1} \left(1 - e^{-\Gamma_\Sigma\tau}\right) \right] \equiv \frac{\Delta^2}{(e^{\Delta/T} + 1)^2} \left(1 + e^{\Delta/T} e^{-\Gamma_\Sigma\tau}\right). \end{aligned} \quad (5.172)$$

From here and the last of Eqs. (168), the correlation function of energy fluctuations is⁷³

$$\begin{aligned} K_E(\tau) &\equiv \langle \tilde{E}(t)\tilde{E}(t+\tau) \rangle = \langle (E(t) - \langle E(t) \rangle)(E(t+\tau) - \langle E(t) \rangle) \rangle \\ &= \langle E(t)E(t+\tau) \rangle - \langle E(\infty) \rangle^2 = \Delta^2 \frac{e^{\Delta/T}}{(e^{\Delta/T} + 1)^2} e^{-\Gamma_\Sigma \tau}, \end{aligned} \quad (5.173)$$

so that its variance, equal to $K_E(0)$, does not depend on the transition rates Γ_\uparrow and Γ_\downarrow . However, since the rates have to obey the detailed balance relation (4.103), $\Gamma_\downarrow/\Gamma_\uparrow = \exp\{\Delta/T\}$, for this variance we may formally write

$$\frac{K_E(0)}{\Delta^2} = \frac{e^{\Delta/T}}{(e^{\Delta/T} + 1)^2} = \frac{\Gamma_\downarrow/\Gamma_\uparrow}{(\Gamma_\downarrow/\Gamma_\uparrow + 1)^2} = \frac{\Gamma_\uparrow\Gamma_\downarrow}{(\Gamma_\uparrow + \Gamma_\downarrow)^2} \equiv \frac{\Gamma_\uparrow\Gamma_\downarrow}{\Gamma_\Sigma^2}, \quad (5.174)$$

so that Eq. (173) may be represented in a simpler form:

$$K_E(\tau) = \Delta^2 \frac{\Gamma_\uparrow\Gamma_\downarrow}{\Gamma_\Sigma^2} e^{-\Gamma_\Sigma \tau}. \quad (5.175)$$

Energy fluctuations:
two-level system

We see that the correlation function of energy fluctuations decays exponentially with time, with the net rate Γ_Σ . Now using the Wiener-Khinchin theorem (58) to calculate its spectral density, we get

$$S_E(\omega) = \frac{1}{\pi} \int_0^\infty \Delta^2 \frac{\Gamma_\uparrow\Gamma_\downarrow}{\Gamma_\Sigma^2} e^{-\Gamma_\Sigma \tau} \cos \omega \tau d\tau = \frac{\Delta^2}{\pi \Gamma_\Sigma} \frac{\Gamma_\uparrow\Gamma_\downarrow}{\Gamma_\Sigma^2 + \omega^2}. \quad (5.176)$$

Such Lorentzian dependence on frequency is very typical for discrete-state systems described by master equations. It is interesting that the most widely accepted explanation of the *1/f noise* (also called the “flicker” or “excess” noise), which was mentioned in Sec. 5, is that it is a result of thermally-activated jumps between states of two-level systems with an exponentially-broad statistical distribution of the transition rates $\Gamma_{\uparrow\downarrow}$. Such a broad distribution follows from the Kramers formula (155), which is approximately valid for the lifetimes of both states of systems with double-well potential profiles (Fig. 13), for a statistical ensemble with a smooth statistical distribution of the energy barrier heights U_0 . Such profiles are typical, in particular, for electrons in disordered (amorphous) solid-state materials, which indeed feature high *1/f* noise.

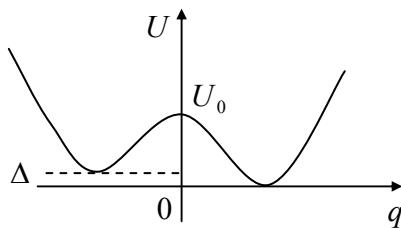

Fig. 5.13. Typical double-well potential profile.

Returning to the Fokker-Planck equation, we may use the following evident generalization of Eq. (167) to the continuous-variable case:

⁷³ The step from the first line of Eq. (173) to its second line utilizes the fact that our system is stationary, so that $\langle E(t+\tau) \rangle = \langle E(t) \rangle = \langle E(\infty) \rangle = \text{const.}$

$$\langle f(t)f(t+\tau) \rangle = \int d^3q d^3p \int d^3q' d^3p' f(\mathbf{q}, \mathbf{p}) w(\mathbf{q}, \mathbf{p}, \infty) f(\mathbf{q}', \mathbf{p}') w(\mathbf{q}', \mathbf{p}', \tau), \quad (5.177)$$

were both probability densities are particular values of the equation's solution with the delta-functional initial condition

$$w(\mathbf{q}', \mathbf{p}', 0) = \delta(\mathbf{q}' - \mathbf{q}) \delta(\mathbf{p}' - \mathbf{p}). \quad (5.178)$$

For the Smoluchowski equation valid in the high-damping limit, the expressions are similar, albeit with a lower dimensionality:

$$\langle f(t)f(t+\tau) \rangle = \int d^3q \int d^3q' f(\mathbf{q}) w(\mathbf{q}, \infty) f(\mathbf{q}') w(\mathbf{q}', \tau), \quad (5.179)$$

$$w(\mathbf{q}', 0) = \delta(\mathbf{q}' - \mathbf{q}). \quad (5.180)$$

To see this formalism in action, let us use it to calculate the correlation function $K_q(\tau)$ of a *linear relaxator*, i.e. an overdamped 1D harmonic oscillator with $m\omega_0 \ll \eta$. In this limit, as Eq. (65) shows, the oscillator's coordinate, averaged over the ensemble of environments, obeys a linear equation,

$$\eta \langle \dot{q} \rangle + \kappa \langle q \rangle = 0, \quad (5.181)$$

which describes its exponential relaxation from the initial position q_0 to the equilibrium position $q = 0$, with the reciprocal time constant $\Gamma = \kappa/\eta$:

$$\langle q \rangle(t) = q_0 e^{-\Gamma t}. \quad (5.182)$$

The deterministic equation (181) corresponds to the quadratic potential energy $U(q) = \kappa q^2/2$, so that the 1D version of the corresponding Smoluchowski equation (122) takes the form

$$\eta \frac{\partial w}{\partial t} = \kappa \frac{\partial}{\partial q} (wq) + T \frac{\partial^2 w}{\partial q^2}. \quad (5.183)$$

It is straightforward to check, by substitution, that this equation, rewritten for the function $w(q', \tau)$, with the 1D version of the delta-functional initial condition (180), $w(q', 0) = \delta(q' - q)$, is satisfied with a Gaussian function:

$$w(q', \tau) = \frac{1}{(2\pi)^{1/2} \delta q(\tau)} \exp \left\{ -\frac{(q' - \langle q \rangle(\tau))^2}{2\delta q^2(\tau)} \right\}, \quad (5.184)$$

with its center $\langle q \rangle(\tau)$ moving in accordance with Eq. (182), and a time-dependent variance

$$\delta q^2(\tau) = \delta q^2(\infty) (1 - e^{-2\Gamma\tau}), \quad \text{where } \delta q^2(\infty) = \langle q^2 \rangle = \frac{T}{\kappa}. \quad (5.185)$$

(As a sanity check, the last equality coincides with the equipartition theorem's result.) Finally, the first probability under the integral in Eq. (179) may be found from Eq. (184) in the limit $\tau \rightarrow \infty$ (in which $\langle q \rangle(\tau) \rightarrow 0$), by replacing q' with q :

$$w(q, \infty) = \frac{1}{(2\pi)^{1/2} \delta q(\infty)} \exp \left\{ -\frac{q^2}{2\delta q^2(\infty)} \right\}. \quad (5.186)$$

Now all ingredients of the recipe (179) are ready, and we can spell it out, for $f(q) = q$, as

$$\langle q(t)q(t+\tau) \rangle = \frac{1}{2\pi\delta q(\tau)\delta q(\infty)} \int_{-\infty}^{+\infty} dq \int_{-\infty}^{+\infty} dq' q \exp\left\{-\frac{q^2}{2\delta q^2(\infty)}\right\} q' \exp\left\{-\frac{(q'-qe^{-\Gamma\tau})^2}{2\delta q^2(\tau)}\right\}. \quad (5.187)$$

The integral over q' may be worked out first, by replacing this integration variable with $(q'' + qe^{-\Gamma\tau})$ and hence dq' with dq'' :

$$\langle q(t)q(t+\tau) \rangle = \frac{1}{2\pi\delta q(\tau)\delta q(\infty)} \int_{-\infty}^{+\infty} q \exp\left\{-\frac{q^2}{2\delta q^2(\infty)}\right\} dq \int_{-\infty}^{+\infty} (q'' + qe^{-\Gamma\tau}) \exp\left\{-\frac{q''^2}{2\delta q^2(\tau)}\right\} dq''. \quad (5.188)$$

The internal integral of the first term in the parentheses equals zero (as that of an odd function in symmetric integration limits), while that with the second term is the standard Gaussian integral, so that

$$\langle q(t)q(t+\tau) \rangle = \frac{1}{(2\pi)^{1/2}\delta q(\infty)} e^{-\Gamma\tau} \int_{-\infty}^{+\infty} q^2 \exp\left\{-\frac{q^2}{2\delta q^2(\infty)}\right\} dq \equiv \frac{2T}{\pi^{1/2}\kappa} e^{-\Gamma\tau} \int_{-\infty}^{+\infty} \xi^2 \exp\{-\xi^2\} d\xi. \quad (5.189)$$

The last integral⁷⁴ equals $\pi^{1/2}/2$, so that taking into account that for this stationary system centered at the coordinate origin, $\langle q(\infty) \rangle = 0$, we finally get a very simple result,

$$K_q(\tau) \equiv \langle \tilde{q}(t)\tilde{q}(t+\tau) \rangle = \langle q(t)q(t+\tau) \rangle - \langle q(\infty) \rangle^2 = \langle q(t)q(t+\tau) \rangle = \frac{T}{\kappa} e^{-\Gamma\tau}. \quad (5.190)$$

Correlation
function:
linear
relaxator

As a sanity check, for $\tau = 0$ it yields $K_q(0) \equiv \langle q^2 \rangle = T/\kappa$, in accordance with Eq. (185). As τ is increased the correlation function decreases monotonically – see the solid-line sketch in Fig. 8.

So, the solution of this very simple problem has required straightforward but somewhat bulky calculations. On the other hand, the same result may be obtained literally in one line using the Langevin formalism – namely, as the Fourier transform (59) of the spectral density (68) in the corresponding limit $m\omega \ll \eta$, with $S_A(\omega)$ given by Eq. (73a):⁷⁵

$$K_q(\tau) = 2 \int_0^\infty S_q(\omega) \cos \omega\tau d\omega = 2 \int_0^\infty \frac{\eta T}{\pi} \frac{1}{\kappa^2 + (\eta\omega)^2} \cos \omega\tau d\omega = 2 \frac{T\Gamma}{\pi} \int_0^\infty \frac{\cos \xi}{(\Gamma\tau)^2 + \xi^2} d\xi = \frac{T}{\kappa} e^{-\Gamma\tau}. \quad (5.191)$$

This example illustrates the fact that for linear systems (and small fluctuations in nonlinear systems) the Langevin approach is usually much simpler than the one based on the Fokker-Planck or Smoluchowski equations. However, again, the latter approach is indispensable for the analysis of fluctuations of arbitrary intensity in nonlinear systems.

To conclude this chapter, I have to emphasize again that the Fokker-Planck and Smoluchowski equations give a quantitative description of the time evolution of nonlinear Brownian systems with dissipation in the *classical* limit. The description of the corresponding properties of such dissipative (“open”) and nonlinear *quantum* systems is more complex,⁷⁶ and only a few simple problems of their theory have been solved analytically so far,⁷⁷ typically using a particular model of the environment, e.g.,

⁷⁴ See, e.g., MA Eq. (6.9c).

⁷⁵ The involved table integral may be found, e.g., in MA Eq. (6.11).

⁷⁶ See, e.g., QM Sec. 7.6.

⁷⁷ See, e.g., the solutions of the 1D Kramers problem for quantum systems with low damping by A. Caldeira and A. Leggett, *Phys. Rev. Lett.* **46**, 211 (1981), and with high damping by A. Larkin and Yu. Ovchinnikov, *JETP Lett.* **37**, 382 (1983).

as a large set of harmonic oscillators with different statistical distributions of their parameters, leading to different frequency dependences of the generalized susceptibility $\chi(\omega)$.

5.10. Exercise problems

5.1. Treating the first 30 digits of number $\pi = 3.1415\dots$ as a statistical ensemble of integers k (equal to 3, 1, 4, 1, 5,...), calculate the average $\langle k \rangle$ and the r.m.s. fluctuation δk . Compare the results with those for the ensemble of completely random decimal integers 0, 1, 2,..,9, and comment.

5.2. Calculate the variance of fluctuations of a magnetic moment \mathbf{m} placed into an external magnetic field \mathcal{H} , within the same two models as in Problem 2.4:

- (i) a spin- $\frac{1}{2}$ with a gyromagnetic ratio γ , and
- (ii) a classical magnetic moment \mathbf{m} , of a fixed magnitude m_0 , but an arbitrary orientation,

both in thermal equilibrium at temperature T . Discuss and compare the results.⁷⁸

Hint: Mind all three Cartesian components of the vector \mathbf{m} .

5.3. For a field-free, two-site Ising system with energy values $E_m = -J s_1 s_2$, in thermal equilibrium at temperature T , calculate the variance of energy fluctuations. Explore the low-temperature and high-temperature limits of the result.

5.4. For a uniform, three-site Ising ring with ferromagnetic coupling (and no external field), calculate the correlation coefficients $K_s \equiv \langle s_k s_k \rangle$ for both $k = k'$ and $k \neq k'$.

5.5.* For a field-free 1D Ising system of $N \gg 1$ “spins”, in thermal equilibrium at temperature T , calculate the correlation coefficient $K_s \equiv \langle s_l s_{l+n} \rangle$, where l and $(l+n)$ are the numbers of two specific spins in the chain.

Hint: You may like to start with the calculation of the statistical sum for an open-ended chain with arbitrary $N > 1$ and arbitrary coupling coefficients J_k , and then consider its mixed partial derivative over a part of these parameters.

5.6. Within the framework of the Weiss molecular-field theory, calculate the variance of spin fluctuations in the d -dimensional Ising model. Use the result to derive the conditions of its validity.

5.7. Calculate the variance of energy fluctuations in a quantum harmonic oscillator with frequency ω , in thermal equilibrium at temperature T , and express it via the average value of the energy.

5.8. The spontaneous electromagnetic field inside a closed volume V is in thermal equilibrium at temperature T . Assuming that V is sufficiently large, calculate the variance of fluctuations of the total

⁷⁸ Note that these two cases may be considered as the non-interacting limits of, respectively, the Ising model (4.23) and the classical limit of the Heisenberg model (4.21), whose analysis within the Weiss approximation was the subject of Problem 4.18.

energy of the field, and express the result via its average energy and temperature. How large should the volume V be for your results to be quantitatively valid? Evaluate this limitation for room temperature.

5.9. Express the r.m.s. uncertainty of the occupancy N_k of a certain energy level ε_k by non-interacting:

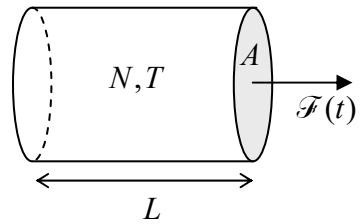

- (i) classical particles,
- (ii) fermions, and
- (iii) bosons,

in thermodynamic equilibrium, via the level's average occupancy $\langle N_k \rangle$, and compare the results.

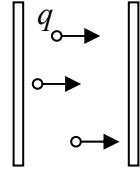

5.10. Express the variance of the number of particles, $\langle \tilde{N}^2 \rangle_{V,T,\mu}$, of a single-phase system in equilibrium, via its isothermal compressibility $\kappa_T \equiv -(1/V)(\partial V/\partial P)_{T,N}$.

5.11.* Starting from the Maxwell distribution of velocities, calculate the low-frequency spectral density of fluctuations of the pressure $P(t)$ of an ideal gas of N classical particles, in thermal equilibrium at temperature T , and estimate their variance. Compare the former result with the solution of Problem 3.2.

Hints: You may consider a cylindrically-shaped container of volume $V = LA$ (see the figure on the right), calculate fluctuations of the force $\mathcal{F}(t)$ exerted by the confined particles on its plane lid of area A , approximating it as a delta-correlated process (62), and then re-calculate the fluctuations into those of pressure $P \equiv \mathcal{F}/A$.

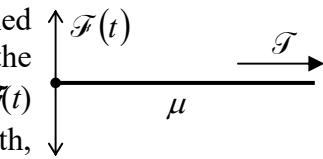

5.12. Calculate the low-frequency spectral density of fluctuations of the electric current $I(t)$ due to the random passage of charged particles between two conducting electrodes – see the figure on the right. Assume that the particles are emitted, at random times, by one of the electrodes, and are fully absorbed by the counterpart electrode. Can your result be mapped on some aspect of the electromagnetic blackbody radiation?

Hint: For the current $I(t)$, use the same delta-correlated-process approximation as for the force $\mathcal{F}(t)$ in the previous problem.

5.13.⁷⁹ A very long, uniform string, of mass μ per unit length, is attached to a firm support, and stretched with a constant force (“tension”) \mathcal{T} – see the figure on the right. Calculate the spectral density of the random force $\mathcal{F}(t)$ exerted by the string on the support point, within the plane normal to its length, in thermal equilibrium at temperature T .

Hint: You may assume that the string is so long that a transverse wave, propagating along it from the support point, never comes back.

⁷⁹ This problem, conceptually important for the quantum mechanics of open systems, was given in Chapter 7 of the QM part of this series, and is repeated here for the benefit of the readers who, by any reason, skipped that course.

5.14.⁸⁰ Each of two 3D harmonic oscillators, with mass m , resonance frequency ω_0 , and damping $\delta > 0$, has electric dipole moment $\mathbf{d} = q\mathbf{s}$, where \mathbf{s} is the vector of oscillator's displacement from its equilibrium position. Use the Langevin formalism to calculate the average potential of electrostatic interaction of these two oscillators (a particular case of the so-called *London dispersion force*), separated by distance $r \gg (T/m)^{1/2}/\omega_0$, in thermal equilibrium at temperature $T \gg \hbar\omega_0$. Also, explain why the approach used to solve a very similar Problem 2.15 is not directly applicable to this case.

Hint: You may like to use the following integral:
$$\int_0^{\infty} \frac{1 - \xi^2}{[(1 - \xi^2)^2 + (a\xi)^2]^2} d\xi = \frac{\pi}{4a}.$$

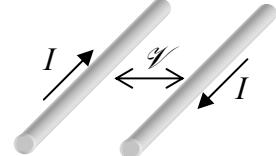

5.15.^{*} Within the van der Pol approximation,⁸¹ calculate major statistical properties of fluctuations of classical self-oscillations, at:

- (i) the free (“autonomous”) run of the oscillator, and
- (ii) their phase been locked by an external sinusoidal force,

assuming that the fluctuations are caused by a weak external noise with a smooth spectral density $S_f(\omega)$. In particular, calculate the self-oscillation linewidth.

5.16. Calculate the correlation function of the coordinate of a 1D harmonic oscillator with small Ohmic damping at thermal equilibrium. Compare the result with that for the autonomous self-oscillator (the subject of the previous problem).

5.17. Consider a very long, uniform, two-wire transmission line (see the figure on the right) with wave impedance \mathcal{Z} , which allows propagation of TEM electromagnetic waves with negligible attenuation, in thermal equilibrium at temperature T . Calculate the variance $\langle \mathcal{V}^2 \rangle_{\Delta\nu}$ of the voltage \mathcal{V} between the wires within a small interval $\Delta\nu$ of cyclic frequencies.

Hint: As an E&M reminder,⁸² in the absence of dispersive materials, TEM waves propagate with a frequency-independent velocity (equal to the speed c of light, if the wires are in free space), with the voltage \mathcal{V} and the current I (see Fig. above) related as $\mathcal{V}(x,t)/I(x,t) = \pm\mathcal{Z}$, where \mathcal{Z} is line's wave impedance.

5.18. Now consider a similar long transmission line but terminated, at one end, with an impedance-matching Ohmic resistor $R = \mathcal{Z}$. Calculate the variance $\langle \mathcal{V}^2 \rangle_{\Delta\nu}$ of the voltage across the

⁸⁰ This problem, for the case of arbitrary temperature, was the subject of QM Problem 7.6, with Problem 5.15 of that course serving as the background. However, the method used in the model solutions of those problems requires one to prescribe, to the oscillators, different frequencies ω_1 and ω_2 at first, and only after this more general problem has been solved, pursue the limit $\omega_1 \rightarrow \omega_2$, while neglecting dissipation altogether. The goal of this problem is to show that the result of that solution is valid even at non-zero damping.

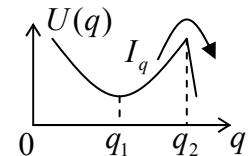

⁸¹ See, e.g., CM Secs. 5.2-5.5. Note that in quantum mechanics, a similar approach is called the *rotating-wave approximation* (RWA) – see, e.g., QM Secs. 6.5, 7.6, 9.2, and 9.4.

⁸² See, e.g., EM Sec. 7.6.

resistor, and discuss the relation between the result and the Nyquist formula (81b), including numerical factors.

Hint: A termination with resistance $R = \mathcal{F}$ absorbs incident TEM waves without reflection.

5.19. An overdamped classical 1D particle escapes from a potential well with a smooth bottom, but a sharp top of the barrier – see the figure on the right. Perform the necessary modification of the Kramers formula (139).

5.20. Perhaps the simplest model of the diffusion is the 1D *discrete random walk*: each time interval τ , a particle leaps, with equal probability, to any of two adjacent sites of a 1D lattice with spatial period a . Prove that the particle's displacement during a time interval $t \gg \tau$ obeys Eq. (77), and calculate the corresponding diffusion coefficient D .

5.21. A classical particle may occupy any of N similar sites. Its weak interaction with the environment induces random, incoherent jumps from the occupied site to any other site, with the same time-independent rate Γ . Calculate the correlation function and the spectral density of fluctuations of the instant occupancy $n(t)$ (equal to either 1 or 0) of a site.

Chapter 6. Elements of Kinetics

This chapter gives a brief introduction to the basic notions of physical kinetics. Its main focus is on the Boltzmann transport equation, especially within the simple relaxation-time approximation (RTA), which allows an approximate but reasonable and simple description of transport phenomena (such as the electric current and thermoelectric effects) in gases, including electron gases in metals and semiconductors.

6.1. The Liouville theorem and the Boltzmann equation

Physical kinetics (not to be confused with “kinematics”!) is the branch of statistical physics that deals with systems out of thermodynamic equilibrium. Major effects addressed by kinetics include:

- (i) for *autonomous* systems (those out of external fields): the transient processes (*relaxation*), that lead from an arbitrary initial state of a system to its thermodynamic equilibrium;
- (ii) for systems in time-dependent (say, sinusoidal) external fields: the field-induced periodic oscillations of the system’s variables; and
- (iii) for systems in time-independent (“dc”) external fields: dc transport.

In the last case, we are dealing with stationary ($\partial/\partial t = 0$ everywhere), but *non-equilibrium* situations, in which the effect of an external field, continuously driving the system out of equilibrium, is balanced by the simultaneous relaxation – the trend back to equilibrium. Perhaps the most important effect of this class is the dc current in conductors and semiconductors,¹ which alone justifies the inclusion of the basic notions of kinetics into any set of core physics courses.

The reader who has reached this point of the notes already has some taste of physical kinetics, because the subject of the last part of Chapter 5 was the kinetics of a “Brownian particle”, i.e. of a “heavy” system interacting with an environment consisting of many “lighter” components. Indeed, the equations discussed in that part – whether the Smoluchowski equation (5.122) or the Fokker-Planck equation (5.149) – are valid if the environment is in thermodynamic equilibrium, but the system of our interest is not necessarily so. As a result, we could use those equations to discuss such non-equilibrium phenomena as the Kramers problem of the metastable state’s lifetime.

In contrast, this chapter is devoted to the more traditional subject of kinetics: systems of many *similar* particles – generally, interacting with each other, but not too strongly, so that the energy of the system still may be partitioned into a sum of single-particle components, with the interparticle interactions considered as a weak perturbation. Actually, we have already started the job of describing such a system at the beginning of Sec. 5.7. Indeed, in the absence of particle interactions (i.e. when it is unimportant whether the particle of our interest is “light” or “heavy”), the probability current densities in the coordinate and momentum spaces are given, respectively, by Eq. (5.142) and the first form of Eq. (5.143a), so that the continuity equation (5.140) takes the form

$$\frac{\partial w}{\partial t} + \nabla_q \cdot (w \dot{\mathbf{q}}) + \nabla_p \cdot (w \dot{\mathbf{p}}) = 0. \quad (6.1)$$

¹ This topic was briefly addressed in EM Chapter 4, carefully avoiding the aspects related to the thermal effects.

If similar particles do *not* interact, this equation for the single-particle probability density $w(\mathbf{q}, \mathbf{p}, t)$ is valid for each of them, and the result of its solution may be used to calculate any ensemble-average characteristic of the system as a whole.

Let us rewrite Eq. (1) in the Cartesian-component form,

$$\frac{\partial w}{\partial t} + \sum_j \left[\frac{\partial}{\partial q_j} (w \dot{q}_j) + \frac{\partial}{\partial p_j} (w \dot{p}_j) \right] = 0, \quad (6.2)$$

where the index j lists all degrees of freedom of the particle under consideration, and assume that its motion (perhaps in an external, time-dependent field) may be described by a Hamiltonian function $\mathcal{H}(q_j, p_j, t)$. Plugging into Eq. (2) the Hamiltonian equations of motion:²

$$\dot{q}_j = \frac{\partial \mathcal{H}}{\partial p_j}, \quad \dot{p}_j = -\frac{\partial \mathcal{H}}{\partial q_j}, \quad (6.3)$$

we get

$$\frac{\partial w}{\partial t} + \sum_j \left[\frac{\partial}{\partial q_j} \left(w \frac{\partial \mathcal{H}}{\partial p_j} \right) - \frac{\partial}{\partial p_j} \left(w \frac{\partial \mathcal{H}}{\partial q_j} \right) \right] = 0. \quad (6.4)$$

After differentiation of both parentheses by parts, the equal mixed terms $w \partial^2 \mathcal{H} / \partial q_j \partial p_j$ and $w \partial^2 \mathcal{H} / \partial p_j \partial q_j$ cancel, and using Eq. (3) again, we get the so-called *Liouville theorem*³

$$\frac{\partial w}{\partial t} + \sum_j \left(\frac{\partial w}{\partial q_j} \dot{q}_j + \frac{\partial w}{\partial p_j} \dot{p}_j \right) = 0.$$

(6.5)

Liouville theorem

Since the left-hand side of this equation is just the full derivative of the probability density w considered as a function of the generalized coordinates $q_j(t)$ of a particle, its generalized momenta components $p_j(t)$, and (possibly) time t ,⁴ the Liouville theorem (5) may be represented in a surprisingly simple form:

$$\frac{dw(\mathbf{q}, \mathbf{p}, t)}{dt} = 0. \quad (6.6)$$

Physically this means that the elementary probability $dW = w d^3q d^3p$ to find a Hamiltonian particle in a small volume of the coordinate-momentum space $[\mathbf{q}, \mathbf{p}]$, with its center moving in accordance to the deterministic law (3), does not change with time – see Fig. 1.

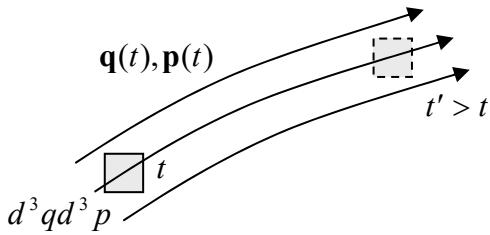

Fig. 6.1. The Liouville theorem's interpretation: probability's conservation at its flow through the $[\mathbf{q}, \mathbf{p}]$ space.

² See, e.g., CM Sec. 10.1.

³ Actually, this is just one of several theorems bearing the name of Joseph Liouville (1809-1882).

⁴ See, e.g., MA Eq. (4.2).

At the first glance, this may not look surprising because according to the fundamental Einstein relation (5.78), one needs non-Hamiltonian forces (such as the kinematic friction) to have diffusion. On the other hand, it is striking that the Liouville theorem is valid even for (Hamiltonian) systems with deterministic chaos,⁵ in which the deterministic trajectories corresponding to slightly different initial conditions become increasingly mixed with time.

For an ideal gas of 3D particles, we may use the ordinary Cartesian coordinates r_j (with $j = 1, 2, 3$) for the generalized coordinates q_j , so that p_j become the Cartesian components mv_j of the usual (linear) momentum, and the elementary volume is just $d^3r d^3p$ – see Fig. 1. In this case, Eqs. (3) are just

$$\dot{r}_j = \frac{p_j}{m} \equiv v_j, \quad \dot{p}_j = \mathcal{F}_j, \quad (6.7)$$

where \mathcal{F} is the force exerted on the particle, so that the Liouville theorem may be rewritten as

$$\frac{\partial w}{\partial t} + \sum_{j=1}^3 \left(v_j \frac{\partial w}{\partial r_j} + \mathcal{F}_j \frac{\partial w}{\partial p_j} \right) = 0, \quad (6.8)$$

and conveniently represented in the vector form

$$\frac{\partial w}{\partial t} + \mathbf{v} \cdot \nabla_r w + \mathcal{F} \cdot \nabla_p w = 0. \quad (6.9)$$

Of course, the situation becomes much more complex if the particles interact. Generally, a system of N similar particles in 3D space has to be described by the probability density being a function of $6N + 1$ arguments (3 N Cartesian coordinates, plus 3 N momentum components, plus time). An analytical or numerical solution of any equation describing the time evolution of such a function for a typical system of $N \sim 10^{23}$ particles is evidently a hopeless task. Hence, any theory of realistic systems' kinetics has to rely on making reasonable approximations that would simplify the situation.

One of the most useful approximations (sometimes called *Stosszahlansatz* – German for the “collision-number assumption”) was suggested by Ludwig Boltzmann for gas of particles that move freely most of the time but interact during short time intervals, when a particle comes close to either an immobile scattering center (say, an impurity in a conductor's crystal lattice) or to another particle of the gas. Such brief *scattering events* may change the particle's momentum. Boltzmann argued that they may be still approximately described Eq. (9), with the addition of a special term (called the *scattering integral*) to its right-hand side:

$$\frac{\partial w}{\partial t} + \mathbf{v} \cdot \nabla_r w + \mathcal{F} \cdot \nabla_p w = \frac{\partial w}{\partial t} \Big|_{\text{scattering}}. \quad (6.10)$$

Boltzmann
equation

This is the *Boltzmann equation*, also called the “Boltzmann transport equation”. As will be discussed below, it may give a very reasonable description of not only classical but also quantum particles, though it evidently neglects the quantum-mechanical coherence/entanglement effects⁶ – besides those that may be hidden inside the scattering integral.

⁵ See, e.g., CM Sec. 9.3.

⁶ Indeed, the quantum state coherence is described by off-diagonal elements of the density matrix, while the classical probability w represents only the diagonal elements of that matrix. However, at least for the ensembles close to thermal equilibrium, this is a reasonable approximation – see the discussion in Sec. 2.1.

The concrete form of the scattering integral depends on the type of particle scattering. If the scattering centers do not belong to the ensemble under consideration (an example is given, again, by impurity atoms in a conductor), then the scattering integral may be expressed as an evident generalization of the master equation (4.100):

$$\frac{\partial w}{\partial t} \Big|_{\text{scattering}} = \int d^3 p' \left[\Gamma_{\mathbf{p}' \rightarrow \mathbf{p}} w(\mathbf{r}, \mathbf{p}', t) - \Gamma_{\mathbf{p} \rightarrow \mathbf{p}'} w(\mathbf{r}, \mathbf{p}, t) \right], \quad (6.11)$$

where the physical sense of $\Gamma_{\mathbf{p} \rightarrow \mathbf{p}'}$ is the rate (i.e. the probability per unit time) for the particle to be scattered from the state with the momentum \mathbf{p} into the state with the momentum \mathbf{p}' – see Fig. 2.

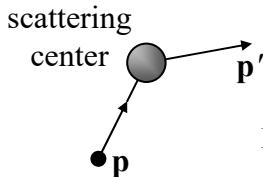

Fig. 6.2. A single-particle scattering event.

Most elastic interactions are *reciprocal*, i.e. obey the following relation (closely related to the reversibility of time in Hamiltonian systems): $\Gamma_{\mathbf{p} \rightarrow \mathbf{p}'} = \Gamma_{\mathbf{p}' \rightarrow \mathbf{p}}$, so that Eq. (11) may be rewritten as⁷

$$\frac{\partial w}{\partial t} \Big|_{\text{scattering}} = \int d^3 p' \Gamma_{\mathbf{p} \rightarrow \mathbf{p}'} [w(\mathbf{r}, \mathbf{p}', t) - w(\mathbf{r}, \mathbf{p}, t)]. \quad (6.12)$$

With such scattering integral, Eq. (10) stays linear in w but becomes an *integro-differential equation*, typically harder to solve analytically than differential equations.

The equation becomes even more complex if the scattering is due to the mutual interaction of the particle members of the system – see Fig. 3.

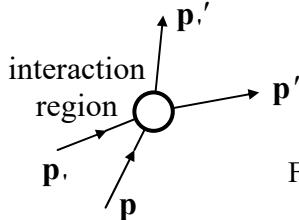

Fig. 6.3. A particle-particle scattering event.

In this case, the probability of a scattering event scales as a product of two single-particle probabilities, and the simplest reasonable form of the scattering integral is⁸

⁷ One may wonder whether this approximation may work for Fermi particles, such as electrons, for whom the Pauli principle forbids scattering into the already occupied state, so that for the scattering $\mathbf{p} \rightarrow \mathbf{p}'$, the term $w(\mathbf{r}, \mathbf{p}, t)$ in Eq. (12) has to be multiplied by the probability $[1 - w(\mathbf{r}, \mathbf{p}', t)]$ that the final state is available. This is a valid argument, but one should notice that if this modification has been done with both terms of Eq. (12), it becomes

$$\frac{\partial w}{\partial t} \Big|_{\text{scattering}} = \int d^3 p' \Gamma_{\mathbf{p} \rightarrow \mathbf{p}'} \{w(\mathbf{r}, \mathbf{p}', t)[1 - w(\mathbf{r}, \mathbf{p}, t)] - w(\mathbf{r}, \mathbf{p}, t)[1 - w(\mathbf{r}, \mathbf{p}', t)]\}.$$

Opening both square brackets, we see that the probability density products cancel, bringing us back to Eq. (12).

⁸ This was the approximation used by L. Boltzmann to prove the famous *H-theorem*, stating that entropy of the gas described by Eq. (13) may only grow (or stay constant) in time, $dS/dt \geq 0$. Since the model is very approximate, that result does not seem too fundamental nowadays, despite all its historic significance.

$$\frac{\partial w}{\partial t} \Big|_{\text{scattering}} = \int d^3 p' \int d^3 p \left[\begin{array}{l} \Gamma_{\mathbf{p}' \rightarrow \mathbf{p}, \mathbf{p}' \rightarrow \mathbf{p}, \mathbf{p}'} w(\mathbf{r}, \mathbf{p}', t) w(\mathbf{r}, \mathbf{p}', t) \\ - \Gamma_{\mathbf{p} \rightarrow \mathbf{p}', \mathbf{p} \rightarrow \mathbf{p}', \mathbf{p}'} w(\mathbf{r}, \mathbf{p}, t) w(\mathbf{r}, \mathbf{p}, t) \end{array} \right]. \quad (6.13)$$

The integration dimensionality in Eq. (13) takes into account the fact that due to the conservation of the total momentum at scattering,

$$\mathbf{p} + \mathbf{p}_+ = \mathbf{p}' + \mathbf{p}', \quad (6.14)$$

one of the momenta is not an independent argument, so that the integration in Eq. (13) may be restricted to a 6D p -space rather than the 9D one. For the reciprocal interaction, Eq. (13) may also be a bit simplified, but it still keeps Eq. (10) a *nonlinear* integro-differential transport equation, excluding such powerful solution methods as the Fourier expansion – which hinges on the linear superposition principle.

This is why most useful results based on the Boltzmann transport equation depend on its further simplifications, most notably the *relaxation-time approximation* – RTA for short.⁹ This approximation is based on the fact that in the absence of spatial gradients ($\nabla = 0$), and external forces ($\mathcal{F} = 0$), in at the thermal equilibrium, Eq. (10) yields

$$\frac{\partial w}{\partial t} = \frac{\partial w}{\partial t} \Big|_{\text{scattering}}, \quad (6.15)$$

so that the equilibrium probability distribution $w_0(\mathbf{r}, \mathbf{p}, t)$ has to turn any scattering integral to zero. Hence at a *small* deviation from the equilibrium,

$$\tilde{w}(\mathbf{r}, \mathbf{p}, t) \equiv w(\mathbf{r}, \mathbf{p}, t) - w_0(\mathbf{r}, \mathbf{p}, t) \rightarrow 0, \quad (6.16)$$

the scattering integral should be proportional to the deviation \tilde{w} , and its simplest reasonable model is

$$\frac{\partial w}{\partial t} \Big|_{\text{scattering}} = -\frac{\tilde{w}}{\tau}, \quad (6.17)$$

where τ is a phenomenological constant (which, according to Eq. (15), has to be positive for the system's stability) called the *relaxation time*. Its physical meaning will be more clear in the next section.

The relaxation-time approximation is quite reasonable if the angular distribution of the scattering rate is dominated by small angles between vectors \mathbf{p} and \mathbf{p}' – as it is, for example, for the Rutherford scattering by a Coulomb center.¹⁰ Indeed, in this case the two values of the function w , participating in Eq. (12), are close to each other for most scattering events so that the loss of the second momentum argument (\mathbf{p}') is not too essential. However, using the Boltzmann-RTA equation that results from combining Eqs. (10) and (17),

$$\frac{\partial w}{\partial t} + \mathbf{v} \cdot \nabla_r w + \mathcal{F} \cdot \nabla_p w = -\frac{\tilde{w}}{\tau}, \quad (6.18)$$

we should always remember that this is just a phenomenological model, sometimes giving completely wrong results. For example, it prescribes the same time scale (τ) to the relaxation of the net *momentum*

⁹ Sometimes this approximation is called the “BGK model”, after P. Bhatnager, E. Gross, and M. Krook who suggested it in 1954. (The same year, a similar model was considered by P. Welander.)

¹⁰ See, e.g., CM Sec. 3.7.

of the system, and to its *energy relaxation*, while in many real systems the latter process (that results from inelastic collisions) may be substantially longer. Naturally, in the following sections, I will describe only those applications of the Boltzmann-RTA equation that give a reasonable description of physical reality.

6.2. The Ohm law and the Drude formula

Despite its shortcomings, Eq. (18) is adequate for quite a few applications. Perhaps the most important of them is deriving the Ohm law for dc current in a “nearly-ideal” gas of charged particles, whose only important deviation from ideality is the rare scattering effects described by Eq. (17). As a result, in equilibrium it is described by the stationary probability w_0 of an ideal gas (see Sec. 3.1):

$$w_0(\mathbf{r}, \mathbf{p}, t) = \frac{g}{(2\pi\hbar)^3} \langle N(\varepsilon) \rangle, \quad (6.19)$$

where g is the internal degeneracy factor (say, $g = 2$ for electrons due to their spin), and $\langle N(\varepsilon) \rangle$ is the average occupancy of a quantum state with momentum \mathbf{p} , that obeys either the Fermi-Dirac or the Bose-Einstein distribution:

$$\langle N(\varepsilon) \rangle = \frac{1}{\exp\{(\varepsilon - \mu)/T\} \pm 1}, \quad \varepsilon = \varepsilon(\mathbf{p}). \quad (6.20)$$

(The following calculations will be valid, up to a point, for both statistics and hence, in the limit $\mu/T \rightarrow -\infty$, for a classical gas as well.)

Now let a uniform dc electric field \mathcal{E} be applied to the gas of particles with electric charge q , exerting force $\mathcal{F} = q\mathcal{E}$ on each of them. Then the stationary solution to Eq. (18), with $\partial/\partial t = 0$, should also be stationary and spatially-uniform ($\nabla_r = 0$), so that this equation is reduced to

$$q\mathcal{E} \cdot \nabla_p w = -\frac{\tilde{w}}{\tau}. \quad (6.21)$$

Let us require the electric field to be relatively low, so that the perturbation \tilde{w} it produces is relatively small, as required by our basic assumption (16).¹¹ Then on the left-hand side of Eq. (21), we can neglect that perturbation, by replacing w with w_0 , because that side already has a small factor (\mathcal{E}). As a result, this equation yields

$$\tilde{w} = -\tau q \mathcal{E} \cdot \nabla_p w_0 \equiv -\tau q \mathcal{E} \cdot \left(\nabla_p \varepsilon \right) \frac{\partial w_0}{\partial \varepsilon}, \quad (6.22)$$

where the second step implies isotropy of the parameters μ and T , i.e. their independence of the direction of the particle’s momentum \mathbf{p} . But the gradient $\nabla_p \varepsilon$ is nothing else than the particle’s velocity

¹¹ Since the scale of the fastest change of w_0 in the momentum space is of the order of $\partial w_0 / \partial p = (\partial w_0 / \partial \varepsilon)(d\varepsilon/dp) \sim (1/T)v$, where v is the scale of particle’s speed, the necessary condition of the linear approximation (22) is $e\mathcal{E}\tau \ll T/v$, i.e. if $e\mathcal{E}l \ll T$, where $l \equiv v\tau$ has the meaning of the effective mean-free path. Since the left-hand side of the last inequality is just the average energy given to the particle by the electric field between two scattering events, the condition may be interpreted as the smallness of the gas’ “overheating” by the applied field. However, another condition is also necessary – see the last paragraph of this section.

\mathbf{v} – for a quantum particle, its group velocity.¹² (This fact is easy to verify for the isotropic and parabolic dispersion law, pertinent to classical particles moving in free space,

$$\epsilon(\mathbf{p}) = \frac{\mathbf{p}^2}{2m} \equiv \frac{p_1^2 + p_2^2 + p_3^2}{2m}. \quad (6.23)$$

Indeed, in this case, the j^{th} Cartesian components of the vector $\nabla_p \epsilon$ is

$$(\nabla_p \epsilon)_j \equiv \frac{\partial \epsilon}{\partial p_j} = \frac{p_j}{m} = v_j, \quad (6.24)$$

so that $\nabla_p \epsilon = \mathbf{v}$.) Hence, Eq. (22) may be rewritten as

$$\tilde{w} = -\tau q \mathcal{E} \cdot \mathbf{v} \frac{\partial w_0}{\partial \epsilon}. \quad (6.25)$$

Let us use this result to calculate the electric current density \mathbf{j} . The contribution of each particle to the current density is $q\mathbf{v}$ so that the total density is

$$\mathbf{j} = \int q\mathbf{v} w d^3 p \equiv q \int \mathbf{v} (w_0 + \tilde{w}) d^3 p. \quad (6.26)$$

Since in the equilibrium state (with $w = w_0$), the current has to be zero, the integral of the first term in the parentheses has to vanish. For the integral of the second term, plugging in Eq. (25), and then using Eq. (19), we get

$$\mathbf{j} = q^2 \tau \int \mathbf{v} (\mathcal{E} \cdot \mathbf{v}) \left(-\frac{\partial w_0}{\partial \epsilon} \right) d^3 p = \frac{gq^2 \tau}{(2\pi\hbar)^3} \int \mathbf{v} (\mathcal{E} \cdot \mathbf{v}) \left[-\frac{\partial \langle N(\epsilon) \rangle}{\partial \epsilon} \right] d^2 p_{\perp} dp_{||}, \quad (6.27)$$

where $d^2 p_{\perp}$ is the elementary area of the constant energy surface in the momentum space, while $dp_{||}$ is the momentum differential's component normal to that surface. The real power of this result¹³ is that it is valid even for particles with an arbitrary dispersion law $\epsilon(\mathbf{p})$ (which may be rather complicated, for example, for particles moving in space-periodic potentials¹⁴), and gives, in particular, a fair description of conductivity's anisotropy in crystals.

For free particles whose dispersion law is isotropic and parabolic, as in Eq. (23), the constant energy surface is a sphere of radius p , so that $d^2 p_{\perp} = p^2 d\Omega = p^2 \sin\theta d\theta d\varphi$, while $dp_{||} = dp$. In the spherical coordinates, with the polar axis directed along the electric field vector \mathcal{E} , we get $(\mathcal{E} \cdot \mathbf{v}) = \mathcal{E} v \cos\theta$. Now separating the vector \mathbf{v} outside the parentheses into the component $v \cos\theta$ directed along the vector \mathcal{E} , and two perpendicular components, $v \sin\theta \cos\varphi$ and $v \sin\theta \sin\varphi$, we see that the integrals of the last two components over the angle φ give zero. Hence, as we could expect, in the isotropic case the net current is directed along the electric field and obeys the linear *Ohm law*,

$$\mathbf{j} = \sigma \mathcal{E}, \quad (6.28)$$

Ohm
law

¹² See, e.g., QM Sec. 2.1.

¹³ It was obtained by Arnold Sommerfeld in 1927.

¹⁴ See, e.g., QM Secs. 2.7, 2.8, and 3.4. (In this case, \mathbf{p} should be understood as the quasimomentum rather than the genuine momentum.)

with a field-independent, scalar¹⁵ *electric conductivity*

$$\sigma = \frac{gq^2\tau}{(2\pi\hbar)^3} \int_0^{2\pi} d\varphi \int_0^\pi \sin\theta d\theta \cos^2\theta \int_0^\infty p^2 dp v^2 \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right]. \quad (6.29)$$

(Note that σ is proportional to q^2 and hence does not depend on the particle charge sign.¹⁶)

Since $\sin\theta d\theta$ is just $-d(\cos\theta)$, the integral over θ equals $(2/3)$. The integral over $d\varphi$ is of course just 2π , while that over p may be readily transformed to one over the particle's energy $\varepsilon(\mathbf{p}) = p^2/2m$: $p^2 = 2m\varepsilon$, $v^2 = 2\varepsilon/m$, $p = (2m\varepsilon)^{1/2}$, so that $dp = (m/2\varepsilon)^{1/2}d\varepsilon$, and $p^2 dp v^2 = (2m\varepsilon)(m/2\varepsilon)^{1/2}d\varepsilon (2\varepsilon/m) \equiv (8m\varepsilon^3)^{1/2}d\varepsilon$. As a result, the conductivity equals

$$\sigma = \frac{gq^2\tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \int_0^\infty (8m\varepsilon^3)^{1/2} \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon. \quad (6.30)$$

Now we may work out the integral in Eq. (30) by parts, first rewriting $[-\partial \langle N(\varepsilon) \rangle / \partial \varepsilon] d\varepsilon$ as $-d[\langle N(\varepsilon) \rangle]$. Due to the fast (exponential) decay of the factor $\langle N(\varepsilon) \rangle$ at $\varepsilon \rightarrow \infty$, its product by the factor $(8m\varepsilon^3)^{1/2}$ vanishes at both integration limits, and we get

$$\begin{aligned} \sigma &= \frac{gq^2\tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \int_0^\infty \langle N(\varepsilon) \rangle d[(8m\varepsilon^3)^{1/2}] = \frac{gq^2\tau}{(2\pi\hbar)^3} \frac{4\pi}{3} (8m)^{1/2} \int_0^\infty \langle N(\varepsilon) \rangle \frac{3}{2} \varepsilon^{1/2} d\varepsilon \\ &\equiv \frac{q^2\tau}{m} \times \frac{gm^{3/2}}{\sqrt{2\pi^2\hbar^3}} \int_0^\infty \langle N(\varepsilon) \rangle \varepsilon^{1/2} d\varepsilon. \end{aligned} \quad (6.31)$$

But according to Eq. (3.40), the last factor in this expression (after the \times sign) is just the particle density $n \equiv N/V$, so that the Sommerfeld's result is reduced, for arbitrary temperature, and any particle statistics, to the very simple *Drude formula*,¹⁷

$$\sigma = \frac{q^2\tau}{m} n, \quad (6.32)$$

Drude formula

which should be well familiar to the reader from an undergraduate physics course.

As a reminder, here is its simple classical derivation.¹⁸ Let 2τ be the average time interval between two sequential scattering events that cause a particle to lose the deterministic component of its velocity, $\mathbf{v}_{\text{drift}}$, provided by the electric field \mathcal{E} on the top of particle's random thermal motion – which does not contribute to the net current. Using the 2nd Newton law to describe particle's acceleration by

¹⁵ As Eq. (27) shows, if the dispersion law $\varepsilon(\mathbf{p})$ is anisotropic, the current density direction may be different from that of the electric field. In this case, conductivity should be described by a tensor $\sigma_{jj'}$, rather than a scalar. However, in most important conducting materials, the anisotropy is rather small – see, e.g., EM Table 4.1.

¹⁶ This is why to determine the dominating type of charge carriers in semiconductors (electrons or holes, see Sec. 4 below), the Hall effect, which lacks such ambivalence (see, e.g., QM 3.2), is frequently used.

¹⁷ It was derived in 1900 by Paul Drude. Note that Drude also used the same arguments to derive a very simple (and very reasonable) approximation for the complex electric conductivity in the ac field of frequency ω : $\sigma(\omega) = \sigma(0)/(1 - i\omega\tau)$, with $\sigma(0)$ given by Eq. (32); sometimes the name “Drude formula” is used for this expression rather than for Eq. (32). Let me leave its derivation, from the Boltzmann-RTA equation, for the reader's exercise.

¹⁸ See also EM Sec. 4.2.

the field, $d\mathbf{v}_{\text{drift}}/dt = q\mathcal{E}/m$, we get $\langle \mathbf{v}_{\text{drift}} \rangle = \tau q \mathcal{E}/m$. Multiplying this result by the particle's charge q and density $n \equiv N/V$, we get the Ohm law $\mathbf{j} = \sigma \mathcal{E}$, with σ given by Eq. (32).

Sommerfeld's derivation of the Drude formula poses an important conceptual question. The structure of Eq. (30) implies that the only quantum states contributing to the electric conductivity are those whose derivative $[-\partial\langle N(\mathcal{E})\rangle/\partial\mathcal{E}]$ is significant. For the Fermi particles such as electrons, in the limit $T \ll \epsilon_F$, these are the states at the very surface of the Fermi sphere. On the other hand, Eq. (32) and the whole Drude reasoning, involves the density n of *all* electrons. So, what exactly electrons are responsible for the conductivity: all of them, or only those at the Fermi surface? For the resolution of this paradox, let us return to Eq. (22) and analyze the physical meaning of that result. Let us compare it with the following model distribution:

$$w_{\text{model}} \equiv w_0(\mathbf{r}, \mathbf{p} - \tilde{\mathbf{p}}, t), \quad (6.33)$$

where $\tilde{\mathbf{p}}$ is some constant, small vector, which describes a small shift of the unperturbed distribution w_0 as a whole, in the momentum space. Performing the Taylor expansion of Eq. (33) in this small parameter, and keeping only two leading terms, we get

$$w_{\text{model}} \approx w_0(\mathbf{r}, \mathbf{p}, t) + \tilde{w}_{\text{model}}, \quad \text{with } \tilde{w}_{\text{model}} = -\tilde{\mathbf{p}} \cdot \nabla_p w_0(\mathbf{r}, \mathbf{p}, t). \quad (6.34)$$

Comparing the last expression with the first form of Eq. (22), we see that they coincide if

$$\tilde{\mathbf{p}} = q\mathcal{E}\tau \equiv \mathcal{F}\tau. \quad (6.35)$$

This means that Eq. (22) describes a small shift of the equilibrium distribution of all particles (in the momentum space) by $q\mathcal{E}\tau$ along the electric field's direction, justifying the cartoon shown in Fig. 4.

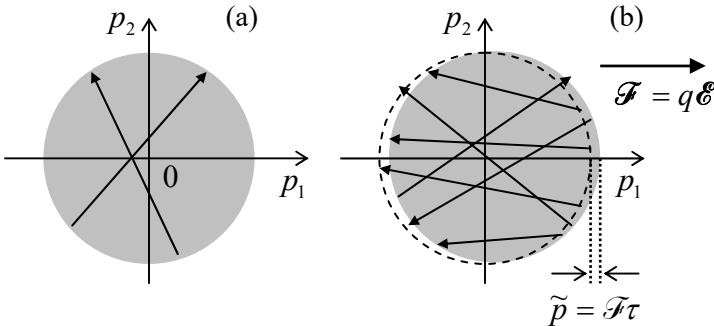

Fig. 6.4. Filling of momentum states by a degenerate electron gas: (a) in the absence and (b) in the presence of an external electric field \mathcal{E} . Arrows show representative scattering events.

At $\mathcal{E} = 0$, the system is in equilibrium, so that the quantum states inside the Fermi sphere ($p < p_F$), are occupied, while those outside of it are empty – see Fig. 4a. Electron scattering events may happen only between states within a very thin layer ($|p^2/2m - \epsilon_F| \sim T$) at the Fermi surface, because only in this layer the states are partially occupied, so that both components of the product $w(\mathbf{r}, \mathbf{p}, t)[1 - w(\mathbf{r}, \mathbf{p}', t)]$, mentioned in Sec. 1, do not vanish. These scattering events, on average, do not change the equilibrium probability distribution, because they are uniformly spread over the Fermi surface.

Now let the electric field be turned on instantly. Immediately it starts accelerating all electrons in its direction, i.e. the whole Fermi sphere starts moving in the momentum space, along the field's direction in the real space. For elastic scattering events (with $|\mathbf{p}'| = |\mathbf{p}|$), this creates an addition of occupied states at the leading edge of the accelerating sphere and an addition of free states on its trailing

edge (Fig. 4b). As a result, now there are more scattering events bringing electrons from the leading edge to the trailing edge of the sphere than in the opposite direction. This creates the average backflow of the state occupancy in the momentum space. These two trends eventually cancel each other, and the Fermi sphere approaches a stationary (though not a thermal-equilibrium!) state, with the shift (35) relatively to its thermal-equilibrium position.

Now Fig. 4b may be used to answer the question of which of the two different interpretations of the Drude formula is correct, and the answer is: *either*. On one hand, we can look at the electric current as a result of the shift (35) of *all* electrons in the momentum space. On the other hand, each filled quantum state deep inside the sphere gives exactly the same contribution to the net current density as it did without the field. All these internal contributions to the net current cancel each other so that the applied field changes the situation only at the Fermi surface. Thus it is equally legitimate to say that only the surface states are responsible for the non-zero net current.¹⁹

Let me also mention another paradox related to the Drude formula, which is often misunderstood (not only by students :-). As was emphasized above, τ is finite even at *elastic* scattering – that by itself does not change the total energy of the gas. The question is how can such scattering be responsible for the Ohmic resistivity $\rho \equiv 1/\sigma$, and hence for the Joule heat production, with the power density $p = j \cdot \mathcal{E} = \rho j^2$?²⁰ The answer is that the Drude/Sommerfeld formulas describe just the “bottleneck” of the Joule heat formation. In the scattering picture (Fig. 4b) the states filled by elastically scattered electrons are located above the (shifted) Fermi surface, and these electrons eventually need to relax onto it via some inelastic process, which releases their excessive energy in the form of heat (in solid state, described by phonons – see Sec. 2.6). The rate and other features of these inelastic phenomena do not participate in the Drude formula directly, but for keeping the theory valid (in particular, keeping the probability distribution w close to its equilibrium value w_0), their intensity has to be sufficient to avoid gas overheating by the applied field. In some poorly conducting materials, charge carrier overheating effects, resulting in deviations from the Ohm law, i.e. from the linear relation (28) between j and \mathcal{E} , may be observed already at rather practicable electric fields.

One final comment is that the Sommerfeld theory of the Ohmic conductivity works very well for the electron gas in most conductors. The scheme shown in Fig. 4 helps to understand why: for degenerate Fermi gases the energies of all particles whose scattering contributes to transport properties, are close ($\varepsilon \approx \varepsilon_F$) and prescribing them all the same relaxation time τ is very reasonable. In contrast, in classical gases, with their relatively broad distribution of ε , some results given by the Boltzmann-RTA equation (18) are valid only by the order of magnitude.

6.3. Electrochemical potential and the drift-diffusion equation

Now let us generalize our calculation to the case when the particle transport takes place in the presence of a time-independent spatial gradient of the probability distribution, $\nabla_r w \neq 0$, caused for example by that of the particle concentration $n = N/V$ (and hence, according to Eq. (3.40), of the

¹⁹ So here, as it frequently happens in physics, formulas (or graphical sketches, such as Fig. 4b) give a more clear and unambiguous description of reality than words – the privilege lacked by many “scientific” disciplines, rich with unending, shallow verbal debates. Note also that, as frequently happens in physics, the dual interpretation of σ is expressed by two different but equal integrals (30) and (31), related by the integration-by-parts rule.

²⁰ This formula is probably self-evident, but if you need you may revisit EM Sec. 4.4.

chemical potential μ), while still assuming that temperature T is constant. For this generalization, we should keep the second term on the left-hand side of Eq. (18). If the gradient of w is sufficiently small, we can repeat the arguments of the last section and replace w with w_0 in this term as well. With the applied electric field \mathcal{E} represented as $(-\nabla\phi)$,²¹ where ϕ is the electrostatic potential, Eq. (25) becomes

$$\tilde{w} = \tau \mathbf{v} \cdot \left(\frac{\partial w_0}{\partial \varepsilon} q \nabla \phi - \nabla w_0 \right). \quad (6.36)$$

Since in any of the equilibrium distributions (20), $\langle N(\varepsilon) \rangle$ is a function of ε and μ only in the combination $(\varepsilon - \mu)$, it obeys the following relation:

$$\frac{\partial \langle N(\varepsilon) \rangle}{\partial \mu} = - \frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon}. \quad (6.37)$$

Using this relation, the gradient of $w_0 \propto \langle N(\varepsilon) \rangle$ may be represented as²²

$$\nabla w_0 = - \frac{\partial w_0}{\partial \varepsilon} \nabla \mu, \quad \text{for } T = \text{const}, \quad (6.38)$$

so that Eq. (36) becomes

$$\tilde{w} = \tau \frac{\partial w_0}{\partial \varepsilon} \mathbf{v} \cdot (q \nabla \phi + \nabla \mu) \equiv \tau \frac{\partial w_0}{\partial \varepsilon} \mathbf{v} \cdot \nabla \mu', \quad (6.39)$$

where the following sum,

$$\mu' \equiv \mu + q\phi, \quad (6.40)$$

is called the *electrochemical potential*. Now repeating the calculation of the electric current, carried out in the last section, we get the following generalization of the Ohm law (28):

$$\mathbf{j} = \sigma(-\nabla \mu' / q) \equiv \sigma \mathcal{E}, \quad (6.41)$$

where the *effective electric field* \mathcal{E} is proportional to the gradient of the electrochemical potential, rather than the electrostatic potential:

$$\mathcal{E} \equiv -\frac{\nabla \mu'}{q} = \mathcal{E} - \frac{\nabla \mu}{q}. \quad (6.42)$$

The physics of this extremely important and general result²³ may be explained in two ways. First, let us have a look at the energy spectrum of a degenerate Fermi-gas confined in a volume of finite size, but otherwise free. To ensure such a confinement we need a piecewise-constant potential $U(\mathbf{r})$ – a “hard-wall, flat-bottom potential well” – see Fig. 5a. (For conduction electrons in a metal, such profile is

²¹ Since we will not encounter ∇_p in the balance of this chapter, from this point on, the subscript r of the operator ∇_r is dropped for the notation brevity.

²² Since we consider w_0 as a function of two *independent* arguments \mathbf{r} and \mathbf{p} , taking its gradient, i.e. the differentiation of this function over \mathbf{r} , does not involve its differentiation over the kinetic energy ε – which is a function of \mathbf{p} only.

²³ Note that Eq. (42) does not include the phenomenological parameter τ of the relaxation-time approximation, signaling that it is much more general than the RTA. Indeed, this equality is based entirely on the relation between the second and third terms on the left-hand side of the general Boltzmann equation (10), rather than on any details of the scattering integral on its right-hand side.

provided by the positively charged ions of the crystal lattice.) The well should be of a sufficient depth $U_0 > \varepsilon_F \equiv \mu|_{T=0}$ to provide the confinement of the overwhelming majority of the particles, with energies below and somewhat above the Fermi level ε_F . This means that there should be a substantial energy gap,

$$\psi \equiv U_0 - \mu \gg T, \quad (6.43)$$

between the Fermi energy of a particle inside the well, and its potential energy U_0 outside the well. (The latter value of energy is usually called the *vacuum level*.) The difference defined by Eq. (43) is called the *workfunction*,²⁴ for most metals, it is between 4 and 5 eV, so that the relation $\psi \gg T$ is well fulfilled for room temperatures ($T \sim 0.025$ eV) – and actually for all temperatures up to the metal’s evaporation point.

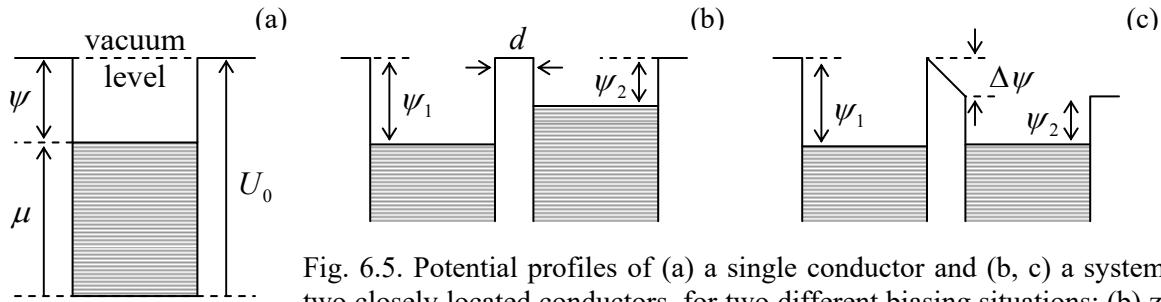

Fig. 6.5. Potential profiles of (a) a single conductor and (b, c) a system of two closely located conductors, for two different biasing situations: (b) zero electrostatic field (the “flat-band condition”), and (c) zero voltage $\Delta\mu'$.

Now let us consider two conductors, with different values of ψ , separated by a small spatial gap d – see Figs. 5b,c. Panel (b) shows the case when the electric field $\mathcal{E} = -\nabla\phi$ in the free-space gap between the conductors equals zero, i.e. their *electrostatic* potentials ϕ are equal.²⁵ If there is an opportunity for particles to cross the gap (e.g., by either the thermally-activated hopping *over* the potential barrier, discussed in Secs. 5.6-5.7, or the quantum-mechanical tunneling *through* it), there will be an average flow of particles from the conductor with the higher Fermi level to that with the lower Fermi level,²⁶ because the chemical equilibrium requires their equality – see Secs. 1.5 and 2.7. If the particles have an electric charge (as electrons do), the equilibrium will be automatically achieved by them recharging the effective capacitor formed by the conductors, until the electrostatic energy difference $q\Delta\phi$ reaches the value reproducing that of the workfunctions (Fig. 5c). So for the equilibrium potential difference²⁷ we may write

$$q\Delta\phi = \Delta\psi = -\Delta\mu. \quad (6.44)$$

At this equilibrium, the electric field in the gap between the conductors is

²⁴ Sometimes it is also called the “electron affinity”, though this term is mostly used for atoms and molecules.

²⁵ In semiconductor physics and engineering, the situation shown in Fig. 5b is called the *flat-band condition*, because any electric field applied normally to a surface of a semiconductor leads to the so-called energy *band bending* – see the next section.

²⁶ As measured from a common reference value, for example from the vacuum level – rather than from the bottom of an individual potential well as in Fig. 5a.

²⁷ In physics literature, it is usually called the *contact potential difference*, while in electrochemistry (for which it is one of the key notions), the term *Volta potential* is more common.

$$\mathcal{E} \equiv -\frac{\Delta\phi}{d} \mathbf{n} = \frac{\Delta\mu}{qd} \mathbf{n} = \frac{\nabla\mu}{q}; \quad (6.45)$$

in Fig. 5c this field is clearly visible as the tilt of the electric potential profile. Comparing Eq. (45) with the definition (42) of the effective electric field \mathcal{E} , we see that the equilibrium, i.e. the absence of current through the potential barrier, is achieved exactly when $\mathcal{E} = 0$, in accordance with Eq. (41).

The electric field dichotomy, $\mathcal{E} \leftrightarrow \mathcal{E}$, raises a natural question: which of these fields we are speaking about in the everyday and laboratory practice? Upon some contemplation, the reader should agree that most of our electric field measurements are done indirectly, by measuring corresponding voltages – with voltmeters. A vast majority of these instruments belong to the so-called *electrodynamic* variety, which is based on the measurement of a small current flowing through the voltmeter.²⁸ As Eq. (41) shows, such electrodynamic voltmeters measure the *electrochemical* potential difference $\Delta\mu'/q$. However, there exists a rare breed of *electrostatic* voltmeters (also called “electrometers”) that measure the *electrostatic* potential difference $\Delta\phi$ between two conductors. One way to implement such an instrument is to use an ordinary, electrodynamic voltmeter, but with the reference point set at the flat-band condition (Fig. 5b) between the conductors. (This condition may be detected by vanishing electric charge on the adjacent surfaces of the conductors, and hence by the absence of its modulation in time if the distance between the surfaces is periodically modulated.)

Now let me return to Eq. (41) and make two very important remarks. First, it says that in the presence of an electric field, the current vanishes only if $\nabla\mu' = 0$, i.e. that the electrochemical potential μ' , rather than the chemical potential μ , has to be position-independent in a system in thermodynamic (thermal, chemical, and electric) equilibrium of a conducting system. This result by no means contradicts the fundamental thermodynamic relations for μ discussed in Sec. 1.5, or the statistical relations involving μ , which were discussed in Sec. 2.7 and beyond. Indeed, according to Eq. (40), $\mu'(\mathbf{r})$ is “merely” the chemical potential referred to the local value of the electrostatic energy $q\phi(\mathbf{r})$, and in all previous parts of the course, this energy was assumed to be constant through the system.

Second, note another interpretation of Eq. (41), which may be achieved by modifying Eq. (38) for the particular case of the classical gas. Indeed, the local density $n \equiv N/V$ of the gas obeys Eq. (3.32), which may be rewritten as

$$n(\mathbf{r}) = \text{const} \times \exp\left\{\frac{\mu(\mathbf{r})}{T}\right\}. \quad (6.46)$$

Taking the spatial gradient of both sides of this relation (still at constant T), we get

$$\nabla n = \text{const} \times \frac{1}{T} \exp\left\{\frac{\mu}{T}\right\} \nabla \mu = \frac{n}{T} \nabla \mu, \quad (6.47)$$

so that $\nabla\mu = (T/n)\nabla n$, and Eq. (41), with σ given by Eq. (32), may be recast as

$$\mathbf{j} = \sigma \left(-\frac{\nabla\mu'}{q} \right) \equiv \frac{q^2\tau}{m} n \left(-\nabla\phi - \frac{1}{q} \nabla\mu \right) \equiv q \frac{\tau}{m} (nq\mathcal{E} - T\nabla n). \quad (6.48)$$

²⁸ The devices for such measurement may be based on the interaction between the measured current and a permanent magnet, as pioneered by A.-M. Ampère in the 1820s – see, e.g., EM Chapter 5. Such devices are sometimes called *galvanometers*, honoring another pioneer of electricity, Luigi Galvani.

Hence the current density may be viewed as consisting of two independent parts: one due to particle *drift* induced by the “usual” electric field $\mathcal{E} = -\nabla\phi$, and another due to their *diffusion* – see Eq. (5.118) and its discussion. This is exactly the physics of the “mysterious” term $\nabla\mu$ in Eq. (42), though its simple form (48) is valid only in the classical limit.

Besides being very useful for applications, Eq. (48) also gives us a pleasant surprise. Namely, plugging it into the continuity equation for electric charge,²⁹

$$\frac{\partial(qn)}{\partial t} + \nabla \cdot \mathbf{j} = 0, \quad (6.49)$$

we get (after the division of all terms by $q\tau/m$) the so-called *drift-diffusion equation*:³⁰

$$\frac{m}{\tau} \frac{\partial n}{\partial t} = \nabla(n\nabla U) + T\nabla^2 n, \quad \text{with } U \equiv q\phi. \quad (6.50)$$

Drift-diffusion equation

Comparing it with Eq. (5.122), we see that the drift-diffusion equation is identical to the Smoluchowski equation,³¹ provided that we parallel the ratio τ/m with the mobility $\mu_m = 1/\eta$ of the Brownian particle. Now using the Einstein relation (5.78), we see that the effective diffusion constant D of the classical gas of similar particles is

$$D = \frac{\tau T}{m}. \quad (6.51a)$$

This important relation is more frequently represented in either of two other forms. First, since the rare scattering events we are considering do not change the statistics of the gas in thermal equilibrium, we may still use the Maxwell-distribution result (3.9) for the average-square velocity $\langle v^2 \rangle$, to recast Eq. (51a) as

$$D = \frac{1}{3} \langle v^2 \rangle \tau. \quad (6.51b)$$

One more popular form of the same relation uses the notion of the *mean free path* l , which may be defined as the average distance passed by the particle between two sequential scattering events:

$$D = \frac{1}{3} l \langle v^2 \rangle^{1/2}, \quad \text{with } l \equiv \langle v^2 \rangle^{1/2} \tau. \quad (6.51c)$$

In the forms (51b)-(51c), the result for D makes more physical sense, because it may be readily derived (admittedly, with some uncertainty of the numerical coefficient) from simple kinematic arguments – the task left for the reader’s exercise. Note that since the definition of τ in Eq. (17) is phenomenological, so is the above definition of l ; this is why several definitions of this parameter, which may differ by a numerical factor of the order of 1, are possible.

Note also that using Eq. (51a), Eq. (48) may be rewritten as an expression for the *particle flow density* $\mathbf{j}_n \equiv n\mathbf{j}_w = \mathbf{j}/q$:

$$\mathbf{j}_n = n\mu_m q \mathcal{E} - D \nabla n, \quad (6.52)$$

²⁹ If this relation is not evident, please revisit EM Sec. 4.1.

³⁰ Sometimes this term is associated with Eq. (52). One may also run into the term “convection-diffusion equation” for Eq. (50) with the replacement (51a).

³¹ And hence, at negligible ∇U , identical to the diffusion equation (5.116).

with the first term on the right-hand side describing particles' drift, while the second one, their diffusion. I will discuss the application of this equation to the most important case of non-degenerate ("quasiclassical") gases of electrons and holes in semiconductors, in the next section.

To complete this section, let me emphasize again that the mathematically similar drift-diffusion equation (50) and the Smoluchowski equation (5.122) describe different physical situations. Indeed, our (or rather Einstein and Smoluchowski's :-) treatment of the Brownian motion in Chapter 5 was based on a strong hierarchy of the system, consisting of a large "Brownian particle" in an environment of many smaller particles – "molecules". On the other hand, in this chapter we are considering a gas of similar particles. Nevertheless, the equations describing the dynamics of their probability distribution, are the same – at least within the framework of the Boltzmann transport equation with the relaxation-time approximation (17) of the scattering integral. The origin of this similarity is the fact that Eq. (12) is clearly applicable to a Brownian particle as well, with each "scattering" event being the particle's hit by a random molecule of its environment. Since, due to the mass hierarchy, the particle momentum change at each such event is very small, the scattering integral has to be local, i.e. depend only on w at the same momentum \mathbf{p} as the left-hand side of the Boltzmann equation, so that the relaxation time approximation (17) is absolutely natural – indeed, more natural than for our current case of similar particles.

6.4. Charge carriers in semiconductors

Now let me demonstrate the application of the concepts discussed in the last section to understanding the basic kinetic properties of semiconductors and a few key semiconductor structures – which are the basis of most modern electronic and optoelectronic devices, and hence of all our IT civilization. For that, I will need to take a detour to discuss their equilibrium properties first.

I will use an approximate but reasonable picture in which the energy of the electron subsystem in a solid may be partitioned into the sum of effective energies ε of independent electrons. Quantum mechanics says³² that in such periodic structures as crystals, the stationary state energy ε of a particle interacting with the atomic lattice follows one of periodic functions $\varepsilon_n(\mathbf{q})$ of the *quasimomentum* \mathbf{q} , oscillating between two extreme values $\varepsilon_{n\text{min}}$ and $\varepsilon_{n\text{max}}$. These *allowed energy bands* are separated by *bandgaps*, of widths $\Delta_n \equiv \varepsilon_{n\text{min}} - \varepsilon_{n-1\text{max}}$, with no allowed states inside them. Semiconductors and insulators (dielectrics) are defined as such crystals that in equilibrium at $T = 0$, all electron states in several energy bands (with the highest of them called the *valence band*) are completely filled, $\langle N(\varepsilon_v) \rangle = 1$, while those in the upper bands, starting from the lowest, *conduction band*, are completely empty, $\langle N(\varepsilon_c) \rangle = 0$.^{33, 34} Since the electrons follow the Fermi-Dirac statistics (2.115), this means that at $T \rightarrow 0$,

³² See, e.g., QM Sec. 2.7 and 3.4, but the thorough knowledge of this material is not necessary for following discussions of this section. If the reader is not familiar with the notion of quasimomentum (alternatively called the "crystal momentum"), its following semi-quantitative interpretation may be useful: \mathbf{q} is the result of quantum averaging of the genuine electron momentum \mathbf{p} over the crystal lattice period. In contrast to \mathbf{p} , which is not conserved because of the electron's interaction with the atomic lattice, \mathbf{q} is an integral of motion – in the absence of other forces.

³³ This mapping of electrical properties of crystals on their band structure was pioneered in 1931-32 by Alan H. Wilson.

³⁴ In insulators, the bandgap Δ is so large (e.g., ~9 eV in SiO₂) that the conduction band remains unpopulated in all practical situations, so that the following discussion is only relevant for semiconductors, with their moderate bandgaps – such as 1.14 eV in the most important case of silicon at room temperature.

the Fermi energy $\varepsilon_F \equiv \mu(0)$ is located somewhere between the valence band's maximum $\varepsilon_{V\max}$ (usually called simply ε_V), and the conduction band's minimum $\varepsilon_{C\min}$ (called ε_C) – see Fig. 6.

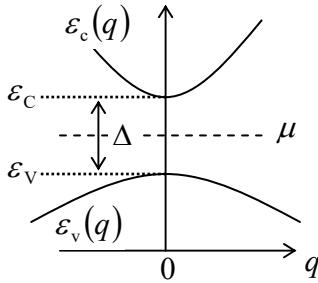

Fig. 6.6. Calculating μ in an intrinsic semiconductor.

Let us calculate the population of both branches $\varepsilon_n(\mathbf{q})$, and the chemical potential μ in equilibrium at $T > 0$. Since the functions $\varepsilon_n(\mathbf{q})$ are typically smooth, near the bandgap edges the dispersion laws $\varepsilon_c(\mathbf{q})$ and $\varepsilon_v(\mathbf{q})$ may be well approximated with quadratic parabolas. For our analysis, let us take the parabolas the simplest, isotropic form, with origins at the same quasimomentum, taking it for the reference point.³⁵

$$\varepsilon = \begin{cases} \varepsilon_C + q^2 / 2m_C, & \text{for } \varepsilon \geq \varepsilon_C, \\ \varepsilon_V - q^2 / 2m_V, & \text{for } \varepsilon \leq \varepsilon_V, \end{cases} \quad \text{with } \varepsilon_C - \varepsilon_V \equiv \Delta. \quad (6.53)$$

The positive constants m_C and m_V are usually called the effective masses of, respectively, electrons and holes. (In a typical semiconductor, m_C is a few times smaller than the free electron mass m_e , while m_V is closer to m_e .)

Due to the similarity between the top line of Eq. (53) and the dispersion law (3.3) of free particles, we may re-use Eq. (3.40), with the appropriate particle mass m , the degeneracy factor g , and the energy origin, to calculate the full spatial density of populated states (in semiconductor physics, called *electrons* in the narrow sense of the word):

$$n \equiv \frac{N_e}{V} = \int_{\varepsilon_C}^{\infty} \langle N(\varepsilon) \rangle g_3(\varepsilon) d\varepsilon \equiv \frac{g_C m_C^{3/2}}{\sqrt{2\pi^2 \hbar^3}} \int_0^{\infty} \langle N(\tilde{\varepsilon} + \varepsilon_C) \rangle \tilde{\varepsilon}^{1/2} d\tilde{\varepsilon}, \quad (6.54)$$

where $\tilde{\varepsilon} \equiv \varepsilon - \varepsilon_C \geq 0$. Similarly, the density p of “no-electron” excitations (called *holes*) in the valence band is the number of *unfilled* states in the band, and hence may be calculated as

$$p \equiv \frac{N_h}{V} = \int_{-\infty}^{\varepsilon_V} [1 - \langle N(\varepsilon) \rangle] g_3(\varepsilon) d\varepsilon \equiv \frac{g_V m_V^{3/2}}{\sqrt{2\pi^2 \hbar^3}} \int_0^{\infty} [1 - \langle N(\varepsilon_V - \tilde{\varepsilon}) \rangle] \tilde{\varepsilon}^{1/2} d\tilde{\varepsilon}, \quad (6.55)$$

where in this case, $\tilde{\varepsilon} \geq 0$ is defined as $(\varepsilon_V - \varepsilon)$. If the electrons and holes³⁶ are in the thermal and chemical equilibrium, the functions $\langle N(\varepsilon) \rangle$ in these two relations should follow the Fermi-Dirac

³⁵ It is easy (and hence is left for the reader's exercise) to verify that all equilibrium properties of charge carriers remain the same (with some effective values of m_C and m_V) if $\varepsilon_c(\mathbf{q})$ and $\varepsilon_v(\mathbf{q})$ are arbitrary quadratic forms of the Cartesian components of the quasimomentum. A mutual displacement of the branches $\varepsilon_c(\mathbf{q})$ and $\varepsilon_v(\mathbf{q})$ in the quasimomentum space is also unimportant for statistical and most transport properties of the semiconductors, though it is very important for their optical properties – which I will not have time to discuss in any detail.

³⁶ The collective name for them in semiconductor physics is *charge carriers* – or just “carriers”.

distribution (2.115) with the same temperature T and the same chemical potential μ . Moreover, in our current case of an undoped (*intrinsic*) semiconductor, these densities have to be equal,

$$n = p \equiv n_i, \quad (6.56)$$

because if this *electroneutrality condition* was violated, the volume would acquire a non-zero electric charge density $\rho = e(p - n)$, which would result, in a bulk sample, in an extremely high electric field energy. From this condition, we get a system of two equations,

$$n_i = \frac{g_C m_C^{3/2}}{\sqrt{2\pi^2 \hbar^3}} \int_0^\infty \frac{\tilde{\varepsilon}^{1/2} d\tilde{\varepsilon}}{\exp\{(\tilde{\varepsilon} + \varepsilon_C - \mu)/T\} + 1} = \frac{g_V m_V^{3/2}}{\sqrt{2\pi^2 \hbar^3}} \int_0^\infty \frac{\tilde{\varepsilon}^{1/2} d\tilde{\varepsilon}}{\exp\{(\tilde{\varepsilon} - \varepsilon_V + \mu)/T\} + 1}, \quad (6.57)$$

whose solution gives both the requested charge carrier density n_i and the Fermi level μ .

For an arbitrary ratio Δ/T , this solution may be found only numerically, but in most practical cases, this ratio is very large. (Again, for Si at room temperature, $\Delta \approx 1.14$ eV, while $T \approx 0.025$ eV.) In this case, we may use the same classical approximation as in Eq. (3.45), to reduce Eqs. (54) and (55) to simple expressions

$$n = n_C \exp\left\{\frac{\mu - \varepsilon_C}{T}\right\}, \quad p = n_V \exp\left\{\frac{\varepsilon_V - \mu}{T}\right\}, \quad \text{for } T \ll \Delta, \quad (6.58)$$

where the temperature-dependent parameters

$$n_C \equiv \frac{g_C}{\hbar^3} \left(\frac{m_C T}{2\pi} \right)^{3/2} \quad \text{and} \quad n_V \equiv \frac{g_V}{\hbar^3} \left(\frac{m_V T}{2\pi} \right)^{3/2} \quad (6.59)$$

may be interpreted as the effective numbers of states (per unit volume) available for occupation in, respectively, the conduction and valence bands, in thermal equilibrium. For usual semiconductors (with $g_C \sim g_V \sim 1$, and $m_C \sim m_V \sim m_e$), at room temperature, these numbers are of the order of $3 \times 10^{25} \text{ m}^{-3} \equiv 3 \times 10^{19} \text{ cm}^{-3}$. (Note that all results based on Eqs. (58) are only valid if both n and p are much lower than, respectively, n_C and n_V .)

With the substitution of Eqs. (58), the system of equations (56) allows a straightforward solution:

$$\mu = \frac{\varepsilon_V + \varepsilon_C}{2} + \frac{T}{2} \left(\ln \frac{g_V}{g_C} + \frac{3}{2} \ln \frac{m_V}{m_C} \right), \quad n_i = (n_C n_V)^{1/2} \exp\left\{-\frac{\Delta}{2T}\right\}. \quad (6.60)$$

Since in all practical materials the logarithms in the first of these expressions are never much larger than 1,³⁷ it shows that the Fermi level in intrinsic semiconductors never deviates substantially from the so-called *midgap value* $(\varepsilon_V + \varepsilon_C)/2$ – see the (schematic) Fig. 6. In the result for n_i , the last (exponential) factor is very small, so that the equilibrium number of charge carriers is much lower than that of the atoms – for the most important case of silicon at room temperature, $n_i \sim 10^{10} \text{ cm}^{-3}$. The exponential temperature dependence of n_i (and hence of the electric conductivity $\sigma \propto n_i$) of intrinsic semiconductors is the basis of several applications, for example simple *germanium resistance thermometers*, efficient in the whole range from $\sim 0.5\text{K}$ to $\sim 100\text{K}$. Another useful application of the same fact is the extraction of

³⁷ Note that in the case of simple electron spin degeneracy ($g_V = g_C = 2$), the first logarithm vanishes altogether. However, in many semiconductors, the degeneracy is factored by the number of similar energy bands (e.g., six similar conduction bands in silicon), and the factor $\ln(g_V/g_C)$ may slightly affect quantitative results.

the bandgap of a semiconductor from the experimental measurement of the temperature dependence of $\sigma \propto n_i$ – frequently, in just two well-separated temperature points.

However, most applications require a much higher concentration of carriers. It may be increased quite dramatically by planting into a semiconductor a relatively small number of slightly different atoms – either *donors* (e.g., phosphorus atoms for Si) or *acceptors* (e.g., boron atoms for Si). Let us analyze the first opportunity, called *n-doping*, using the same simple energy band model (53). If the donor atom is only slightly different from those in the crystal lattice, it may be easily ionized – giving an additional electron to the conduction band, and hence becoming a positive ion. This means that the effective ground state energy ε_D of the additional electrons is just slightly below the conduction band edge ε_C – see Fig. 7a.³⁸

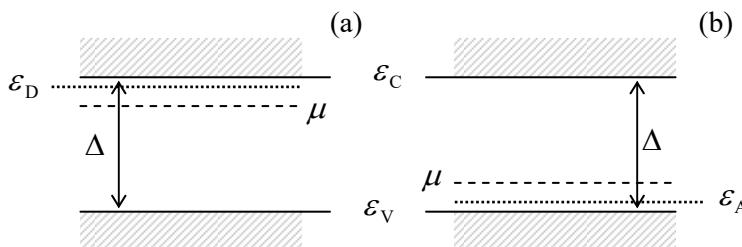

Fig. 6.7. The Fermi levels μ in (a) *n*-doped and (b) *p*-doped semiconductors. Hatching shows the ranges of unlocalized state energies.

Reviewing the arguments that have led us to Eqs. (58), we see that at relatively low doping, when the strong inequalities $n \ll n_C$ and $p \ll n_V$ still hold, these relations are not affected by the doping, so that the concentrations of electrons and holes given by these equalities still obey a universal (doping-independent) relation following from Eqs. (58) and (60):³⁹

$$np = n_i^2. \quad (6.61)$$

However, for a doped semiconductor, the electroneutrality condition looks differently from Eq. (56), because the total density of positive charges in a unit volume is not p , but rather $(p + n_+)$, where n_+ is the density of positively-ionized (“activated”) donor atoms, so that the electroneutrality condition becomes

$$n = p + n_+. \quad (6.62)$$

If virtually all dopants are activated, as it is in most practical cases,⁴⁰ then we may take $n_+ = n_D$, where n_D is the total concentration of donor atoms, i.e. their number per unit volume, and Eq. (62) becomes

$$n = p + n_D. \quad (6.63)$$

Plugging in the expression $p = n_i^2/n$, following from Eq. (61), we get a simple quadratic equation for n , with the following physically acceptable (positive) solution:

³⁸ Note that in comparison with Fig. 6, here the (for most purposes, redundant) information on the q -dependence of the energies is collapsed, leaving the horizontal axis of such a *band-edge diagram* free for showing their possible spatial dependences – see Figs. 8, 10, and 11 below.

³⁹ Very similar relations may be met in the theory of chemical reactions (where it is called the *law of mass action*), and other disciplines – including such exotic examples as the theoretical ecology.

⁴⁰ Let me leave it for the reader’s exercise to prove that this assumption is always valid unless the doping density n_D becomes comparable to n_C , and as a result, the Fermi energy μ moves into a $\sim T$ -wide vicinity of ε_D .

$$n = \frac{n_D}{2} + \left(\frac{n_D^2}{4} + n_i^2 \right)^{1/2}. \quad (6.64)$$

This result shows that the doping affects n (and hence $\mu = \varepsilon_C - T \ln(n_C/n)$ and $p = n_i^2/n$) only if the dopant concentration n_D is comparable with, or higher than the intrinsic carrier density n_i given by Eq. (60). For most applications, n_D is made *much* higher than n_i ; in this case Eq. (64) yields

$$n \approx n_D \gg n_i, \quad p = \frac{n_i^2}{n} \approx \frac{n_i^2}{n_D} \ll n, \quad \mu \approx \mu_p \equiv \varepsilon_C - T \ln \frac{n_C}{n_D}. \quad (6.65)$$

Because of the reasons to be discussed very soon, modern electron devices require doping densities above 10^{18} cm^{-3} , so that the logarithm in Eq. (65) is not much larger than 1. This means that the Fermi level rises from the midgap to a position only slightly below the conduction band edge ε_C – see Fig. 7a.

The opposite case of purely *p*-doping, with n_A acceptor atoms per unit volume, and a small activation (negative ionization) energy $\varepsilon_A - \varepsilon_V \ll \Delta$,⁴¹ may be considered absolutely similarly, using the electroneutrality condition in the form

$$n + n_- = p, \quad (6.66)$$

where n_- is the number of activated (and hence negatively charged) acceptors. For the relatively high concentration ($n_i \ll n_A \ll n_V$), virtually all acceptors are activated, so that $n_- \approx n_A$, Eq. (66) may be approximated as $n + n_A = p$, and the analysis gives the results dual to Eq. (65):

$$p \approx n_A \gg n_i, \quad n = \frac{n_i^2}{p} \approx \frac{n_i^2}{n_A} \ll p, \quad \mu \approx \mu_n \equiv \varepsilon_V + T \ln \frac{n_V}{n_A}, \quad (6.67)$$

so that in this case, the Fermi level is just slightly above the valence band edge (Fig. 7b), and the number of holes far exceeds that of electrons – again, in the narrow sense of the word. Let me leave the analysis of the simultaneous *n*- and *p*-doping (which enables, in particular, so-called *compensated semiconductors* with the sign-variable difference $n - p \approx n_D - n_A$) for the reader's exercise.

Now let us consider how a sample of a doped semiconductor (say, a *p*-doped one) responds to a static external electrostatic field \mathcal{E} applied normally to its surface.⁴² (In semiconductor integrated circuits, such field is usually created by the voltage applied to a special highly-conducting *gate electrode* separated from the semiconductor surface by a thin insulating layer.) Assuming that the field penetrates into the sample by a distance λ much larger than the crystal lattice period a (the assumption to be verified *a posteriori*), we may calculate the distribution of the electrostatic potential ϕ using the macroscopic version of the Poisson equation.⁴³ Assuming that the semiconductor occupies the semi-space $x > 0$ and that $\mathcal{E} = \mathbf{n}_x \mathcal{E}$, the equation reduces to the following 1D form⁴⁴

⁴¹ For the typical donors (P) and acceptors (B) in silicon, both ionization energies, $(\varepsilon_C - \varepsilon_D)$ and $(\varepsilon_A - \varepsilon_V)$, are close to 45 meV, i.e. are indeed much smaller than $\Delta \approx 1.14 \text{ eV}$.

⁴² A simplified version of this analysis was discussed in EM Sec. 2.1.

⁴³ See, e.g., EM Sec. 3.4.

⁴⁴ I am sorry for using, for the SI electric constant ε_0 , the same Greek letter as for single-particle energies, but both notations are traditional, and the difference between these uses will be clear from the context.

$$\frac{d^2\phi}{dx^2} = -\frac{\rho(x)}{\kappa\epsilon_0}. \quad (6.68)$$

Here κ is the dielectric constant of the semiconductor matrix – excluding the dopants and charge carriers, which in this approach are treated as explicit (“stand-alone”) charges, with the volumic density

$$\rho = e(p - n_- - n). \quad (6.69)$$

(As a sanity check, Eqs. (68)-(69) show that if $\mathcal{E} \equiv -d\phi/dx = 0$, then $\rho = 0$, bringing us back to the electroneutrality condition (66), and hence the “flat” band-edge diagrams shown in Figs. 7b and 8a.)

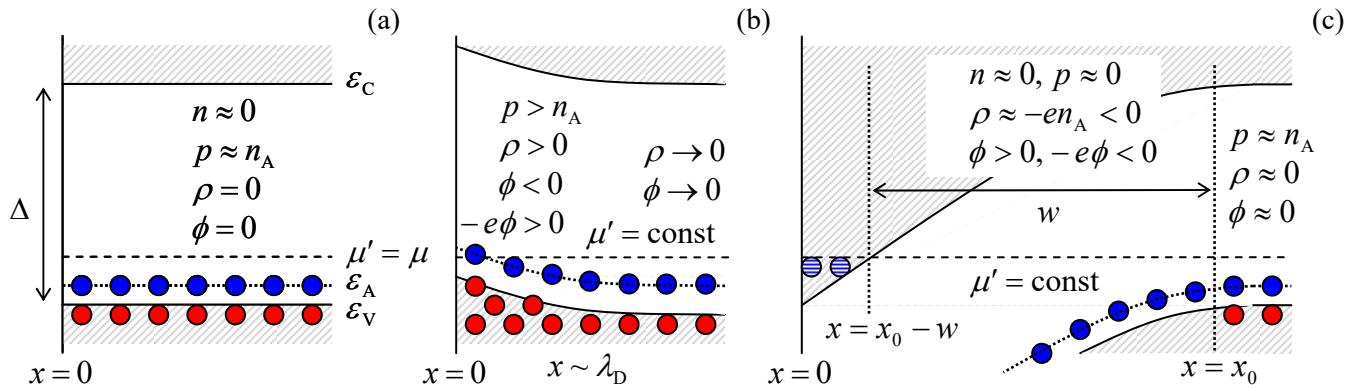

Fig. 6.8. The band-edge diagrams of the electric field penetration into a uniform p -doped semiconductor: (a) $\mathcal{E} = 0$, (b) $\mathcal{E} < 0$, and (c) $\mathcal{E} > \mathcal{E}_c > 0$. Solid red points depict positive charges; solid blue points, negative charges; and hatched blue points, possible electrons in the inversion layer – all very schematically.

In order to get a closed system of equations for the case $\mathcal{E} \neq 0$, we should take into account that the electrostatic potential $\phi \neq 0$, penetrating into the sample with the field,⁴⁵ adds the potential component $q\phi(x) = -e\phi(x)$ to the energy of each electron, and hence shifts the whole local system of single-electron energy levels “vertically” by this amount – down for $\phi > 0$, and up for $\phi < 0$. As a result, the field penetration leads to what is called *band bending* – see the band-edge diagrams schematically shown in Figs. 8b,c for two possible polarities of the applied field, which affects the distribution $\phi(x)$ via the boundary condition⁴⁶

$$\frac{d\phi}{dx}(0) = -\mathcal{E}. \quad (6.70)$$

Note that the electrochemical potential μ' (which, in accordance with the discussion in Sec. 3, replaces the chemical potential in presence of the electric field),⁴⁷ has to stay constant through the system in equilibrium, keeping the electric current equal to zero – see Eq. (41). For arbitrary doping parameters, the system of equations (58) (with the replacements $\epsilon_V \rightarrow \epsilon_V - e\phi$, and $\mu \rightarrow \mu'$) and (68)-(70), plus the

⁴⁵ It is common (though not necessary) to select the energy reference so that deep inside the semiconductor, $\phi = 0$; in what follows I will use this convention.

⁴⁶ Here \mathcal{E} is the field *just inside* the semiconductor. The free-space field necessary to create it is κ times larger – see, e.g., the same EM Sec. 3.4, in particular Eq. (3.56).

⁴⁷ In semiconductor physics literature, the value of μ' is usually called the *Fermi level*, even in the absence of the degenerate Fermi sea typical for metals – cf. Sec. 3.3. In this section, I will follow this common terminology.

relation between n_- and n_A (describing the acceptor activation), does not allow an analytical solution. However, as was discussed above, in the most practical cases $n_A \gg n_i$, we may use the approximate relations $n_- \approx n_A$ and $n \approx 0$ at virtually any values of μ' within the locally shifted bandgap [$\varepsilon_V - e\phi(x)$, $\varepsilon_C - e\phi(x)$], so that the substitution of these relations, and the second of Eqs. (58), with the mentioned replacements, into Eq. (69) yields

$$\rho \approx en_V \exp\left\{\frac{\varepsilon_V - e\phi - \mu'}{T}\right\} - en_A = en_A \left[\left(\frac{n_V}{n_A} \exp\left\{\frac{\varepsilon_V - \mu'}{T}\right\} \right) \exp\left\{-\frac{e\phi}{T}\right\} - 1 \right]. \quad (6.71)$$

The x -independent electrochemical potential (a.k.a. Fermi level) μ' in this relation should be equal to the value of the chemical potential $\mu(x \rightarrow \infty)$ in the semiconductor's bulk, given by the last of Eqs. (67), which turns the expression in the parentheses into 1. With these substitutions, Eq. (68) becomes

$$\frac{d^2\phi}{dx^2} = -\frac{en_A}{\kappa\varepsilon_0} \left[\exp\left\{-\frac{e\phi}{T}\right\} - 1 \right], \quad \text{for } \varepsilon_V - e\phi(x) < \mu' < \varepsilon_C - e\phi(x). \quad (6.72)$$

This nonlinear differential equation may be solved analytically, but in order to avoid a distraction by this (rather bulky) solution, let me first consider the case when the electrostatic potential is sufficiently small – either because the external field is small, or because we focus on the distances sufficiently far from the surface – see Fig. 8 again. In this case, in the Taylor expansion of the exponent in Eq. (72), with respect to small ϕ , we may keep only two leading terms, turning it into a linear equation:

$$\frac{d^2\phi}{dx^2} = \frac{e^2 n_A}{\kappa\varepsilon_0 T} \phi, \quad \text{i.e. } \frac{d^2\phi}{dx^2} = \frac{\phi}{\lambda_D^2}, \quad \text{where } \lambda_D \equiv \left(\frac{\kappa\varepsilon_0 T}{e^2 n_A} \right)^{1/2}, \quad (6.73)$$

with the well-known exponential solution, satisfying also the boundary condition $\phi \rightarrow 0$ at $x \rightarrow \infty$:

$$\phi = C \exp\left\{-\frac{x}{\lambda_D}\right\}, \quad \text{at } e|\phi| \ll T. \quad (6.74)$$

The constant λ_D given by the last of Eqs. (73) is called the *Debye screening length*. It may be rather substantial; for example, at $T_K = 300K$, even for the relatively high doping, $n_A \approx 10^{18} \text{ cm}^{-3}$ typical for modern silicon ($\kappa \approx 12$) integrated circuits, it is close to 4 nm – still much larger than the crystal lattice constant $a \sim 0.3$ nm, so that the above analysis is indeed quantitatively valid. Note also that λ_D does not depend on the charge's sign; hence it should be no large surprise that repeating our analysis for an n -doped semiconductor, we may find out that Eqs. (73)-(74) are valid for that case as well, with the only replacement $n_A \rightarrow n_D$.

If the applied field \mathcal{E} is weak, Eq. (74) is valid in the whole sample, and the constant C in it may be readily calculated using the boundary condition (70), giving

$$\phi|_{x=0} \equiv C = \lambda_D \mathcal{E} \equiv \left(\frac{\kappa\varepsilon_0 T}{e^2 n_A} \right)^{1/2} \mathcal{E}. \quad (6.75)$$

This formula allows us to express the condition of validity of the linear approximation leading to Eq. (74), $e|\phi| \ll T$, in terms of the applied field:

$$|\mathcal{E}| \ll \mathcal{E}_{\max}, \quad \text{with } \mathcal{E}_{\max} \equiv \frac{T}{e\lambda_D} \equiv \left(\frac{Tn_A}{\kappa\epsilon_0} \right)^{1/2}; \quad (6.76)$$

in the above example, $\mathcal{E}_{\max} \sim 60 \text{ kV/cm}$. On the lab scale, such field is not low at all (it is twice higher than the threshold of electric breakdown in the air at ambient conditions), but may be sustained by many solid-state materials that are much less prone to the breakdown.⁴⁸ This is why we should be interested in what happens if the applied field is higher than this value.

The semi-quantitative answer is relatively simple if the field is directed out of the *p*-doped semiconductor (in our nomenclature, $\mathcal{E} < 0$ – see Fig. 8b). As the valence band bends up by a few T , the local hole concentration $p(x)$, and hence the charge density $\rho(x)$, grow exponentially – see Eq. (71). Hence the effective local length of the nonlinear field's penetration, $\lambda_{\text{ef}}(x) \propto \rho^{-1/2}(x)$, shrinks exponentially. A detailed analysis of this effect using Eq. (72) does not make much sense, because as soon as $\lambda_{\text{ef}}(0)$ decreases to $\sim a$, the macroscopic Poisson equation (68) is no longer valid quantitatively. For typical semiconductors, this happens at the field that raises the edge $\epsilon_V - e\phi(0)$ of the bent valence band at the sample's surface above the Fermi level μ' . In this case, the valence-band electrons near the surface form a degenerate Fermi gas, with an “open” Fermi surface – essentially a metal, which a very small (atomic-size) *Thomas-Fermi screening length*:⁴⁹

$$\lambda_{\text{ef}}(0) \sim \lambda_{\text{TF}} \equiv \left[\frac{\kappa\epsilon_0}{e^2 g_3(\epsilon_F)} \right]^{1/2}. \quad (6.77)$$

The effects taking place at the opposite polarity of the field, $\mathcal{E} > 0$, are much more interesting – and more useful for applications. Indeed, in this case, the band bending down leads to an exponential decrease of $\rho(x)$ as soon as the valence band edge $\epsilon_V - e\phi(x)$ drops down by just a few T below its unperturbed value ϵ_V . If the applied field is large enough, $\mathcal{E} > \mathcal{E}_{\max}$ (as it is in the situation shown in Fig. 8c), it forms, on the left of such point x_0 the so-called *depletion layer*, of a certain width w . Within this layer, not only the electron density n , but the hole density p as well, are negligible, so that the only substantial contribution to the charge density ρ is given by the fully ionized acceptors: $\rho \approx -en_- \approx -en_A$, and Eq. (72) becomes very simple:

$$\frac{d^2\phi}{dx^2} = \frac{en_A}{\kappa\epsilon_0} = \text{const}, \quad \text{for } x_0 - w < x < x_0. \quad (6.78)$$

Let us use this equation to calculate the largest possible width w of the depletion layer, and the critical value, \mathcal{E}_c , of the applied field necessary for this. (By definition, at $\mathcal{E} = \mathcal{E}_c$, the left boundary of the layer, where $\epsilon_V - e\phi(x) = \epsilon_c$, i.e. $e\phi(x) = \epsilon_V - \epsilon_A \equiv \Delta$, just touches the semiconductor surface: $x_0 - w = 0$, i.e. $x_0 = w$. (Figure 8c shows the case when \mathcal{E} is slightly larger than \mathcal{E}_c .) For this, Eq. (78) has to be solved with the following boundary conditions:

$$\phi(0) = \frac{\Delta}{e}, \quad \frac{d\phi}{dx}(0) = -\mathcal{E}_c, \quad \phi(w) = 0, \quad \frac{d\phi}{dx}(w) = 0. \quad (6.79)$$

⁴⁸ Even some amorphous thin-film insulators, such as properly grown silicon and aluminum oxides, can withstand fields up to $\sim 10 \text{ MV/cm}$.

⁴⁹ As a reminder, the derivation of this formula was the task of Problem 3.14.

Note that the first of these conditions is strictly valid only if $T \ll \Delta$, i.e. at the assumption we have made from the very beginning, while the last two conditions are asymptotically correct only if $\lambda_D \ll w$ – the assumption we should not forget to check after the solution.

After all the undergraduate experience with projectile motion problems, the reader certainly knows by heart that the solution of Eq. (78) is a quadratic parabola, so that let me immediately write its final form satisfying the boundary conditions (79):

$$\phi(x) = \frac{en_A}{\kappa\varepsilon_0} \frac{(w-x)^2}{2}, \quad \text{with } w = \left(\frac{2\kappa\varepsilon_0\Delta}{e^2 n_A} \right)^{1/2}, \quad \text{at } \mathcal{E}_c = \frac{2\Delta}{e\varepsilon_0 w}. \quad (6.80)$$

Comparing the result for w with Eq. (73), we see that if our basic condition $T \ll \Delta$ is fulfilled, then $\lambda_D \ll w$, confirming the qualitative validity of the whole solution (80). For the same particular parameters as in the example before ($n_A \approx 10^{18} \text{ cm}^{-3}$, $\kappa \approx 10$), and $\Delta \approx 1 \text{ eV}$, Eqs. (80) give $w \approx 40 \text{ nm}$ and $\mathcal{E}_c \approx 600 \text{ kV/cm}$ – still a practicable field. (As Fig. 8c shows, to create it, we need a gate voltage only slightly larger than Δ/e , i.e. close to 1 V for typical semiconductors.)

Figure 8c also shows that if the applied field exceeds this critical value, near the surface of the semiconductor the conduction band edge drops below the Fermi level. This is the so-called *inversion layer*, in which electrons with energies below μ' form a highly conductive degenerate Fermi gas. However, typical rates of electron tunneling from the bulk through the depletion layer are very low, so that after the inversion layer has been created (say, by the gate voltage application), it may be only populated from another source – hence the hatched blue points in Fig. 8c. This is exactly the fact used in the workhorse device of semiconductor integrated circuits – the *field-effect transistor* (FET) – see Fig. 9.⁵⁰

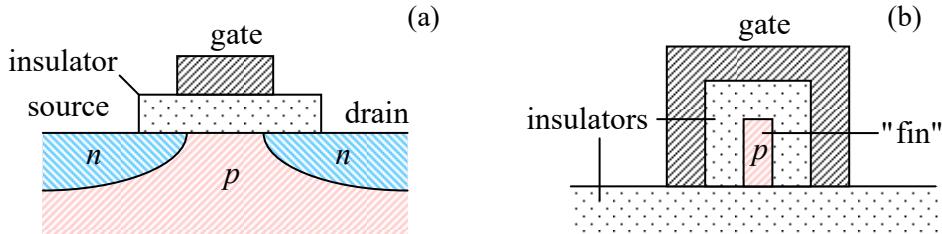

Fig. 6.9. Two main species of the *n*-FET: (a) the *bulk FET*, and (b) the *FinFET*. While on panel (a), the current flow from the source to the drain is parallel to the plane of the drawing, on panel (b) it is normal to the plane, with the *n*-doped source and drain contacting the thin “fin” from two sides off this plane.

In the “bulk” variety of this structure (Fig. 9a), a gate electrode overlaps a gap between two similar highly-*n*-doped regions near the surface, called *source* and *drain*, formed by *n*-doping inside a *p*-doped semiconductor. It is more or less obvious (and will be shown in a moment) that in the absence of gate voltage, the electrons cannot pass through the *p*-doped region, so that virtually no current flows between the source and the drain, even if a modest voltage is applied between these electrodes. However, if the gate voltage is positive and large enough to induce the electric field $\mathcal{E} > \mathcal{E}_c$ at the surface of the *p*-doped semiconductor, it creates the inversion layer as shown in Fig. 8c, and the electron current

⁵⁰ This device was invented (by Julius E. Lilienfeld) in 1930, but demonstrated only in the mid-1950s.

between the source and drain electrodes may readily flow through this *surface channel*. (Very unfortunately, in this course I would not have time/space for a detailed analysis of transport properties of this keystone electron device, and have to refer the reader to special literature.⁵¹⁾

Fig. 9a makes it obvious that another major (and virtually unavoidable) structure of semiconductor integrated circuits is the famous *p-n junction* – an interface between *p*- and *n*-doped regions. Let us analyze its simple model, in which the interface is in the plane $x = 0$, and the doping profiles $n_D(x)$ and $n_A(x)$ are step-like, making an abrupt jump at the interface:

$$n_A(x) = \begin{cases} n_A = \text{const}, & \text{at } x < 0, \\ 0, & \text{at } x > 0, \end{cases} \quad n_D(x) = \begin{cases} 0, & \text{at } x < 0, \\ n_D = \text{const}, & \text{at } x > 0. \end{cases} \quad (6.81)$$

(This model is very reasonable for modern integrated circuits, where the doping is performed by *implantation*, using high-energy ion beams.)

To start with, let us assume that no voltage is applied between the *p*- and *n*-regions, so that the system may be in thermodynamic equilibrium. In the equilibrium, the Fermi level μ' should be flat through the structure, and at $x \rightarrow -\infty$ and $x \rightarrow +\infty$, where $\phi \rightarrow 0$, the level structure has to approach the positions shown, respectively, on panels (a) and (b) of Fig. 7. In addition, the distribution of the electric potential $\phi(x)$, shifting the level structure vertically by $-e\phi(x)$, has to be continuous to avoid unphysical infinite electric fields. With that, we inevitably arrive at the band-edge diagram that is (schematically) shown in Fig. 10.

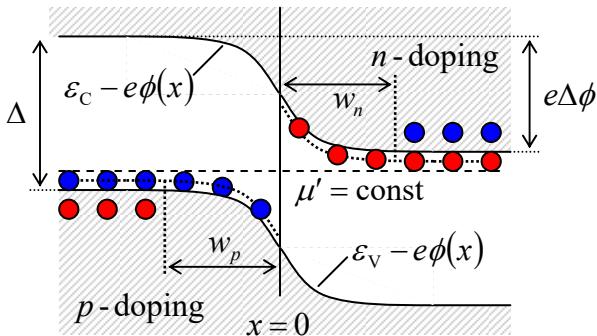

Fig. 6.10. The band-edge diagram of a *p-n* junction in thermodynamic equilibrium ($T = \text{const}$, $\mu' = \text{const}$). The notation is the same as in Figs. 7 and 8.

The diagram shows that the contact of differently doped semiconductors gives rise to a built-in electric potential difference $\Delta\phi$, equal to the difference of their values of μ in the absence of the contact – see Eqs. (65) and (67):

$$e\Delta\phi \equiv e\phi(+\infty) - e\phi(-\infty) = \mu_n - \mu_p = \Delta - T \ln \frac{n_C n_V}{n_D n_A}, \quad (6.82)$$

which is usually just slightly smaller than the bandgap.⁵² (Qualitatively, this is the same contact potential difference that was discussed, for the case of metals, in Sec. 3 – see Fig. 5.) The arising

⁵¹ The classical monograph in this field is S. Sze, *Physics of Semiconductor Devices*, 2nd ed., Wiley 1981. (The 3rd edition, circa 2006, co-authored with K. Ng, is more tilted toward technical details.) I can also recommend a detailed textbook by R. Pierret, *Semiconductor Device Fundamentals*, 2nd ed., Addison Wesley, 1996.

internal electrostatic field $\mathcal{E} = -d\phi/dx$ induces, in both semiconductors, depletion layers similar to that induced by an external field (Fig. 8c). Their widths w_p and w_n may also be calculated similarly, by solving the following boundary problem of electrostatics, mostly similar to that given by Eqs. (78)-(79):

$$\frac{d^2\phi}{dx^2} = \frac{e}{\kappa\epsilon_0} \times \begin{cases} n_A, & \text{for } -w_p < x < 0, \\ (-n_D), & \text{for } 0 < x < +w_n, \end{cases} \quad (6.83)$$

$$\phi(w_n) = \phi(-w_p) + \Delta\phi, \quad \frac{d\phi}{dx}(w_n) = \frac{d\phi}{dx}(-w_p) = 0, \quad \phi(-0) = \phi(+0), \quad \frac{d\phi}{dx}(-0) = \frac{d\phi}{dx}(+0), \quad (6.84)$$

also exact only in the limit $T \ll \Delta$, $n_i \ll n_D, n_A$. Its (easy) solution gives the result similar to Eq. (80):

$$\phi = \text{const} + \begin{cases} en_A(w_p + x)^2 / 2\kappa\epsilon_0, & \text{for } -w_p < x < 0, \\ \Delta\phi - en_D(w_n - x)^2 / 2\kappa\epsilon_0, & \text{for } 0 < x < +w_n, \end{cases} \quad (6.85)$$

with expressions for w_p and w_n giving the following formula for the full depletion layer width:

$$w \equiv w_p + w_n = \left(\frac{2\kappa\epsilon_0 \Delta\phi}{en_{\text{ef}}} \right)^{1/2}, \quad \text{with } n_{\text{ef}} \equiv \frac{n_A n_D}{n_A + n_D}, \quad \text{i.e. } \frac{1}{n_{\text{ef}}} = \frac{1}{n_A} + \frac{1}{n_D}. \quad (6.86)$$

This expression is similar to that given by Eq. (80), so that for typical highly doped semiconductors ($n_{\text{ef}} \sim 10^{18} \text{ cm}^{-3}$) it gives for w a similar estimate of a few tens nm.⁵³ Returning to Fig. 9a, we see that this scale imposes an essential limit on the reduction of bulk FETs (whose scaling down is at the heart of the well-known *Moore's law*),⁵⁴ explaining why such high doping is necessary. In the early 2010s, the problems with implementing even higher doping, plus issues with dissipated power management, have motivated the transition of advanced silicon integrated circuit technology from the bulk FETs to the *FinFET* (also called “double-gate”, or “tri-gate”, or “wrap-around-gate”) variety of these devices, schematically shown in Fig. 9b, despite their essentially 3D structure and hence a more complex fabrication technology. In the FinFETs, the role of *p-n* junctions is reduced, but these structures remain an important feature of semiconductor integrated circuits.

Now let us have a look at the *p-n* junction in equilibrium from the point of view of Eq. (52). In the simple model we are considering now (in particular, at $T \ll \Delta$), this equation is applicable separately to the electron and hole subsystems, because in this model the gases of these charge carriers are classical in all parts of the system, and the *generation-recombination* processes⁵⁵ coupling these subsystems have relatively small rates – see below. Hence, for the electron subsystem, we may rewrite Eq. (52) as

⁵² Frequently, Eq. (82) is also rewritten in the form $e\Delta\phi = T \ln(n_D n_A / n_i^2)$. In the view of the second of Eqs. (60), this equality is formally correct but may be misleading because the intrinsic carrier density n_i is an exponential function of temperature and is physically irrelevant for this particular problem.

⁵³ Note that such w is again much larger than λ_D – the fact that justifies the first two boundary conditions (84).

⁵⁴ Another important limit is quantum-mechanical tunneling through the gate insulator, whose thickness has to be scaled down in parallel with lateral dimensions of a FET, including its channel length.

⁵⁵ In the semiconductor physics lingo, the “carrier generation” event is the thermal excitation of an electron from the valence band to the conduction band, leaving a hole behind, while the reciprocal event of filling such a hole by a conduction-band electron is called the “carrier recombination”.

$$j_n = n\mu_m q\mathcal{E} - D_n \frac{\partial n}{\partial x}, \quad (6.87)$$

where $q = -e$. Let us discuss how each term of the right-hand of this equality depends on the system's parameters. Because of the n -doping at $x > 0$, there are many more electrons in this part of the system. According to the Boltzmann distribution (58), some number of them,

$$n_s \propto \exp\left\{-\frac{e\Delta\phi}{T}\right\}, \quad (6.88)$$

have energies above the conduction band edge in the p -doped part (see Fig. 11a) and try to diffuse into this part through the depletion layer; this diffusion flow of electrons from the n -side to the p -side of the structure (in Fig. 11, from the right to the left) is described by the second term on the right-hand side of Eq. (87). On the other hand, the intrinsic electric field $\mathcal{E} = -\partial\phi/\partial x$ inside the depletion layer, directed as Fig. 11a shows, exerting on the electrons the force $\mathcal{F} = q\mathcal{E} \equiv -e\mathcal{E}$ pushing them in the opposite direction (from p to n), is described by the first, "drift" term on the right-hand side of Eq. (87).⁵⁶

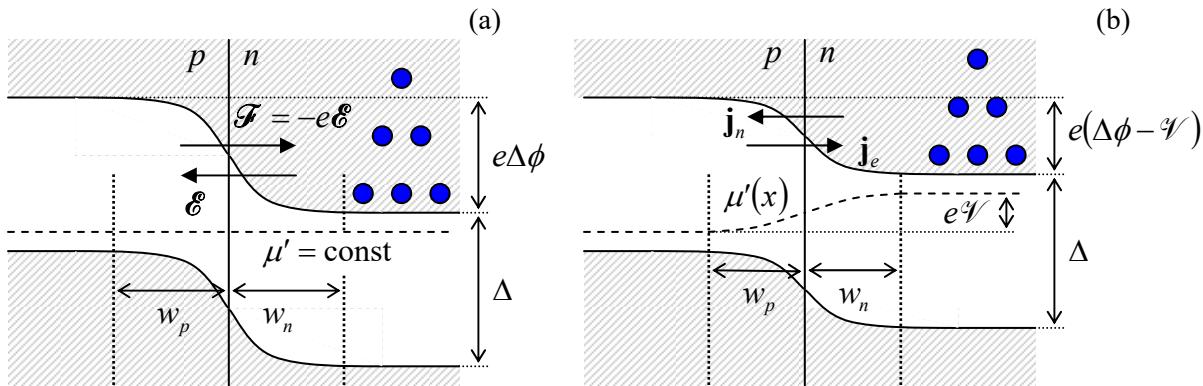

Fig. 6.11. Electrons in the conduction band of a p - n junction at: (a) $V=0$, and (b) $V>0$.

For clarity, other charges (of the holes and all ionized dopant atoms) are not shown.

The explicit calculation of these two flows⁵⁷ shows, unsurprisingly, that in the equilibrium, they are exactly equal and opposite, so that $j_n = 0$, and such analysis does not give us any new information. However, the picture of two electron counter-flows, given by Eq. (87), enables us to predict the functional dependence of j_n on a modest external voltage V , with $|V| < \Delta\phi$, applied to the junction. Indeed, since the doped semiconductor regions outside the depletion layer are much more conductive

⁵⁶ Note that if an external photon with energy $\hbar\omega > \Delta$ generates an electron-hole pair somewhere inside the depletion layer, this electric field immediately drives its electron component to the right, and the hole component to the left, thus generating a pulse of electric current through the junction. This is the physical basis of the whole vast technological field of *photovoltaics*, currently strongly driven by the demand for renewable electric power. Due to the progress of this technology, the cost of solar power systems has dropped from ~\$300 per watt in the mid-1950s to the current ~\$1 per watt, and its global generation has increased to almost 10^{15} watt-hours per year – though this is still below 2% of the whole generated electric power.

⁵⁷ I will not try to reproduce this calculation (which may be found in any of the semiconductor physics books mentioned above), because getting all its scaling factors right requires using some model of the recombination process, and in this course, there is just no time for their quantitative discussion. However, see Eq. (93) below.

than it, virtually all applied voltage (i.e. the difference of values of the electrochemical potential μ') drops across this layer, changing the total band edge shift – see Fig. 11b:⁵⁸

$$e\Delta\phi \rightarrow e\Delta\phi + \Delta\mu' \equiv e\Delta\phi + q\mathcal{V} \equiv e(\Delta\phi - \mathcal{V}). \quad (6.89)$$

This change results in an exponential change of the number of electrons able to diffuse into the *p*-side of the junction – cf. Eq. (88):

$$n_>(\mathcal{V}) \approx n_>(0) \exp\left\{\frac{e\mathcal{V}}{T}\right\}, \quad (6.90)$$

and hence in a proportional change of the diffusion flow j_n of electrons from the *n*-side to the *p*-side of the system, i.e. of the oppositely directed density of the electron current $j_e = -ej_n$ – see Fig. 11b.

On the other hand, the drift counter-flow of electrons is not altered too much by the applied voltage: though it does change the electrostatic field $\mathcal{E} = -\nabla\phi$ inside the depletion layer, and also the depletion layer width,⁵⁹ these changes are incremental, not exponential. As the result, the net density of the current carried by electrons may be approximately expressed as

$$j_e(\mathcal{V}) = j_{\text{diffusion}} - j_{\text{drift}} \approx j_e(0) \exp\left\{\frac{e\mathcal{V}}{T}\right\} - \text{const.} \quad (6.91a)$$

As was discussed above, at $\mathcal{V}=0$, the net current has to vanish, so that the constant in Eq. (91a) has to equal $j_e(0)$, and we may rewrite this equality as

$$j_e(\mathcal{V}) = j_e(0) \left(\exp\left\{\frac{e\mathcal{V}}{T}\right\} - 1 \right). \quad (6.91b)$$

Now repeating this analysis for the current j_h of the holes (the exercise highly recommended to the reader), we get a similar expression, with the *same* sign before $e\mathcal{V}$,⁶⁰ though with a different scaling factor, $j_h(0)$ instead of $j_e(0)$. As a result, the total electric current density obeys the famous *Shockley law*

$$j(\mathcal{V}) \equiv j_e(\mathcal{V}) + j_h(\mathcal{V}) = j(0) \left(\exp\left\{\frac{e\mathcal{V}}{T}\right\} - 1 \right), \quad \text{with } j(0) \equiv j_e(0) + j_h(0), \quad (6.92)$$

describing the main *p-n* junction's property as an *electric diode* – a two-terminal device passing the current more “readily” in one direction (from the *p*- to the *n*-terminal) than in the opposite one.⁶¹

⁵⁸ In our model, the positive sign of $\mathcal{V} \equiv \Delta\mu'/q \equiv -\Delta\mu'/e$ corresponds to the additional electric field, $-\nabla\mu'/q \equiv \nabla\mu'/e$, directed in the positive direction of the *x*-axis (in Fig. 11, from the left to the right), i.e. to the positive terminal of the voltage source connected to the *p*-doped semiconductor – which is the common convention.

⁵⁹ This change, schematically shown in Fig. 11b, may be readily calculated by making the replacement (89) in the first of Eqs. (86).

⁶⁰ This sign invariance may look strange, due to the opposite (positive) electric charge of the holes. However, this difference in the charge sign is compensated by the opposite direction of the hole diffusion – see Fig. 10. (Note also that the actual charge carriers in the valence band are still electrons, and the positive charge of holes is just a convenient representation of the specific dispersion law in this energy band, with a negative effective mass – see Fig. 6, the second line of Eq. (53), and a more detailed discussion of this issue in QM Sec. 2.8.)

Besides numerous practical applications in electrical and electronic engineering, such diodes have very interesting statistical properties, in particular performing very non-trivial transformations of the spectra of deterministic and random signals. Very unfortunately, I would not have time for their discussion and have to refer the interested reader to the special literature.⁶²

Still, before proceeding to our next (and last!) topic, let me give for the reader reference, without proof, the expression for the scaling factor $j(0)$ in Eq. (92), which follows from a simple, but broadly used model of the recombination process:

$$j(0) = en_i^2 \left(\frac{D_e}{l_e n_A} + \frac{D_h}{l_h n_D} \right). \quad (6.93)$$

Here l_e and l_h are the characteristic lengths of diffusion of electrons and holes before their recombination, which may be expressed by Eq. (5.113), $l_e = (2D_e\tau_e)^{1/2}$ and $l_h = (2D_h\tau_h)^{1/2}$, with τ_e and τ_h being the characteristic times of recombination of the so-called *minority carriers* – of electrons in the *p*-doped part, and of holes in the *n*-doped part of the structure. Since the recombination is an inelastic process, its times are typically rather long – of the order of 10^{-7} s, i.e. much longer than the typical times of elastic scattering of the same carriers, that define their diffusion coefficients – see Eq. (51).

6.5. Heat transfer and thermoelectric effects

Now let us return to our analysis of kinetic effects using the Boltzmann-RTA equation, and extend it even further, to the effects of a non-zero (albeit small) temperature gradient. Again, since for any of the statistics (20), the average occupancy $\langle N(\varepsilon) \rangle$ is a function of just one combination of all its arguments, $\xi \equiv (\varepsilon - \mu)/T$, its partial derivatives obey not only Eq. (37), but also the following relation:

$$\frac{\partial \langle N(\varepsilon) \rangle}{\partial T} = -\frac{\varepsilon - \mu}{T^2} \frac{\partial \langle N(\varepsilon) \rangle}{\partial \xi} = \frac{\varepsilon - \mu}{T} \frac{\partial \langle N(\varepsilon) \rangle}{\partial \mu}. \quad (6.94)$$

As a result, Eq. (38) is generalized as

$$\nabla w_0 = -\frac{\partial w_0}{\partial \varepsilon} \left(\nabla \mu + \frac{\varepsilon - \mu}{T} \nabla T \right), \quad (6.95)$$

giving the following generalization of Eq. (39):

$$\tilde{w} = \tau \frac{\partial w_0}{\partial \varepsilon} \mathbf{v} \cdot \left(\nabla \mu' + \frac{\varepsilon - \mu}{T} \nabla T \right). \quad (6.96)$$

Now, calculating current density as in Sec. 3, we get the result that is traditionally represented as

$$\mathbf{j} = \sigma \left(-\frac{\nabla \mu'}{q} \right) + \sigma \mathcal{S}(-\nabla T), \quad (6.97)$$

⁶¹ Some metal-semiconductor junctions, called *Schottky diodes*, have similar rectifying properties (and may be better fitted for high-power applications than silicon *p-n* junctions), but their properties are more complex because of the rather involved chemistry and physics of interfaces between different materials.

⁶² See, e.g., the monograph by R. Strattonovich cited in Sec. 4.2.

where the constant \mathcal{S} , called the *Seebeck coefficient*⁶³ (or the “thermoelectric power”, or just “thermopower”) is given by the following relation:

Seebeck coefficient

$$\sigma \mathcal{S} = \frac{gq\tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \int_0^{\infty} (8m\varepsilon^3)^{1/2} \frac{(\varepsilon - \mu)}{T} \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon. \quad (6.98)$$

Working out this integral for the most important case of a degenerate Fermi gas, with $T \ll \varepsilon_F$, we have to be careful because the center of the sharp peak of the last factor under the integral coincides with the zero point of the previous factor, $(\varepsilon - \mu)/T$. This uncertainty may be resolved using the Sommerfeld expansion formula (3.59). Indeed, for a smooth function $f(\varepsilon)$ obeying Eq. (3.60), so that $f(0) = 0$, we may use Eq. (3.61) to rewrite Eq. (3.59) as

$$\int_0^{\infty} f(\varepsilon) \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon = f(\mu) + \frac{\pi^2 T^2}{6} \frac{d^2 f(\varepsilon)}{d\varepsilon^2} \Big|_{\varepsilon=\mu}. \quad (6.99)$$

In particular, for working out the integral (98), we may take $f(\varepsilon) \equiv (8m\varepsilon^3)^{1/2}(\varepsilon - \mu)/T$. (For this function, the condition $f(0) = 0$ is evidently satisfied.) Then $f(\mu) = 0$, $d^2f/d\varepsilon^2|_{\varepsilon=\mu} = 3(8m\mu)^{1/2}/T \approx 3(8m\varepsilon_F)^{1/2}/T$, and Eq. (98) yields

$$\sigma \mathcal{S} = \frac{gq\tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \frac{\pi^2 T^2}{6} \frac{3(8m\varepsilon_F)^{1/2}}{T}. \quad (6.100)$$

Comparing the result with Eqs. (3.54) and (32), for the constant \mathcal{S} we get a simple expression independent of τ :⁶⁴

$$\mathcal{S} = \frac{\pi^2}{2q} \frac{T}{\varepsilon_F} = \frac{c_V}{q}, \quad \text{for } T \ll \varepsilon_F, \quad (6.101)$$

where $c_V \equiv C_V/N$ is the heat capacity of the gas per unit particle, in this case given by Eq. (3.70).

In order to understand the physical meaning of the Seebeck coefficient, it is sufficient to consider a conductor carrying no current. For this case, Eq. (97) yields

Seebeck effect

$$\nabla(\mu'/q + \mathcal{S}T) = 0. \quad (6.102)$$

So, at these conditions, a temperature gradient creates a proportional gradient of the electrochemical potential μ' , and hence the effective electric field \mathcal{E} defined by Eq. (42). This is the *Seebeck effect*. Figure 12 shows the standard way of its measurement, using an ordinary (electrodynamic) voltmeter that measures the difference of μ'/e at its terminals, and a pair of junctions (in this context, called the *thermocouple*) of two materials with different coefficients \mathcal{S} .

⁶³ Named after Thomas Johann Seebeck who experimentally discovered, in 1822, the effect described by the second term in Eq. (97) – and hence by Eq. (103).

⁶⁴ Again, such independence hints that Eq. (101) has a broader validity than in our simple model of an isotropic gas. This is indeed the case: this result turns out to be valid for any form of the Fermi surface, and for any dispersion law $\alpha(\mathbf{p})$. Note, however, that all calculations of this section are valid for the simplest RTA model in that τ is an energy-independent parameter; for real metals, a more accurate description of experimental results may be obtained by tweaking this model to take this dependence into account – see, e.g., Chapter 13 in the monograph by N. Ashcroft and N. D. Mermin, cited in Sec. 3.5.

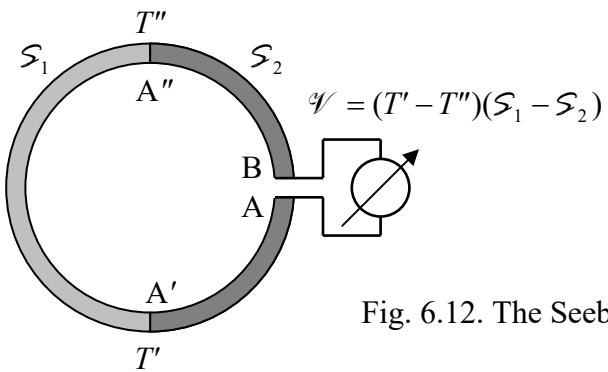

Fig. 6.12. The Seebeck effect in a thermocouple.

Integrating Eq. (102) around the loop from point A to point B , and neglecting the temperature drop across the voltmeter, we get the following simple expression for the thermally-induced difference of the electrochemical potential, usually called either the *thermoelectric power* or the “thermo e.m.f.”:

$$\begin{aligned} \mathcal{V} &\equiv \frac{\mu'_B - \mu'_A}{q} = \frac{1}{q} \int_A^B \nabla \mu' \cdot d\mathbf{r} = - \int_A^B \mathcal{S} \nabla T \cdot d\mathbf{r} = -\mathcal{S}_1 \int_{A'}^{A''} \nabla T \cdot d\mathbf{r} - \mathcal{S}_2 \left(\int_A^{A'} \nabla T \cdot d\mathbf{r} + \int_{A''}^B \nabla T \cdot d\mathbf{r} \right) \\ &= -\mathcal{S}_1(T'' - T') - \mathcal{S}_2(T' - T'') \equiv (\mathcal{S}_1 - \mathcal{S}_2)(T' - T''). \end{aligned} \quad (6.103)$$

(Note that according to Eq. (103), any attempt to measure such voltage across any two points of a *uniform* conductor would give results depending on the voltmeter wire materials, due to an unintentional gradient of temperature in them.)

Using thermocouples is a very popular, inexpensive method of temperature measurement – especially in the few-hundred-°C range where gas- and fluid-based thermometers are not too practicable, if a 1°C-scale accuracy is sufficient. The *temperature responsivity* ($\mathcal{S}_1 - \mathcal{S}_2$) of a typical popular thermocouple, chromel-constantan,⁶⁵ is about 70 $\mu\text{V}/^\circ\text{C}$. To understand why the typical values of \mathcal{S} are so small, let us discuss the Seebeck effect’s physics. Superficially, it is very simple: particles, heated by an external source, diffuse from it toward the colder parts of the conductor, carrying electrical current with them if they are electrically charged. However, this naïve argument neglects the fact that at $\mathbf{j} = 0$, there is no total flow of particles. For a more accurate interpretation, note that inside the integral (98), the Seebeck effect is described by the factor $(\varepsilon - \mu)/T$, which changes its sign at the Fermi surface, i.e. at the same energy where the term $[-\partial\langle N(\varepsilon)\rangle/\partial\varepsilon]$, describing the availability of quantum states for transport (due to their intermediate occupancy $0 < \langle N(\varepsilon)\rangle < 1$), reaches its peak. The only reason why that integral does not vanish completely, and hence $\mathcal{S} \neq 0$, is the growth of the first factor under the integral (which describes the density of available quantum states on the energy scale) with ε , so the hotter particles (with $\varepsilon > \mu$) are more numerous and hence carry more heat than the colder ones.

The Seebeck effect is not the only result of a temperature gradient; the same diffusion of particles also causes the less subtle effect of *heat flow* from the region of higher T to that with lower T , i.e. the effect of *thermal conductivity*, well known from our everyday practice. The density of this flow (i.e. that of thermal energy) may be calculated similarly to that of the electric current – see Eq. (26), with the natural replacement of the electric charge q of each particle with its thermal energy $(\varepsilon - \mu)$:

⁶⁵ Both these materials are *alloys*, i.e. solid solutions: chromel is 10% chromium in 90% nickel, while constantan is 45% nickel and 55% copper.

$$\mathbf{j}_h = \int (\varepsilon - \mu) \mathbf{v} w d^3 p. \quad (6.104)$$

(Indeed, we may look at this expression as at the difference between the total energy flow density, $\mathbf{j}_\varepsilon = [\varepsilon w d^3 p]$, and the product of the average energy needed to add a particle to the system (μ) by the particle flow density, $\mathbf{j}_n = \int w d^3 p \equiv \mathbf{j}/q$.)⁶⁶ Again, at equilibrium ($w = w_0$) the heat flow vanishes, so that w in Eq. (104) may be replaced with its perturbation \tilde{w} , which already has been calculated – see Eq. (96). The substitution of that expression into Eq. (104), and its transformation exactly similar to the one performed above for the electric current \mathbf{j} , yields

$$\mathbf{j}_h = \sigma \Pi \left(-\frac{\nabla \mu'}{q} \right) + \kappa (-\nabla T), \quad (6.105)$$

with the coefficients Π and κ given, in our approximation, by the following formulas:

Peltier coefficient

$$\sigma \Pi = \frac{g q \tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \int_0^\infty (8m\varepsilon^3)^{1/2} (\varepsilon - \mu) \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon, \quad (6.106)$$

Thermal conductivity

$$\kappa = \frac{g \tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \int_0^\infty (8m\varepsilon^3)^{1/2} \frac{(\varepsilon - \mu)^2}{T} \left[-\frac{\partial \langle N(\varepsilon) \rangle}{\partial \varepsilon} \right] d\varepsilon. \quad (6.107)$$

Besides the missing factor T in the denominator, the integral in Eq. (106) is the same as the one in Eq. (98), so that the constant Π (called the *Peltier coefficient*⁶⁷), is simply and fundamentally related to the Seebeck coefficient:

Π vs. S

$$\Pi = ST. \quad (6.108)$$

The simplicity of this relation (first discovered experimentally in 1854 by W. Thompson, a.k.a. Lord Kelvin) is not occasional. This is one of the so-called *Onsager reciprocal relations* between kinetic coefficients (suggested by L. Onsager in 1931), which are model-independent, i.e. valid within very general assumptions. Unfortunately, I have no time/space left for a discussion of this interesting topic (closely related to the fluctuation-dissipation theorem discussed in Sec. 5.5), and have to refer the interested reader to its detailed discussions available in the literature.⁶⁸

On the other hand, the integral in Eq. (107) is different, but may be readily calculated, for the most important case of a degenerate Fermi gas, using the Sommerfeld expansion in the form (99), with $f(\varepsilon) \equiv (8m\varepsilon^3)^{1/2}(\varepsilon - \mu)^2/T$, for which $f(\mu) = 0$ and $d^2f/d\varepsilon^2|_{\varepsilon=\mu} = 2(8m\mu^3)^{1/2}/T \approx 2(8m\varepsilon_F^3)^{1/2}/T$, so that

$$\kappa = \frac{g \tau}{(2\pi\hbar)^3} \frac{4\pi}{3} \frac{\pi^2}{6} T^2 \frac{2(8m\varepsilon_F^3)^{1/2}}{T} \equiv \frac{\pi^2}{3} \frac{n \tau T}{m}. \quad (6.109)$$

⁶⁶ An alternative explanation of the factor $(\varepsilon - \mu)$ in Eq. (104) is that according to Eqs. (1.37) and (1.56), for a uniform system of N particles this factor is just $(E - G)/N \equiv (TS - PV)/N$. The full differential of the numerator is $TdS + SdT - PdV - VdP$, so that in the absence of the mechanical work $dW = -PdV$, and changes of temperature and pressure, it is just $TdS \equiv dQ$ – see Eq. (1.19).

⁶⁷ Named after Jean Charles Athanase Peltier who experimentally discovered, in 1834, the effect expressed by the first term in Eq. (105) – and hence by Eq. (112).

⁶⁸ See, for example, Sec. 15.7 in R. Pathria and P. Beale, *Statistical Mechanics*, 3rd ed., Elsevier, 2011. Note, however, that the range of validity of the Onsager relations is still debated – see, e.g., K.-T. Chen and P. Lee, *Phys. Rev. B* **79**, 18 (2009).

Comparing the result with Eq. (32), we get the so-called *Wiedemann-Franz law*⁶⁹

$$\frac{\kappa}{\sigma} = \frac{\pi^2}{3} \frac{T}{q^2}. \quad (6.110)$$
Wiedemann-Franz law

This relation between the electric conductivity σ and the *thermal conductivity* κ is more general than our formal derivation might imply. Indeed, it may be shown that the Wiedemann-Franz law is also valid for an arbitrary anisotropy (i.e. an arbitrary Fermi surface shape) and, moreover, well beyond the relaxation-time approximation. (For example, it is also valid for the scattering integral (12) with an arbitrary angular dependence of rate Γ , provided that the scattering is elastic.) Experiments show that the law is well obeyed by most metals, but only at relatively low temperatures, when the thermal conductance due to electrons is well above the one due to lattice vibrations, i.e. phonons – see Sec. 2.6. Moreover, for a non-degenerate gas, Eq. (107) should be treated with the utmost care, in the context of the definition (105) of this coefficient κ . (Let me leave this issue for the reader's analysis.)

Now let us discuss the effects described by Eq. (105), starting from the less obvious, first term on its right-hand side. It describes the so-called *Peltier effect*, which may be measured in the loop geometry similar to that shown in Fig. 12, but now driven by an external voltage source – see Fig. 13.

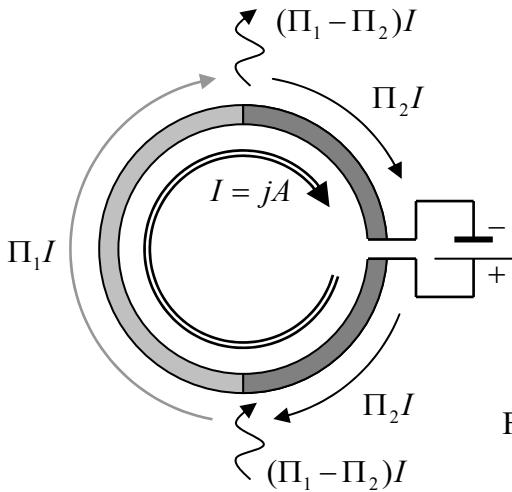

Fig. 6.13. The Peltier effect at $T = \text{const.}$

The voltage drives a certain dc current $I = jA$ (where A is the area of conductor's cross-section), necessarily the same in the whole loop. However, according to Eq. (105), if materials 1 and 2 are different, the power $\mathcal{P} = j_h A$ of the associated heat flow is different in two parts of the loop.⁷⁰ Indeed, if the whole system is kept at the same temperature ($\nabla T = 0$), the integration of that relation over the cross-sections of each part yields

⁶⁹ It was named after Gustav Wiedemann and Rudolph Franz who noticed the constancy of ratio κ/σ for various materials, at the same temperature, as early as 1853. The direct proportionality of the ratio to the absolute temperature was noticed by Ludwig Lorenz in 1872. Due to his contribution, the Wiedemann-Franz law is frequently represented, in the SI temperature units, as $\kappa/\sigma = LT_K$, where the constant $L \equiv (\pi^2/3)k_B/e^2$, called the *Lorenz number*, is close to $2.45 \times 10^{-8} \text{ W}\cdot\Omega\cdot\text{K}^{-2}$. Theoretically, Eq. (110) was derived in 1928 by A. Sommerfeld.

⁷⁰ Let me emphasize that here we are discussing the heat *transferred* through a conductor, not the Joule heat *generated* in it by the current. (The latter effect is quadratic, rather than linear, in current, and hence is much smaller at $I \rightarrow 0$.)

$$\mathcal{P}_{1,2} = \Pi_{1,2} A_{1,2} \sigma_{1,2} \left(-\frac{\nabla \mu'}{q} \right)_{1,2} = \Pi_{1,2} A_{1,2} j_{1,2} = \Pi_{1,2} I_{1,2} = \Pi_{1,2} I, \quad (6.111)$$

where, at the second step, Eq. (41) for the electric current density has been used. This equality means that to sustain a constant temperature, the following power difference,

Peltier effect

$$\Delta \mathcal{P} = (\Pi_1 - \Pi_2) I, \quad (6.112)$$

has to be extracted from one junction of the two materials (in Fig. 13, shown on the top), and inserted into the counterpart junction.

If a constant temperature is not maintained, the former junction is heated (in excess of the bulk, Joule heating), while the latter one is cooled, thus implementing a thermoelectric heat pump/refrigerator. Such *Peltier refrigerators*, which require neither moving parts nor fluids, are very convenient for modest (by a few tens °C) cooling of relatively small components of various systems – from sensitive radiation detectors on mobile platforms (including spacecraft), all the way to cold drinks in vending machines. It is straightforward to use the above formulas to show that the practical efficiency of active materials used in such thermoelectric refrigerators may be characterized by the following dimensionless figure-of-merit,

$$ZT \equiv \frac{\sigma S^2}{\kappa} T. \quad (6.113)$$

For the best thermoelectric materials found so far, the values of ZT at room temperature are in the range from 2 to 3, providing the COP_{cooling}, defined by Eq. (1.69), of the order of 0.5 – a few times lower than that of traditional, mechanical refrigerators. The search for composite materials (including those with nanoparticles) with higher values of ZT is one of very active fields of applied solid-state physics.⁷¹

Finally, let us discuss the second term of Eq. (105), in the absence of $\nabla \mu'$ (and hence of the electric current) giving

Fourier law

$$\mathbf{j}_h = -\kappa \nabla T, \quad (6.114)$$

This equality should be familiar to the reader because it describes the very common effect of *thermal conductivity*. Indeed, this linear relation is much more general than the particular expression (107) for κ : for sufficiently small temperature gradients it is valid for virtually any medium – for example, for insulators. (The left column in Table 6.1 gives typical values of κ for most common and/or representative materials.) Due to its universality and importance, Eq. (114) has deserved its own name – the *Fourier law*.⁷²

Acting absolutely similarly to the derivation of other continuity equations, such as Eqs. (5.117) for the classical probability, and Eq. (49) for the electric charge,⁷³ let us consider the conservation of the aggregate variable corresponding to \mathbf{j}_h – the internal energy E within a time-independent volume V . According to the basic Eq. (1.18), in the absence of media's expansion ($dV = 0$ and hence $dW = 0$), the

⁷¹ See, e.g., D. Rowe (ed.), *Thermoelectrics Handbook: Macro to Nano*, CRC Press, 2005.

⁷² It was suggested (in 1822) by the same universal scientific genius J.-B. J. Fourier who has not only developed such a key mathematical tool as the Fourier series but also discovered what is now called the greenhouse effect!

⁷³ They are all similar to continuity equations for other quantities – e.g., the mass (see CM Sec. 8.3) and the quantum-mechanical probability (see QM Secs. 1.4 and 9.6).

energy change⁷⁴ has only the thermal component, so its only cause may be the heat flow through its boundary surface S :

$$\frac{dE}{dt} = -\oint_S \mathbf{j}_h \cdot d^2\mathbf{r}. \quad (6.115)$$

In the simplest case of thermally-independent heat capacity C_V , we may integrate Eq. (1.22) over temperature to write⁷⁵

$$E = C_V T = \int_V c_V T d^3 r, \quad (6.116)$$

where c_V is the volumic specific heat, i.e. the heat capacity per unit volume (see the right column in Table 6.1).

Table 6.1. Approximate values of two major thermal coefficients of some materials at 20°C.

Material	κ (W·m ⁻¹ ·K ⁻¹)	c_V (J·K ⁻¹ ·m ⁻³)
Air ^{(a),(b)}	0.026	1.2×10^3
Teflon ([C ₂ F ₄] _n)	0.25	0.6×10^6
Water ^(b)	0.60	4.2×10^6
Amorphous silicon dioxide	1.1-1.4	1.5×10^6
Undoped silicon	150	1.6×10^6
Aluminum ^(c)	235	2.4×10^6
Copper ^(c)	400	3.4×10^6
Diamond	2,200	1.8×10^6

^(a) At ambient pressure.

^(b) In fluids (gases and liquids), heat flow may be much enhanced by temperature-gradient-induced turbulent circulation – *convection*, which is highly dependent on the system's geometry. The given values correspond to conditions preventing the convection.

^(c) In the context of the Wiedemann-Franz law (valid for metals only!), the values of κ for Al and Cu correspond to the Lorenz numbers, respectively, 2.22×10^{-8} W·Ω·K⁻² and 2.39×10^{-8} W·Ω·K⁻², in a pretty impressive comparison with the universal theoretical value of 2.45×10^{-8} W·Ω·K⁻² given by Eq. (110).

Now applying to the right-hand side of Eq. (115) the divergence theorem,⁷⁶ and taking into account that for a time-independent volume the full and partial derivatives over time are equivalent, we get

$$\int_V \left(c_V \frac{\partial T}{\partial t} + \nabla \cdot \mathbf{j}_h \right) d^3 r = 0, \quad (6.117)$$

⁷⁴ According to Eq. (1.25), in the case of negligible thermal expansion, it does not matter whether we speak about the internal energy E or the enthalpy H .

⁷⁵ If the dependence of c_V on temperature may be ignored only within a limited temperature interval, Eqs. (116) and (118) may be still used within that interval, for temperature deviations from some reference value.

⁷⁶ I hope the reader knows it by heart by now, but if not – see, e.g., MA Eq. (12.2).

This equality should hold for any time-independent volume V , which is possible only if the function under the integral equals zero at any point. Using Eq. (114), we get the following partial differential equation, called the *heat conduction equation* (or, rather inappropriately, the “heat equation”):

$$c_V(\mathbf{r}) \frac{\partial T}{\partial t} - \nabla \cdot [\kappa(\mathbf{r}) \nabla T] = 0, \quad (6.118)$$

Heat
conduction
equation

where the spatial arguments of the coefficients c_V and κ are spelled out to emphasize that this equation is valid even for nonuniform media. (Note, however, that Eq. (114) and hence Eq. (118) are valid only if the medium is *isotropic*.)

In a uniform medium, the thermal conductivity κ may be taken out from the external spatial differentiation, and the heat conduction equation becomes mathematically similar to the diffusion equation (5.116), and also to the drift-diffusion equation (50) in the absence of drift ($\nabla U = 0$):

$$\frac{\partial T}{\partial t} = D_T \nabla^2 T, \quad \text{with } D_T \equiv \frac{\kappa}{c_V}. \quad (6.119)$$

This means, in particular, that the solutions of these equations, discussed earlier in this course (such as Eqs. (5.112)-(5.113) for the evolution of the delta-functional initial perturbation) are valid for Eq. (119) as well, with the only replacement $D \rightarrow D_T$. This is why I will leave a few other examples of the solution of this equation for the reader’s exercise.

Let me finish this chapter (and this course as a whole) by emphasizing again that due to time/space restrictions I was able to barely scratch the surface of physical kinetics.⁷⁷

6.6. Exercise problems

6.1. Use the Boltzmann equation in the relaxation-time approximation to derive the Drude formula for the complex ac conductivity $\sigma(\omega)$, and give a physical interpretation of the result’s trend at high frequencies.

6.2. Apply the variable separation method⁷⁸ to Eq. (50) to calculate the time evolution of the particle density distribution in an unlimited uniform medium, in the absence of external forces, provided that at $t = 0$ the particles are released from their uniform distribution in a plane layer of thickness $2a$:

$$n = \begin{cases} n_0, & \text{for } -a \leq x \leq +a, \\ 0, & \text{otherwise.} \end{cases}$$

⁷⁷ A much more detailed coverage of this important part of physics may be found, for example, in the textbook by L. Pitaevskii and E. Lifshitz, *Physical Kinetics*, Butterworth-Heinemann, 1981. A deeper discussion of the Boltzmann equation is given, e.g., in the monograph by S. Harris, *An Introduction to the Theory of the Boltzmann Equation*, Dover 2011. For a discussion of applied aspects of kinetics see, e.g., T. Bergman *et al.*, *Fundamentals of Heat and Mass Transfer*, 7th ed., Wiley, 2011.

⁷⁸ A detailed introduction to this method (repeatedly used in this series) may be found, for example, in EM Sec. 2.5.

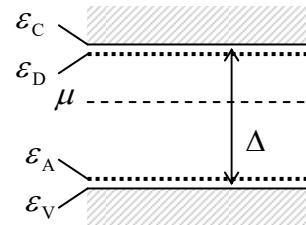

6.3. Solve the previous problem using an appropriate Green's function for the 1D version of the diffusion equation, and discuss the relative convenience of the results.

6.4.* Calculate the electric conductance of a narrow, uniform conducting link between two bulk conductors, in the low-voltage and low-temperature limit, neglecting the electron interaction and scattering inside the link.

6.5. Calculate the effective capacitance (per unit area) of a broad plane sheet of a degenerate 2D electron gas, separated by distance d from a metallic ground plane.

6.6. Give a quantitative description of the dopant atom ionization, which would be consistent with the conduction and valence band occupation statistics, using the same simple model of an n -doped semiconductor as in Sec. 4 (see Fig. 7a), and taking into account that the ground state of the dopant atom is typically doubly degenerate, due to two possible spin orientations of the bound electron. Use the results to verify Eq. (65), within the displayed limits of its validity.

6.7. Generalize the solution of the previous problem to the case when the n -doping of a semiconductor by n_D donor atoms per unit volume is complemented with its simultaneous p -doping by n_A acceptor atoms per unit volume, whose energy $\varepsilon_A - \varepsilon_V$ of activation, i.e. of accepting an additional electron and hence becoming a negative ion, is much lower than the bandgap Δ – see the figure on the right.

6.8. A nearly-ideal classical gas of N particles with mass m , was in thermal equilibrium at temperature T , in a closed container of volume V . At some moment, an orifice of a very small area A is open in one of the container's walls, allowing the particles to escape into the surrounding vacuum.⁷⁹ In the limit of very low density $n \equiv N/V$, use simple kinetic arguments to calculate the r.m.s. velocity of the escaped particles during the time period when the total number of such particles is still much smaller than N . Formulate the limits of validity of your results in terms of V, A , and the mean free path l .

Hint: Here and below, the term “nearly-ideal” means that l is so large that particle collisions do not affect the basic statistical properties of the gas.

6.9. For the system analyzed in the previous problem, calculate the rate of particle flow through the orifice – the so-called *effusion rate*. Discuss the limits of validity of your result.

6.10. Use simple kinetic arguments to estimate:

- (i) the diffusion coefficient D ,
- (ii) the thermal conductivity κ , and
- (iii) the *shear viscosity* η ,

of a nearly-ideal classical gas with mean free path l . Compare the result for D with that calculated in Sec. 3 from the Boltzmann-RTA equation.

⁷⁹ In chemistry-related fields, this process is frequently called *effusion*.

Hint: In fluid dynamics, the shear viscosity (frequently called simply "viscosity") may be defined as the coefficient η in the following relation:⁸⁰

$$\frac{d\mathcal{F}_{j'}}{dA_j} = \eta \frac{\partial v_{j'}}{\partial r_j},$$

where $d\mathcal{F}_{j'}$ is the j' th Cartesian component of the tangential force between two parts of a fluid, separated by an imaginary interface normal to some direction \mathbf{n}_j (with $j \neq j'$, and hence $\mathbf{n}_j \perp \mathbf{n}_{j'}$), exerted over an elementary area dA_j of this surface, and $\mathbf{v}(\mathbf{r})$ is the velocity of the fluid at the interface.

6.11. Use simple kinetic arguments to relate the mean free path l in a nearly-ideal classical gas, with the full cross-section σ of mutual scattering of its particles.⁸¹ Use the result to evaluate the thermal conductivity and the viscosity coefficient estimates made in the previous problem, for the molecular nitrogen, with the molecular mass $m \approx 4.7 \times 10^{-26}$ kg and the effective ("van der Waals") diameter $d_{\text{ef}} \approx 4.5 \times 10^{-10}$ m, at ambient conditions, and compare them with experimental results.

6.12. Use the Boltzmann-RTA equation to calculate the thermal conductivity of a nearly-ideal classical gas, measured in conditions when the applied thermal gradient does not create a net particle flow. Compare the result with that following from the simple kinetic arguments (Problem 6.10), and discuss their relationship.

6.13. Use the heat conduction equation (6.119) to calculate the time evolution of temperature in the center of a uniform solid sphere of radius R , initially heated to a uniformly distributed temperature T_{ini} , and at $t = 0$ placed into a heat bath that keeps its surface at temperature T_0 .

6.14. Suggest a reasonable definition of the entropy production rate (per unit volume), and calculate this rate for stationary thermal conduction, assuming that it obeys the Fourier law, in a material with negligible thermal expansion. Give a physical interpretation of the result. Does the stationary temperature distribution in a sample correspond to the minimum of the total entropy production in it?

6.15.⁸² Use the Boltzmann-RTA equation to calculate the shear viscosity of a nearly-ideal gas. Spell out the result in the classical limit, and compare it with the estimate made in the solution of Problem 10.

⁸⁰ See, e.g., CM Eq. (8.56). Please note the difference between the shear viscosity coefficient η considered in this problem and the drag coefficient η whose calculation was the task of Problem 3.2. Despite the similar (traditional) notation, and belonging to the same realm (kinematic friction), these coefficients have different definitions and even different dimensionalities.

⁸¹ I am sorry for using the same letter for the cross-section as for the electric Ohmic conductivity. (Both notations are very traditional.) Let me hope this would not lead to confusion, because the conductivity is not discussed in this problem.

⁸² This problem does not follow Problem 12 only for historic reasons.

Selected Mathematical Formulas

that are used in this series, but not always remembered by students
(and some instructors :-)

Last corrections: 2021/08/20

1. Constants

– Euclidean circle's *length-to-diameter ratio*:

$$\pi = 3.141\ 592\ 653\dots; \quad \pi^{1/2} \approx 1.77. \quad (1.1)$$

– *Natural logarithm base*:

$$e \equiv \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n = 2.718\ 281\ 828\dots; \quad (1.2a)$$

from that value, the logarithm base conversion factors are as follows ($\xi > 0$):

$$\frac{\ln \xi}{\log_{10} \xi} = \ln 10 \approx 2.303, \quad \frac{\log_{10} \xi}{\ln \xi} = \frac{1}{\ln 10} \approx 0.434. \quad (1.2b)$$

– The *Euler* (or “*Euler-Mascheroni*”) *constant*:

$$\gamma \equiv \lim_{n \rightarrow \infty} \left(1 + \frac{1}{2} + \frac{1}{3} + \dots + \frac{1}{n} - \ln n\right) = 0.5771566490\dots; \quad e^\gamma \approx 1.781. \quad (1.3)$$

2. Combinatorics, sums, and series

(i) Combinatorics

– The number of different *permutations*, i.e. *ordered* sequences of k elements selected from a set of n distinct elements ($n \geq k$), is

$${}^n P_k \equiv n \cdot (n-1) \cdot \dots \cdot (n-k+1) = \frac{n!}{(n-k)!}; \quad (2.1a)$$

in particular, the number of different permutations of *all* elements of the set ($n = k$) is

$${}^k P_k = k \cdot (k-1) \cdot \dots \cdot 2 \cdot 1 = k! \quad (2.1b)$$

– The number of different *combinations*, i.e. *unordered* sequences of k elements from a set of $n \geq k$ distinct elements, is equal to the *binomial coefficient*

$${}^n C_k \equiv \binom{n}{k} \equiv \frac{{}^n P_k}{{}^k P_k} = \frac{n!}{k!(n-k)!}. \quad (2.2)$$

In an alternative, very popular “ball/box language”, ${}^n C_k$ is the number of different ways to put in a box, in an arbitrary order, k balls selected from n distinct balls.

– A generalization of the binomial coefficient notion is the *multinomial coefficient*,

$${}^n C_{k_1, k_2, \dots, k_l} \equiv \frac{n!}{k_1! k_2! \dots k_l!}, \quad \text{with } n = \sum_{j=1}^l k_j, \quad (2.3)$$

which, in the standard mathematical language, is a number of different permutations in a multiset of l distinct element types from an n -element set which contains k_j ($j = 1, 2, \dots, l$) elements of each type. In the less formal “ball/box language”, the coefficient (2.3) is the number of different ways to distribute n distinct balls between l distinct boxes, each time keeping the number (k_j) of balls in the j^{th} box fixed, but ignoring their order inside the box. The binomial coefficient ${}^n C_k$, given by Eq. (2.2), is a particular case of the multinomial coefficient (2.3) for $l = 2$ – counting the explicit box for the first one, and the remaining space for the second box, so that if $k_1 \equiv k$, then $k_2 = n - k$.

– One more important combinatorial quantity is the number $M_n^{(k)}$ of different ways to place n *indistinguishable* balls into k distinct boxes. It may be readily calculated from Eq. (2.2) as the number of different ways to select $(k-1)$ partitions between the boxes in an imagined linear row of $(k-1+n)$ “objects” (balls in the boxes *and* partitions between them):

$$M_n^{(k)} = {}^{n-1+k} C_{k-1} \equiv \frac{(k-1+n)!}{(k-1)! n!}. \quad (2.4)$$

(ii) Sums and series

– *Arithmetic progression:*

$$r + 2r + \dots + nr \equiv \sum_{k=1}^n kr = \frac{n(r+nr)}{2}; \quad (2.5a)$$

in particular, at $r = 1$ it is reduced to the sum of n first natural numbers:

$$1 + 2 + \dots + n \equiv \sum_{k=1}^n k = \frac{n(n+1)}{2}. \quad (2.5b)$$

– Sums of squares and cubes of n first natural numbers:

$$1^2 + 2^2 + \dots + n^2 \equiv \sum_{k=1}^n k^2 = \frac{n(n+1)(2n+1)}{6}; \quad (2.6a)$$

$$1^3 + 2^3 + \dots + n^3 \equiv \sum_{k=1}^n k^3 = \frac{n^2(n+1)^2}{4}. \quad (2.6b)$$

– The *Riemann zeta function*:

$$\zeta(s) \equiv 1 + \frac{1}{2^s} + \frac{1}{3^s} + \dots \equiv \sum_{k=1}^{\infty} \frac{1}{k^s}; \quad (2.7a)$$

the particular values frequently met in applications are

$$\zeta\left(\frac{3}{2}\right) \approx 2.612, \quad \zeta(2) = \frac{\pi^2}{6}, \quad \zeta\left(\frac{5}{2}\right) \approx 1.341, \quad \zeta(3) \approx 1.202, \quad \zeta(4) = \frac{\pi^4}{90}, \quad \zeta(5) \approx 1.037. \quad (2.7b)$$

– Finite geometric progression (for real $\lambda \neq 1$):

$$1 + \lambda + \lambda^2 + \dots + \lambda^{n-1} \equiv \sum_{k=0}^{n-1} \lambda^k = \frac{1 - \lambda^n}{1 - \lambda}; \quad (2.8a)$$

in particular, if $\lambda^2 < 1$, the progression has a finite limit at $n \rightarrow \infty$ (called the *geometric series*):

$$\lim_{n \rightarrow \infty} \sum_{k=0}^{n-1} \lambda^k \equiv \sum_{k=0}^{\infty} \lambda^k = \frac{1}{1 - \lambda}. \quad (2.8b)$$

– *Binomial sum* (also called the “binomial theorem”):

$$(1 + a)^n = \sum_{k=0}^n {}^n C_k a^k, \quad (2.9)$$

where ${}^n C_k$ are the binomial coefficients given by Eq. (2.2).

– The *Stirling formula*:

$$\lim_{n \rightarrow \infty} \ln(n!) = n(\ln n - 1) + \frac{1}{2} \ln(2\pi n) + \frac{1}{12n} - \frac{1}{360n^3} + \dots; \quad (2.10)$$

for most applications in physics, the first term¹ is sufficient.

– The *Taylor* (or “Taylor-Maclaurin”) *series*: for any infinitely differentiable function $f(\xi)$:

$$\lim_{\tilde{\xi} \rightarrow 0} f(\xi + \tilde{\xi}) = f(\xi) + \frac{df}{d\xi}(\xi) \tilde{\xi} + \frac{1}{2!} \frac{d^2 f}{d\xi^2}(\xi) \tilde{\xi}^2 + \dots = \sum_{k=0}^{\infty} \frac{1}{k!} \frac{d^k f}{d\xi^k}(\xi) \tilde{\xi}^k; \quad (2.11a)$$

note that for many functions this series converges only within a limited, sometimes small range of deviations $\tilde{\xi}$. For a function of several arguments, $f(\xi_1, \xi_2, \dots, \xi_N)$, the first terms of the Taylor series are

$$\lim_{\tilde{\xi}_k \rightarrow 0} f(\xi_1 + \tilde{\xi}_1, \xi_2 + \tilde{\xi}_2, \dots) = f(\xi_1, \xi_2, \dots) + \sum_{k=1}^N \frac{\partial f}{\partial \xi_k}(\xi_1, \xi_2, \dots) \tilde{\xi}_k + \frac{1}{2!} \sum_{k,k'=1}^N \frac{\partial^2 f}{\partial \xi_k \partial \xi_{k'}}(\xi_1, \xi_2, \dots) \tilde{\xi}_k \tilde{\xi}_{k'} + \dots \quad (2.11b)$$

– The *Euler-Maclaurin formula*, valid for any infinitely differentiable function $f(\xi)$:

$$\sum_{k=1}^n f(k) = \int_0^n f(\xi) d\xi + \frac{1}{2} [f(n) - f(0)] + \frac{1}{6} \cdot \frac{1}{2!} \left[\frac{df}{d\xi}(n) - \frac{df}{d\xi}(0) \right]$$

¹ Actually, this leading term was conjectured by A. de Moivre in 1733, before J. Stirling’s proof of the series.

$$-\frac{1}{30} \cdot \frac{1}{4!} \left[\frac{d^3 f}{d\xi^3}(n) - \frac{d^3 f}{d\xi^3}(0) \right] + \frac{1}{42} \cdot \frac{1}{6!} \left[\frac{d^5 f}{d\xi^5}(n) - \frac{d^5 f}{d\xi^5}(0) \right] + \dots; \quad (2.12a)$$

the coefficients participating in this formula are the so-called *Bernoulli numbers*:²

$$B_1 = \frac{1}{2}, \quad B_2 = \frac{1}{6}, \quad B_3 = 0, \quad B_4 = \frac{1}{30}, \quad B_5 = 0, \quad B_6 = \frac{1}{42}, \quad B_7 = 0, \quad B_8 = \frac{1}{30}, \dots \quad (2.12b)$$

3. Basic trigonometric functions

– Trigonometric functions of the sum and the difference of two arguments:³

$$\cos(a \pm b) = \cos a \cos b \mp \sin a \sin b, \quad (3.1a)$$

$$\sin(a \pm b) = \sin a \cos b \pm \cos a \sin b. \quad (3.1b)$$

– Sums of two functions of arbitrary arguments:

$$\cos a + \cos b = 2 \cos \frac{a+b}{2} \cos \frac{b-a}{2}, \quad (3.2a)$$

$$\cos a - \cos b = 2 \sin \frac{a+b}{2} \sin \frac{b-a}{2}, \quad (3.2b)$$

$$\sin a \pm \sin b = 2 \sin \frac{a \pm b}{2} \cos \frac{\pm b - a}{2}. \quad (3.2c)$$

– Trigonometric function products:

$$2 \cos a \cos b = \cos(a+b) + \cos(a-b), \quad (3.3a)$$

$$2 \sin a \cos b = \sin(a+b) + \sin(a-b), \quad (3.3b)$$

$$2 \sin a \sin b = \cos(a-b) - \cos(a+b); \quad (3.3c)$$

for the particular case of equal arguments, $b = a$, these three formulas yield the following expressions for the squares of trigonometric functions, and their product:

$$\cos^2 a = \frac{1}{2}(1 + \cos 2a), \quad \sin a \cos a = \frac{1}{2} \sin 2a, \quad \sin^2 a = \frac{1}{2}(1 - \cos 2a). \quad (3.3d)$$

– Cubes of trigonometric functions:

$$\cos^3 a = \frac{3}{4} \cos a + \frac{1}{4} \cos 3a, \quad \sin^3 a = \frac{3}{4} \sin a - \frac{1}{4} \sin 3a. \quad (3.4)$$

– Trigonometric functions of a complex argument:

² Note that definitions of B_k (or rather their signs and indices) vary even in the most popular handbooks.

³ I am confident that the reader is quite capable of deriving the relations (3.1) by representing exponent in the elementary relation $e^{i(a \pm b)} = e^{ia} e^{\pm ib}$ as a sum of its real and imaginary parts, then Eqs. (3.3) directly from Eqs. (3.1), and then Eqs. (3.2) from Eqs. (3.3) by variable replacement; however, I am still providing these formulas to save their time. (Quite a few formulas below are included for the same reason.)

$$\begin{aligned}\sin(a+ib) &= \sin a \cosh b + i \cos a \sinh b, \\ \cos(a+ib) &= \cos a \cosh b - i \sin a \sinh b.\end{aligned}\tag{3.5}$$

– Sums of trigonometric functions of n equidistant arguments:

$$\sum_{k=1}^n \begin{Bmatrix} \sin \\ \cos \end{Bmatrix} k\xi = \begin{Bmatrix} \sin \\ \cos \end{Bmatrix} \left(\frac{n+1}{2} \xi \right) \sin \left(\frac{n}{2} \xi \right) / \sin \left(\frac{\xi}{2} \right). \tag{3.6}$$

4. General differentiation

– Full differential of a product of two functions:

$$d(fg) = (df)g + f(dg). \tag{4.1}$$

– Full differential of a function of several independent arguments, $f(\xi_1, \xi_2, \dots, \xi_n)$:

$$df = \sum_{k=1}^n \frac{\partial f}{\partial \xi_k} d\xi_k. \tag{4.2}$$

– Curvature of the Cartesian plot of a smooth function $f(\xi)$:

$$\kappa \equiv \frac{1}{R} = \frac{\left| d^2 f / d\xi^2 \right|}{\left[1 + (df / d\xi)^2 \right]^{3/2}}. \tag{4.3}$$

5. General integration

– Integration by parts:⁴

$$\int_{g(A)}^{g(B)} f \, dg = fg \Big|_A^B - \int_{f(A)}^{f(B)} g \, df. \tag{5.1}$$

– Numerical (approximate) integration of 1D functions: the simplest *trapezoidal rule*,

$$\int_a^b f(\xi) d\xi \approx h \left[f\left(a + \frac{h}{2}\right) + f\left(a + \frac{3h}{2}\right) + \dots + f\left(b - \frac{h}{2}\right) \right] = h \sum_{n=1}^N f\left(a - \frac{h}{2} + nh\right), \quad h \equiv \frac{b-a}{N}. \tag{5.2}$$

has a relatively low accuracy (error of the order of $(h^3/12)d^2f/d\xi^2$ per step), so that the following *Simpson formula*,

$$\int_a^b f(\xi) d\xi \approx \frac{h}{3} [f(a) + 4f(a+h) + 2f(a+2h) + \dots + 4f(b-h) + f(b)], \quad h \equiv \frac{b-a}{2N}, \tag{5.3}$$

whose error per step scales as $(h^5/180)d^4f/d\xi^4$, is used much more frequently.⁵

⁴ This formula immediately follows from Eq. (4.1).

⁵ Higher-order formulas (e.g., the *Bode rule*), and other guidance including ready-for-use codes for computer calculations may be found, for example, in the popular reference texts by W. H. Press *et al.*, cited in Sec. 16

6. A few 1D integrals⁶

(i) Indefinite integrals

– Integrals with $(1 + \xi^2)^{1/2}$:

$$\int (1 + \xi^2)^{1/2} d\xi = \frac{\xi}{2} (1 + \xi^2)^{1/2} + \frac{1}{2} \ln \left| \xi + (1 + \xi^2)^{1/2} \right|, \quad (6.1)$$

$$\int \frac{d\xi}{(1 + \xi^2)^{1/2}} = \ln \left| \xi + (1 + \xi^2)^{1/2} \right|, \quad (6.2a)$$

$$\int \frac{d\xi}{(1 + \xi^2)^{3/2}} = \frac{\xi}{(1 + \xi^2)^{1/2}}. \quad (6.2b)$$

– Miscellaneous indefinite integrals:

$$\int \frac{d\xi}{\xi(\xi^2 + 2a\xi - 1)^{1/2}} = \cos^{-1} \frac{a\xi - 1}{|\xi|(a^2 + 1)^{1/2}}, \quad (6.3a)$$

$$\int \frac{(\sin \xi - \xi \cos \xi)^2}{\xi^5} d\xi = \frac{2\xi \sin 2\xi + \cos 2\xi - 2\xi^2 - 1}{8\xi^4}, \quad (6.3b)$$

$$\int \frac{d\xi}{a + b \cos \xi} = \frac{2}{(a^2 - b^2)^{1/2}} \tan^{-1} \left[\frac{(a-b)}{(a^2 - b^2)^{1/2}} \tan \frac{\xi}{2} \right], \quad \text{for } a^2 > b^2. \quad (6.3c)$$

$$\int \frac{d\xi}{1 + \xi^2} = \tan^{-1} \xi. \quad (6.3d)$$

(ii) Semi-definite integrals:

– Integrals with $1/(e^\xi \pm 1)$:

$$\int_a^\infty \frac{d\xi}{e^\xi + 1} = \ln(1 + e^{-a}), \quad (6.4a)$$

$$\int_{a>0}^\infty \frac{d\xi}{e^\xi - 1} = \ln \frac{1}{1 - e^{-a}}. \quad (6.4b)$$

(iii) Definite integrals

– Integrals with $1/(1 + \xi^2)$:⁷

$$\int_0^\infty \frac{d\xi}{1 + \xi^2} = \frac{\pi}{2}, \quad (6.5a)$$

below. Besides that, some advanced codes are used as subroutines in the software packages listed in the same section. In some cases, the Euler-Maclaurin formula (2.12) also may be useful for numerical integration.

⁶ A powerful (and free :-) interactive online tool for working out indefinite 1D integrals is available at <http://integrals.wolfram.com/index.jsp>.

⁷ Eq. (6.5a) follows immediately from Eq. (6.3d), and Eq. (6.5b) from Eq. (6.2b) – a couple more examples of the (intentional) redundancies in this list.

$$\int_0^\infty \frac{d\xi}{(1+\xi^2)^{3/2}} = 1; \quad (6.5b)$$

more generally,

$$\int_0^\infty \frac{d\xi}{(1+\xi^2)^n} = \frac{\pi}{2} \frac{(2n-3)!!}{(2n-2)!!} \equiv \frac{\pi}{2} \frac{1 \cdot 3 \cdot 5 \dots (2n-3)}{2 \cdot 4 \cdot 6 \dots (2n-2)}, \quad \text{for } n = 2, 3, \dots \quad (6.5c)$$

– Integrals with $(1 - \xi^{2n})^{1/2}$:

$$\int_0^1 \frac{d\xi}{(1 - \xi^{2n})^{1/2}} = \frac{\pi^{1/2}}{2n} \Gamma\left(\frac{1}{2n}\right) / \Gamma\left(\frac{n+1}{2n}\right), \quad (6.6a)$$

$$\int_0^1 (1 - \xi^{2n})^{1/2} d\xi = \frac{\pi^{1/2}}{4n} \Gamma\left(\frac{1}{2n}\right) / \Gamma\left(\frac{3n+1}{2n}\right), \quad (6.6b)$$

where $\Gamma(s)$ is the *gamma function*, which is most often defined (for $\operatorname{Re} s > 0$) by the following integral:

$$\int_0^\infty \xi^{s-1} e^{-\xi} d\xi = \Gamma(s). \quad (6.7a)$$

The key property of this function is the recurrence relation, which is valid for any $s \neq 0, -1, -2, \dots$:

$$\Gamma(s+1) = s\Gamma(s). \quad (6.7b)$$

Since, according to Eq. (6.7a), $\Gamma(1) = 1$, Eq. (6.7b) for non-negative integers takes the form

$$\Gamma(n+1) = n!, \quad \text{for } n = 0, 1, 2, \dots \quad (6.7c)$$

(where $0! \equiv 1$). Because of this, for integer $s = n+1 \geq 1$, Eq. (6.7a) is reduced to

$$\int_0^\infty \xi^n e^{-\xi} d\xi = n!. \quad (6.7d)$$

Other frequently met values of the gamma function are those for positive semi-integer values:

$$\Gamma\left(\frac{1}{2}\right) = \pi^{1/2}, \quad \Gamma\left(\frac{3}{2}\right) = \frac{1}{2}\pi^{1/2}, \quad \Gamma\left(\frac{5}{2}\right) = \frac{1}{2} \cdot \frac{3}{2}\pi^{1/2}, \quad \Gamma\left(\frac{7}{2}\right) = \frac{1}{2} \cdot \frac{3}{2} \cdot \frac{5}{2}\pi^{1/2}, \dots . \quad (6.7e)$$

– Integrals with $1/(e^\xi \pm 1)$:

$$\int_0^\infty \frac{\xi^{s-1} d\xi}{e^\xi + 1} = (1 - 2^{1-s}) \Gamma(s) \zeta(s), \quad \text{for } s > 0, \quad (6.8a)$$

$$\int_0^\infty \frac{\xi^{s-1} d\xi}{e^\xi - 1} = \Gamma(s) \zeta(s), \quad \text{for } s > 1, \quad (6.8b)$$

where $\zeta(s)$ is the Riemann zeta-function – see Eq. (2.6). Particular cases: for $s = 2n$,

$$\int_0^\infty \frac{\xi^{2n-1} d\xi}{e^\xi + 1} = \frac{2^{2n-1} - 1}{2n} \pi^{2n} B_{2n}, \quad (6.8c)$$

$$\int_0^\infty \frac{\xi^{2n-1} d\xi}{e^\xi - 1} = \frac{(2\pi)^{2n}}{4n} B_{2n}. \quad (6.8d)$$

where B_n are the Bernoulli numbers – see Eq. (2.12). For the particular case $s = 1$ (when Eq. (6.8a) yields uncertainty),

$$\int_0^\infty \frac{d\xi}{e^\xi + 1} = \ln 2. \quad (6.8e)$$

– Integrals with $\exp\{-\xi^2\}$:

$$\int_0^\infty \xi^s e^{-\xi^2} d\xi = \frac{1}{2} \Gamma\left(\frac{s+1}{2}\right), \quad \text{for } s > -1; \quad (6.9a)$$

for applications the most important particular values of s are 0 and 2:

$$\int_0^\infty e^{-\xi^2} d\xi = \frac{1}{2} \Gamma\left(\frac{1}{2}\right) = \frac{\pi^{1/2}}{2}, \quad (6.9b)$$

$$\int_0^\infty \xi^2 e^{-\xi^2} d\xi = \frac{1}{2} \Gamma\left(\frac{3}{2}\right) = \frac{\pi^{1/2}}{4}, \quad (6.9c)$$

though we will also run into the cases $s = 4$ and $s = 6$:

$$\int_0^\infty \xi^4 e^{-\xi^2} d\xi = \frac{1}{2} \Gamma\left(\frac{5}{2}\right) = \frac{3\pi^{1/2}}{8}, \quad \int_0^\infty \xi^6 e^{-\xi^2} d\xi = \frac{1}{2} \Gamma\left(\frac{7}{2}\right) = \frac{15\pi^{1/2}}{16}; \quad (6.9d)$$

for odd integer values $s = 2n + 1$ (with $n = 0, 1, 2, \dots$), Eq. (6.9a) takes a simpler form:

$$\int_0^\infty \xi^{2n+1} e^{-\xi^2} d\xi = \frac{1}{2} \Gamma(n+1) = \frac{n!}{2}. \quad (6.9e)$$

– Integrals with cosine and sine functions:

$$\int_0^\infty \cos(\xi^2) d\xi = \int_0^\infty \sin(\xi^2) d\xi = \left(\frac{\pi}{8}\right)^{1/2}. \quad (6.10)$$

$$\int_0^\infty \frac{\cos \xi}{a^2 + \xi^2} d\xi = \frac{\pi}{2|a|} e^{-|a|}. \quad (6.11)$$

$$\int_0^\infty \left(\frac{\sin \xi}{\xi} \right)^2 d\xi = \frac{\pi}{2}. \quad (6.12)$$

– Integrals with logarithms:

$$\int_0^1 \ln \frac{a + (1 - \xi^2)^{1/2}}{a - (1 - \xi^2)^{1/2}} d\xi = \pi \left[a - (a^2 - 1)^{1/2} \right], \quad \text{for } a \geq 1. \quad (6.13)$$

$$\int_0^1 \ln \frac{1 + (1 - \xi)^{1/2}}{\xi^{1/2}} d\xi = 1. \quad (6.14)$$

– Integral representations of the Bessel functions of integer order:

$$J_n(\alpha) = \frac{1}{2\pi} \int_{-\pi}^{+\pi} e^{i(\alpha \sin \xi - n\xi)} d\xi, \quad \text{so that } e^{i\alpha \sin \xi} = \sum_{k=-\infty}^{\infty} J_k(\alpha) e^{ik\xi}; \quad (6.15a)$$

$$I_n(\alpha) = \frac{1}{\pi} \int_0^\pi e^{\alpha \cos \xi} \cos n\xi d\xi. \quad (6.15b)$$

7. 3D vector products

(i) Definitions:

– *Scalar (“dot-“) product:*

$$\mathbf{a} \cdot \mathbf{b} = \sum_{j=1}^3 a_j b_j, \quad (7.1)$$

where a_j and b_j are vector components in any orthogonal coordinate system. In particular, the vector squared (the same as its norm squared) is the following scalar:

$$a^2 \equiv \mathbf{a} \cdot \mathbf{a} = \sum_{j=1}^3 a_j^2 \equiv \|\mathbf{a}\|^2. \quad (7.2)$$

– *Vector (“cross-“) product:*

$$\mathbf{a} \times \mathbf{b} \equiv \mathbf{n}_1(a_2 b_3 - a_3 b_2) + \mathbf{n}_2(a_3 b_1 - a_1 b_3) + \mathbf{n}_3(a_1 b_2 - a_2 b_1) = \begin{vmatrix} \mathbf{n}_1 & \mathbf{n}_2 & \mathbf{n}_3 \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix}, \quad (7.3)$$

where $\{\mathbf{n}_j\}$ is the set of mutually perpendicular unit vectors⁸ along the corresponding coordinate system axes.⁹ In particular, Eq. (7.3) yields

$$\mathbf{a} \times \mathbf{a} = 0. \quad (7.4)$$

(ii) Corollaries (readily verified by Cartesian components):

– Double vector product (the so-called *bac minus cab rule*):

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}(\mathbf{a} \cdot \mathbf{b}). \quad (7.5)$$

– Mixed scalar-vector product (the *operand rotation rule*):

$$\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = \mathbf{b} \cdot (\mathbf{c} \times \mathbf{a}) = \mathbf{c} \cdot (\mathbf{a} \times \mathbf{b}). \quad (7.6)$$

⁸ Other popular notations for this vector set are $\{\mathbf{e}_j\}$ and $\{\hat{\mathbf{r}}_j\}$.

⁹ It is easy to use Eq. (7.3) to check that the direction of the product vector corresponds to the well-known “right-hand rule” and to the even more convenient *corkscrew rule*: if we rotate a corkscrew’s handle from the first operand toward the second one, its axis moves in the direction of the product.

– Scalar product of vector products:

$$(\mathbf{a} \times \mathbf{b}) \cdot (\mathbf{c} \times \mathbf{d}) = (\mathbf{a} \cdot \mathbf{c})(\mathbf{b} \cdot \mathbf{d}) - (\mathbf{a} \cdot \mathbf{d})(\mathbf{b} \cdot \mathbf{c}); \quad (7.7a)$$

in the particular case of two similar operands (say, $\mathbf{a} = \mathbf{c}$ and $\mathbf{b} = \mathbf{d}$), the last formula is reduced to

$$(\mathbf{a} \times \mathbf{b})^2 = (ab)^2 - (\mathbf{a} \cdot \mathbf{b})^2. \quad (7.7b)$$

8. Differentiation in 3D Cartesian coordinates

– Definition of the *del* (or “nabla”) vector-operator ∇ :¹⁰

$$\nabla \equiv \sum_{j=1}^3 \mathbf{n}_j \frac{\partial}{\partial r_j}, \quad (8.1)$$

where r_j is a set of linear and orthogonal (*Cartesian*) coordinates along directions \mathbf{n}_j . In accordance with this definition, the operator ∇ acting on a *scalar* function of coordinates, $f(\mathbf{r})$,¹¹ gives its gradient, i.e. a new *vector*:

$$\nabla f \equiv \sum_{j=1}^3 \mathbf{n}_j \frac{\partial f}{\partial r_j} \equiv \mathbf{grad} f. \quad (8.2)$$

– The *scalar product* of del by a *vector* function of coordinates (a *vector field*),

$$\mathbf{f}(\mathbf{r}) \equiv \sum_{j=1}^3 \mathbf{n}_j f_j(\mathbf{r}), \quad (8.3)$$

compiled by formally following Eq. (7.1), is a *scalar* function – the *divergence* of the initial function:

$$\nabla \cdot \mathbf{f} \equiv \sum_{j=1}^3 \frac{\partial f_j}{\partial r_j} \equiv \text{div } \mathbf{f}, \quad (8.4)$$

while the *vector product* of ∇ and \mathbf{f} , formed in a formal accordance with Eq. (7.3), is a new vector – the **curl** (in European tradition, called *rotor* and denoted **rot**) of \mathbf{f} :

$$\nabla \times \mathbf{f} \equiv \begin{vmatrix} \mathbf{n}_1 & \mathbf{n}_2 & \mathbf{n}_3 \\ \frac{\partial}{\partial r_1} & \frac{\partial}{\partial r_2} & \frac{\partial}{\partial r_3} \\ f_1 & f_2 & f_3 \end{vmatrix} = \mathbf{n}_1 \left(\frac{\partial f_3}{\partial r_2} - \frac{\partial f_2}{\partial r_3} \right) + \mathbf{n}_2 \left(\frac{\partial f_1}{\partial r_3} - \frac{\partial f_3}{\partial r_1} \right) + \mathbf{n}_3 \left(\frac{\partial f_2}{\partial r_1} - \frac{\partial f_1}{\partial r_2} \right) \equiv \mathbf{curl} \mathbf{f}. \quad (8.5)$$

– One more frequently met “product” is $(\mathbf{f} \cdot \nabla) \mathbf{g}$, where \mathbf{f} and \mathbf{g} are two arbitrary vector functions of \mathbf{r} . This product should be also understood in the sense implied by Eq. (7.1), i.e. as a vector whose j^{th} Cartesian component is

$$[(\mathbf{f} \cdot \nabla) \mathbf{g}]_j = \sum_{j'=1}^3 f_{j'} \frac{\partial g_j}{\partial r_{j'}}. \quad (8.5)$$

¹⁰ One can run into the following notation: $\nabla \equiv \partial/\partial \mathbf{r}$, which is convenient in some cases, but may be misleading in quite a few others, so it will be not used in this series.

¹¹ In this, and four next sections, all scalar and vector functions are assumed to be differentiable.

9. The Laplace operator $\nabla^2 \equiv \nabla \cdot \nabla$

– Expression in Cartesian coordinates – in the formal accordance with Eq. (7.2):

$$\nabla^2 = \sum_{j=1}^3 \frac{\partial^2}{\partial r_j^2}. \quad (9.1)$$

– According to its definition, the Laplace operator acting on a *scalar* function of coordinates gives a new scalar function:

$$\nabla^2 f \equiv \nabla \cdot (\nabla f) = \operatorname{div}(\operatorname{grad} f) = \sum_{j=1}^3 \frac{\partial^2 f}{\partial r_j^2}. \quad (9.2)$$

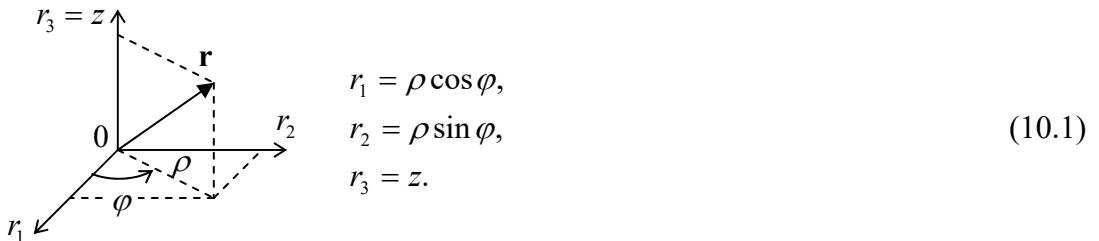

– On the other hand, acting on a *vector* function (8.3), the operator ∇^2 returns another *vector*:

$$\nabla^2 \mathbf{f} = \sum_{j=1}^3 \mathbf{n}_j \nabla^2 f_j. \quad (9.3)$$

Note that Eqs. (9.1)-(9.3) are only valid in Cartesian (i.e. orthogonal and linear) coordinates, but generally not in other orthogonal coordinates – see, e.g., Eqs. (10.3), (10.6), (10.9) and (10.12) below.

10. Operators ∇ and ∇^2 in the most important systems of orthogonal coordinates¹²

(i) Cylindrical¹³ coordinates $\{\rho, \varphi, z\}$ (see Fig. below) may be defined by their relations with the Cartesian coordinates:

– Gradient of a scalar function:

$$\nabla f = \mathbf{n}_\rho \frac{\partial f}{\partial \rho} + \mathbf{n}_\varphi \frac{1}{\rho} \frac{\partial f}{\partial \varphi} + \mathbf{n}_z \frac{\partial f}{\partial z}. \quad (10.2)$$

– The Laplace operator of a scalar function:

$$\nabla^2 f = \frac{1}{\rho} \frac{\partial}{\partial \rho} \left(\rho \frac{\partial f}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2 f}{\partial \varphi^2} + \frac{\partial^2 f}{\partial z^2}, \quad (10.3)$$

– Divergence of a vector function of coordinates ($\mathbf{f} = \mathbf{n}_\rho f_\rho + \mathbf{n}_\varphi f_\varphi + \mathbf{n}_z f_z$):

$$\nabla \cdot \mathbf{f} = \frac{1}{\rho} \frac{\partial (\rho f_\rho)}{\partial \rho} + \frac{1}{\rho} \frac{\partial f_\varphi}{\partial \varphi} + \frac{\partial f_z}{\partial z}. \quad (10.4)$$

¹² Some other orthogonal curvilinear coordinate systems are discussed in EM Sec. 2.3.

¹³ In the 2D geometry with fixed coordinate z , these coordinates are called *polar*.

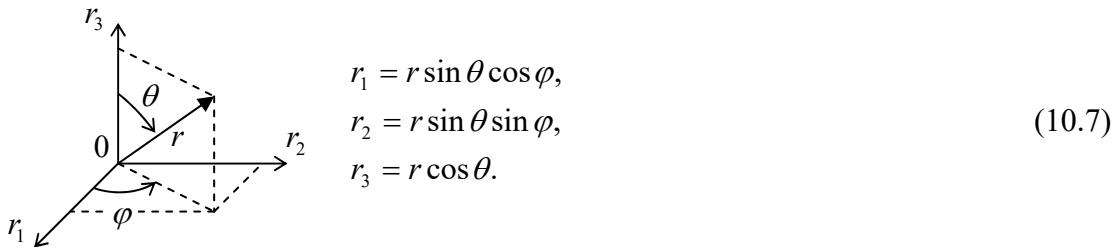

– Curl of a vector function:

$$\nabla \times \mathbf{f} = \mathbf{n}_\rho \left(\frac{1}{\rho} \frac{\partial f_z}{\partial \varphi} - \frac{\partial f_\varphi}{\partial z} \right) + \mathbf{n}_\varphi \left(\frac{\partial f_\rho}{\partial z} - \frac{\partial f_z}{\partial \rho} \right) + \mathbf{n}_z \frac{1}{\rho} \left(\frac{\partial(\rho f_\varphi)}{\partial \rho} - \frac{\partial f_\rho}{\partial \varphi} \right). \quad (10.5)$$

– The Laplace operator of a vector function:

$$\nabla^2 \mathbf{f} = \mathbf{n}_\rho \left(\nabla^2 f_\rho - \frac{1}{\rho^2} f_\rho - \frac{2}{\rho^2} \frac{\partial f_\varphi}{\partial \varphi} \right) + \mathbf{n}_\varphi \left(\nabla^2 f_\varphi - \frac{1}{\rho^2} f_\varphi + \frac{2}{\rho^2} \frac{\partial f_\rho}{\partial \varphi} \right) + \mathbf{n}_z \nabla^2 f_z. \quad (10.6)$$

(ii) Spherical coordinates $\{r, \theta, \varphi\}$ (see Fig. below) may be defined as:

– Gradient of a scalar function:

$$\nabla f = \mathbf{n}_r \frac{\partial f}{\partial r} + \mathbf{n}_\theta \frac{1}{r} \frac{\partial f}{\partial \theta} + \mathbf{n}_\varphi \frac{1}{r \sin \theta} \frac{\partial f}{\partial \varphi}. \quad (10.8)$$

– The Laplace operator of a scalar function:

$$\nabla^2 f = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial f}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) + \frac{1}{(r \sin \theta)^2} \frac{\partial^2 f}{\partial \varphi^2}. \quad (10.9)$$

– Divergence of a vector function $\mathbf{f} = \mathbf{n}_r f_r + \mathbf{n}_\theta f_\theta + \mathbf{n}_\varphi f_\varphi$:

$$\nabla \cdot \mathbf{f} = \frac{1}{r^2} \frac{\partial(r^2 f_r)}{\partial r} + \frac{1}{r \sin \theta} \frac{\partial(f_\theta \sin \theta)}{\partial \theta} + \frac{1}{r \sin \theta} \frac{\partial f_\varphi}{\partial \varphi}. \quad (10.10)$$

– Curl of the similar vector function:

$$\nabla \times \mathbf{f} = \mathbf{n}_r \frac{1}{r \sin \theta} \left(\frac{\partial(f_\varphi \sin \theta)}{\partial \theta} - \frac{\partial f_\theta}{\partial \varphi} \right) + \mathbf{n}_\theta \frac{1}{r} \left(\frac{1}{\sin \theta} \frac{\partial f_r}{\partial \varphi} - \frac{\partial(r f_\varphi)}{\partial r} \right) + \mathbf{n}_\varphi \frac{1}{r} \left(\frac{\partial(r f_\theta)}{\partial r} - \frac{\partial f_r}{\partial \theta} \right). \quad (10.11)$$

– The Laplace operator of a vector function:

$$\begin{aligned} \nabla^2 \mathbf{f} = & \mathbf{n}_r \left(\nabla^2 f_r - \frac{2}{r^2} f_r - \frac{2}{r^2 \sin \theta} \frac{\partial}{\partial \theta} (f_\theta \sin \theta) - \frac{2}{r^2 \sin \theta} \frac{\partial f_\varphi}{\partial \varphi} \right) \\ & + \mathbf{n}_\theta \left(\nabla^2 f_\theta - \frac{1}{r^2 \sin^2 \theta} f_\theta + \frac{2}{r^2} \frac{\partial f_r}{\partial \theta} - \frac{2 \cos \theta}{r^2 \sin^2 \theta} \frac{\partial f_\varphi}{\partial \varphi} \right) \\ & + \mathbf{n}_\varphi \left(\nabla^2 f_\varphi - \frac{1}{r^2 \sin^2 \theta} f_\varphi + \frac{2}{r^2 \sin \theta} \frac{\partial f_r}{\partial \varphi} + \frac{2 \cos \theta}{r^2 \sin^2 \theta} \frac{\partial f_\theta}{\partial \varphi} \right). \end{aligned} \quad (10.12)$$

11. Products involving ∇

(i) Useful zeros:

- For any scalar function $f(\mathbf{r})$,

$$\nabla \times (\nabla f) \equiv \mathbf{curl}(\mathbf{grad} f) = 0. \quad (11.1)$$

- For any vector function $\mathbf{f}(\mathbf{r})$,

$$\nabla \cdot (\nabla \times \mathbf{f}) \equiv \text{div}(\mathbf{curl} \mathbf{f}) = 0. \quad (11.2)$$

(ii) The Laplace operator expressed via the curl of a curl:

$$\nabla^2 \mathbf{f} = \nabla(\nabla \cdot \mathbf{f}) - \nabla \times (\nabla \times \mathbf{f}). \quad (11.3)$$

(iii) Spatial differentiation of a product of a scalar function by a vector function:

- The scalar 3D generalization of Eq. (4.1) is

$$\nabla \cdot (f \mathbf{g}) = (\nabla f) \cdot \mathbf{g} + f(\nabla \cdot \mathbf{g}). \quad (11.4a)$$

- Its vector generalization is similar:

$$\nabla \times (f \mathbf{g}) = (\nabla f) \times \mathbf{g} + f(\nabla \times \mathbf{g}). \quad (11.4b)$$

(iv) 3D spatial differentiation of products of two vector functions:

$$\nabla \times (\mathbf{f} \times \mathbf{g}) = \mathbf{f}(\nabla \cdot \mathbf{g}) - (\mathbf{f} \cdot \nabla) \mathbf{g} - (\nabla \cdot \mathbf{f}) \mathbf{g} + (\mathbf{g} \cdot \nabla) \mathbf{f}, \quad (11.5)$$

$$\nabla(\mathbf{f} \cdot \mathbf{g}) = (\mathbf{f} \cdot \nabla) \mathbf{g} + (\mathbf{g} \cdot \nabla) \mathbf{f} + \mathbf{f} \times (\nabla \times \mathbf{g}) + \mathbf{g} \times (\nabla \times \mathbf{f}), \quad (11.6)$$

$$\nabla \cdot (\mathbf{f} \times \mathbf{g}) = \mathbf{g} \cdot (\nabla \times \mathbf{f}) - \mathbf{f} \cdot (\nabla \times \mathbf{g}). \quad (11.7)$$

12. Integro-differential relations

(i) For an arbitrary surface S limited by closed contour C :

- The *Stokes theorem*, valid for any differentiable vector field $\mathbf{f}(\mathbf{r})$:

$$\int_S (\nabla \times \mathbf{f}) \cdot d^2 \mathbf{r} \equiv \int_S (\nabla \times \mathbf{f})_n d^2 r = \oint_C \mathbf{f} \cdot d\mathbf{r} \equiv \oint_C f_\tau dr, \quad (12.1)$$

where $d^2 \mathbf{r} \equiv \mathbf{n} d^2 r$ is the elementary area vector (normal to the surface), and $d\mathbf{r}$ is the elementary contour length vector (tangential to the contour line).

(ii) For an arbitrary volume V limited by closed surface S :

- *Divergence (or “Gauss”) theorem*, valid for any differentiable vector field $\mathbf{f}(\mathbf{r})$:

$$\int_V (\nabla \cdot \mathbf{f}) d^3 r = \oint_S \mathbf{f} \cdot d^2 \mathbf{r} \equiv \oint_S f_n d^2 r. \quad (12.2)$$

- *Green’s theorem*, valid for two differentiable scalar functions $f(\mathbf{r})$ and $g(\mathbf{r})$:

$$\int_V (f \nabla^2 g - g \nabla^2 f) d^3 r = \oint_S (f \nabla g - g \nabla f)_n d^2 r. \quad (12.3)$$

- An identity valid for any two scalar functions f and g , and a vector field \mathbf{j} with $\nabla \cdot \mathbf{j} = 0$ (all differentiable):

$$\int_V [f(\mathbf{j} \cdot \nabla g) + g(\mathbf{j} \cdot \nabla f)] d^3r = \oint_S fg j_n d^2r. \quad (12.3)$$

13. The Kronecker delta and Levi-Civita permutation symbols

- The *Kronecker delta symbol* (defined for integer indices):

$$\delta_{jj'} \equiv \begin{cases} 1, & \text{if } j' = j, \\ 0, & \text{otherwise.} \end{cases} \quad (13.1)$$

- The *Levi-Civita permutation symbol* for three integer indices (each taking one of the values 1, 2, or 3):

$$\varepsilon_{jj'j''} \equiv \begin{cases} +1, & \text{if the indices follow in any "correct" ("even") order : } 1 \rightarrow 2 \rightarrow 3 \rightarrow 1 \rightarrow 2 \dots, \\ -1, & \text{if the indices follow in any "incorrect" ("odd") order : } 1 \rightarrow 3 \rightarrow 2 \rightarrow 1 \rightarrow 3 \dots, \\ 0, & \text{if any two indices coincide.} \end{cases} \quad (13.2)$$

- Relation between the products of the Levi-Civita and Kronecker symbols:

$$\varepsilon_{jj'j''} \varepsilon_{kk'k''} = \sum_{l,l',l''=1}^3 \begin{vmatrix} \delta_{jl} & \delta_{jl'} & \delta_{jl''} \\ \delta_{j'l} & \delta_{j'l'} & \delta_{j'l''} \\ \delta_{j''l} & \delta_{j''l'} & \delta_{j''l''} \end{vmatrix}; \quad (13.3a)$$

the summation of three such relations written for three different values of $j = k$, yields the so-called *contracted epsilon identity*:

$$\sum_{j=1}^3 \varepsilon_{jj'j''} \varepsilon_{jk'k''} = \delta_{jk} \delta_{j''k''} - \delta_{jk''} \delta_{j''k}. \quad (13.3b)$$

14. Dirac's delta function, sign function, and theta function

- Definition of 1D *delta function* (for real $a < b$):

$$\int_a^b f(\xi) \delta(\xi) d\xi = \begin{cases} f(0), & \text{if } a < 0 < b, \\ 0, & \text{otherwise,} \end{cases} \quad (14.1)$$

where $f(\xi)$ is any function continuous near $\xi = 0$. In particular (if $f(\xi) = 1$ near $\xi = 0$), the definition yields

$$\int_a^b \delta(\xi) d\xi = \begin{cases} 1, & \text{if } a < 0 < b, \\ 0, & \text{otherwise.} \end{cases} \quad (14.2)$$

- Relation to the *theta function* $\theta(\xi)$ and the *sign function* $\text{sgn}(\xi)$

$$\delta(\xi) = \frac{d}{d\xi} \theta(\xi) = \frac{1}{2} \frac{d}{d\xi} \text{sgn}(\xi), \quad (14.3a)$$

where

$$\theta(\xi) \equiv \frac{\operatorname{sgn}(\xi) + 1}{2} = \begin{cases} 0, & \text{if } \xi < 0, \\ 1, & \text{if } \xi > 1, \end{cases} \quad \operatorname{sgn}(\xi) \equiv \frac{\xi}{|\xi|} = \begin{cases} -1, & \text{if } \xi < 0, \\ +1, & \text{if } \xi > 1. \end{cases} \quad (14.3b)$$

– An important integral:¹⁴

$$\int_{-\infty}^{+\infty} e^{is\xi} ds = 2\pi\delta(\xi). \quad (14.4)$$

– 3D generalization: the delta function $\delta(\mathbf{r})$ of the radius-vector is defined as

$$\int_V f(\mathbf{r})\delta(\mathbf{r})d^3r = \begin{cases} f(0), & \text{if } 0 \in V, \\ 0, & \text{otherwise;} \end{cases} \quad (14.5)$$

it may be represented as a product of 1D delta functions of Cartesian coordinates:

$$\delta(\mathbf{r}) = \delta(r_1)\delta(r_2)\delta(r_3). \quad (14.6)$$

(The 2D generalization is similar.)

15. The Cauchy theorem and integral

Let a complex function $f(z)$ be analytic within a part of the complex plane z , which is limited by a closed contour C and includes point z' . Then

$$\oint_C f(z)dz = 0, \quad (15.1)$$

$$\oint_C f(z) \frac{dz}{z - z'} = 2\pi i f(z'). \quad (15.2)$$

The first of these relations is usually called the *Cauchy integral theorem* (or the “Cauchy-Goursat theorem”), and the second one, the *Cauchy integral* (or the “Cauchy integral formula”).

16. References

(i) Properties of some *special functions* are briefly discussed at the relevant points of the lecture notes (in alphabetical order):

- *Airy functions*: QM Sec. 2.4;
- *Bessel functions*: EM Sec. 2.7;
- *Fresnel integrals*: EM Sec. 8.6;
- *Hermite polynomials*: QM Sec. 2.9;

¹⁴ The coefficient in this relation may be readily recalled by considering its left-hand side as the Fourier-integral representation of the function $f(s) \equiv 1$, and applying Eq. (14.1) to the reciprocal Fourier transform:

$$f(s) \equiv 1 = \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{-is\xi} [2\pi\delta(\xi)] d\xi.$$

- *Laguerre polynomials* (both *simple* and *associated*): QM Sec. 3.7;
- *Legendre polynomials, associated Legendre functions*: EM Sec. 2.8 and QM Sec. 3.6;
- *Spherical harmonics*: QM Sec. 3.6;
- *Spherical Bessel functions*: QM Secs. 3.6 and 3.8.

(ii) For *more formulas*, and their discussions, I can recommend the following handbooks (in alphabetical order):¹⁵

- M. Abramowitz and I. Stegun (eds.), *Handbook of Mathematical Formulas*, Dover, 1965 (and numerous later printings);¹⁶
- I. Gradshteyn and I. Ryzhik, *Tables of Integrals, Series, and Products*, 5th ed., Acad. Press, 1980;
- G. Korn and T. Korn, *Mathematical Handbook for Scientists and Engineers*, 2nd ed., Dover, 2000;
- A. Prudnikov *et al.*, *Integrals and Series*, vols. 1 and 2, CRC Press, 1986.

The popular textbook,

- G. Arfken *et al.*, *Mathematical Methods for Physicists*, 7th ed., Acad. Press, 2012,
- may be also used as a formula manual.

Many formulas are also available from the symbolic calculation parts of commercially available software packages listed in Sec. (iv) below.

(iii) Probably the most popular collection of *numerical calculation codes* are the twin manuals

- W. Press *et al.*, *Numerical Recipes in Fortran 77*, 2nd ed., Cambridge U. Press, 1992;
- W. Press *et al.*, *Numerical Recipes [in C++ – KKL]*, 3rd ed., Cambridge U. Press, 2007.

These lecture notes include very brief introductions into numerical methods of differential equation solution:

- ordinary differential equations: CM Sec. 5.7, and
- partial differential equations: CM Sec. 8.5 and EM Sec. 2.11,

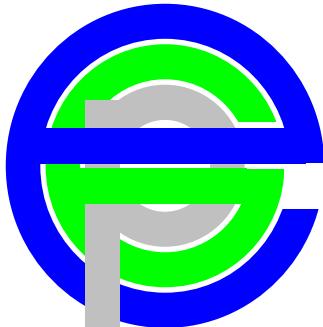

which include references to the literature for further reading.

(iv) The most popular *software packages* for numerical and symbolic calculations, all with plotting capabilities (in alphabetical order):

- *Maple* (<http://www.maplesoft.com/>);
- *MathCAD* (<http://www.ptc.com/products/mathcad/>);
- *Mathematica* (<http://www.wolfram.com/products/mathematica/index.html>);
- *MATLAB* (<http://www.mathworks.com/products/matlab/>).

¹⁵ On a personal note, perhaps 90% of all formula needs throughout my research career were satisfied by a tiny, wonderfully compiled old book: H. Dwight, *Tables of Integrals and Other Mathematical Data*, 4th ed., Macmillan, 1961, whose used copies, rather amazingly, are still available on the Web.

¹⁶ An updated version of this collection is now available online at <http://dlmf.nist.gov/>.

Appendix CA

Selected Physical Constants

according to the 2018 International CODATA recommendation.¹

Last corrections: 2021/08/20

Symbol	Constant	SI value and unit	Gaussian value and unit	Relative r.m.s. uncertainty
c	speed of light in vacuum	$2.997\ 924\ 58 \times 10^8$ m/s	$2.997\ 924\ 58 \times 10^{10}$ cm/s	0 (defined value)
N_A	Avogadro constant	$6.022\ 140\ 76 \times 10^{23}$ 1/mol	$6.022\ 140\ 76 \times 10^{23}$ 1/mol	0 (defined value)
$2\pi\hbar$	Planck constant	$6.626\ 070\ 15 \times 10^{-34}$ J/Hz	$6.626\ 070\ 15 \times 10^{-27}$ erg/Hz	0 (defined value)
k_B	Boltzmann constant	$1.380\ 649\ 000 \times 10^{-23}$ J/K	$1.380\ 649\ 000 \times 10^{-16}$ erg/K	0 (defined value)
e	elementary electric charge	$1.602\ 176\ 634 \times 10^{-19}$ C	$4.803\ 204\ 713 \times 10^{-10}$ statcoulomb	0 (defined value)
ϵ_0	electric constant	$8.854\ 187\ 8128 \times 10^{-12}$ F/m	—	$\sim 1.5 \times 10^{-10}$
μ_0	magnetic constant	$1.256\ 637\ 062\ 12 \times 10^{-6}$ N/A ²	—	$\sim 1.5 \times 10^{-10}$
m_e	electron's rest mass	$0.910\ 938\ 370 \times 10^{-30}$ kg	$0.910\ 938\ 370 \times 10^{-27}$ g	$\sim 3 \times 10^{-10}$
m_p	proton's rest mass	$1.672\ 621\ 923 \times 10^{-27}$ kg	$1.672\ 621\ 923 \times 10^{-24}$ g	$\sim 3 \times 10^{-10}$
G	gravitation constant	$6.674\ 30 \times 10^{-11}$ m ³ /kg·s ²	$6.674\ 30 \times 10^{-8}$ cm ³ /g·s ²	$\sim 2 \times 10^{-5}$

¹ See, e.g., <http://physics.nist.gov/cuu/Constants/index.html>. CODATA is an interdisciplinary Committee on Data for Science and Technology of the International Council of Science (ISCU). Its recommendations, renewed every four years, are widely accepted by the scientific community.

Comments:

1. The fixed value of c transfers the legal definition of the second (as “the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom”) to that of the meter. These values are back-compatible with the legacy definitions of the meter (initially, as the 1/40,000,000th part of the Earth meridian length) and the second (for a long time, as the 1/(24×60×60) = 1/86,400th part of the Earth rotation period), within the experimental errors of those measures.

2. The exact value of the Avogadro number, prescribed by the last CODATA adjustment of fundamental constants in 2018, fixes 1 kg in the atomic units of mass (u), defined as 1/12 of the ¹²C atom’s mass, excluding the legacy etalons of the kilogram from the primary metrology – even though their masses are compatible with the new definition within the experimental accuracy.

3. The exact value of \hbar , also prescribed by CODATA in 2018, together with the fixed value of the second, enables the fundamental definition of energy units (in the SI system, the Joule) in terms of time/frequency.

4. The only role of the Boltzmann constant k_B is to express the kelvin (K) in energy units. If temperature is used in these units (as is done, for example, in the SM part of this series), this constant is unnecessary.

5. ϵ_0 and μ_0 are also not really the fundamental constants; their role is just to fix electric and magnetic units in the SI system. Their product is exactly fixed as $\epsilon_0\mu_0 \equiv 1/c^2$, and μ_0 virtually coincides with the legacy value $4\pi \times 10^{-7}$. (Before the 2018 adjustment, that value was considered exact, but the exact fixation of e in the new system of constants gives it an experimental uncertainty, if only a very small one – see the table above.)

6. The dimensionless *fine structure* (“Sommerfeld’s”) *constant* α is numerically the same in any system of units:

$$\alpha \equiv \left\{ \begin{array}{ll} e^2 / 4\pi\epsilon_0\hbar c & \text{in SI units} \\ e^2 / \hbar c & \text{in Gaussian units} \end{array} \right\} \approx 7.297\,352\,563 \times 10^{-3} \approx \frac{1}{137}.$$

The relative uncertainty of the first value is smaller than 10^{-10} .² The accuracy of the second, mnemonic value is better than 0.03%.

7. The listed proton’s rest mass m_p is close to 1.007 u, while the neutron’s rest mass is close to 1.009 u; their differences from 1 u reflect mostly the binding energy of these baryons in the ¹²C nucleus.

8. Note the relatively poor accuracy with which we know the Newtonian constant of gravitation – due to the extreme weakness of gravity on human scales of mass and distance.
